the greatest. We found the native range had only one size class (351–400 mm) occurring in greater than 10% of the sample, whereas four consecutive size classes (701–900 mm) occur in greater than 10% each of the sample from the Canary Island. Thus, our data from the native range had a bimodal distribution between juvenile and adult captures compared to the Canary Island data (Fig. 4).

The invasive group of CKS did not have greater mean of the top decile compared to snakes in their native range (Table 1). The longest snake in the Canary Islands was 1,474 mm, 14% longer than the longest snake in the California sample (1,290 mm) and 21% longer than the next longest snake in the Canary Islands (1,217 mm). The invasive snakes had 23% greater average mass within the top decile compared to the USGS pit-fall/snake trap captures (Table 1). The heaviest snake in the Canary Islands was 770 g, 35% greater than the heaviest snake within the California sample (570 g).

One of the natural history traits we looked at was the frequency of tail breaks or scarring, as a proxy for predation risk. In the museum dataset, 6.7% of the snakes had broken tails, whereas 16.6% of the CKS on the Canary Islands had broken tails (2.48 times higher frequency of tail breaks compared with snakes in the native range) (Table 1). There was no noticeable association between tail break and colour pattern for either of these datasets.

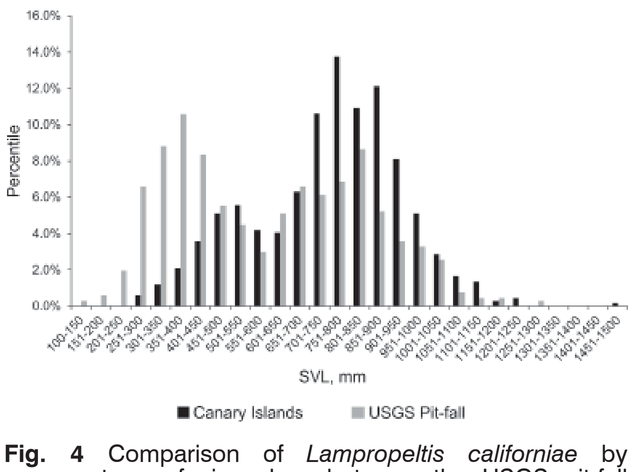

Fig. 4 Comparison of *Lampropeltis californiae* by percentage of size class between the USGS pit-fall snake trap dataset and the Canary Islands dataset. This graph highlights the lack of smaller size classes in the Canary Islands and the greater frequency of the larger size classes.

DISCUSSION

Since 2009, field work on control and eradication of the invasive CKS in the Canary Islands has resulted in the removal of over 4,500 snakes from the invaded habitats (<www.lifelampropeltis.com>). There was one population on Gran Canaria when the snakes were discovered, but now there are at least three populations on the island, indicating they are still spreading even with the control activities. We were able to compare various life history traits for native range CKS to the invasive range in the Canary Islands. Overall, we compiled records for 4,404 CKS for various aspects of their biology from the native range across four different data sources. These data were compared to 668 records for snakes from the Canary Islands. Below, we make comparisons on their biology and then suggestions on how they might be controlled or managed as an invasive species.

Snake community structure in California

We found that CKS was the second most captured species across the 25 species detected by the USGS pit-fall and snake trap sampling in California (Fig. 1). This sampling is based on the species actively entering the traps, and since the traps are passive, they only detect snakes when the snakes are active. Klauber (1931), using primarily road-riding for eight years (1923–1930), found that CKS were the third most detected snake species in his sample. They comprised 14% of the total record of 6,231 snakes across 24 species he detected for San Diego County, following the gopher snake (*Pituophis catenifer*) and the two-striped garter snake (*Thamnophis hammondii*). As our data were collected 70 years after his, this difference could represent actual changes in the abundance of the snakes due to habitat shifts over time, but it most likely represents the different sampling techniques. Both studies found CKS to be in the top three most captured snakes in the region across habitat types, indicating that even in a diverse snake community, CKS is one of the dominant species. This suggests that as an invasive species, it possibly could be successful even in regions with native snake communities, such as mainland Europe. Within the Canary Islands, it appears to have the ability to broadly utilise the habitats present on these islands.

Trap success by size class and lack of juvenile snakes in the Canary Islands

It was a quite striking find that juveniles are not detected in high numbers in the Canary Islands yet the snake is clearly expanding its range every year. This is very difficult to explain. The juvenile detection could be affected by several factors, including trapping technique, foraging distances and activity, growth rate, etc., but with the data we have to date we cannot determine the source of this issue. We know that sampling techniques to detect snakes vary in their effectiveness. We found a distinctive pattern of smaller snakes (<500 mm) being detected primarily by bucket traps (Fig. 2). This indicated there was a size bias in the sampling, with the buckets being necessary to capture the smaller snakes (<500 mm) and the mesh wire snake traps having greater success with the larger snakes (>500 mm) (Fig. 2). In the Canary Islands bucket traps are not being used (Cabrera- Pérez, et al., 2012; Monzón-Arguello, et al., 2015), and this could possibly explain the lack of juveniles being collected in the invasive range (Table 1). However, the museum specimens from animals captured in the wild in California include juvenile snakes, suggesting their absence could be due to something implicit in the Canary Islands. It could be there is some increased predation within the Canary Islands targeting juveniles, but if that was the case, the population might not be expanding as rapidly as it appears to be spreading.

It is likely there is a greater abundance of naïve prey in the Canary Islands reducing the need for juvenile snakes to move long distances to forage, thus limiting their exposure for detection or as prey. Abundant food resources might also increase their growth rate so that detecting individuals while they are still juveniles would be more difficult. When prey presence in captured snakes was evaluated for 270 individuals in the Canary Islands, 36% of these snakes had at least one prey item in their digestive tract (Monzón-Arguello, et al., 2015). In contrast, within their native range, a recently published study found only about 8% of the snakes assessed contained prey items in their digestive tract (Wiseman, et al., 2019). This suggests that the invasive snakes are finding prey at four times the rate of snakes within their native range, which could be a proxy for increased prey abundance in the Canary Islands.

Another possible explanation for lower detection rates of juveniles might be their activity levels compared to adults. Juveniles might only be active when foraging and under cover items between foraging bouts, while adults are active while foraging and also when searching for mates for reproduction, thus even though foraging exposure might be reduced for adults in the Canary Islands, they are still exposed for capture during mating season. Overall this could result in the lower detection of juveniles in the invasive range versus the native range, because the high food availability which could lead to rapid growth rate in the Canary Islands might limit detection probability (Pike, et al., 2008).

Snake detections by month

The effectiveness of detection tools varied with the time of year. Active searches under artificial cover (HerpMapper and BH) were more effective early in the year (March and April) before snakes were fully active as they used cover to thermoregulate (Fig. 3). We found that pit-fall and snake traps which are dependent on active snakes to enter the traps were more effective in May and June. Overall, focused field effort with various sampling techniques from March to July would maximise the detection success for CKS versus other months of the year. November, December, and January had the lowest detection rates across all five datasets, indicating that lowering field efforts during that period of time would be justified.

Body size and tail injury comparisons between California and the Canary Islands

We found no difference in mean SVL of the top decile between snakes in the invasive range versus the native range (Table 1). This result indicates that there has not been a population shift to longer body size within the invasive range, although the maximum length of the largest snake in the Canary Islands was 14% longer than any California snake, and 21% longer than the next largest snake in the Canary Islands. This snake was an outlier, as it was greater than three standard deviations longer than the next longest snake in the Canary Islands. As this snake was the second heaviest snake we don't think this resulted from measurement or recording error. This lack of population shift in body size contrasts with what has been observed in other invasive species, some of which have been shown to grow larger within their invasive range (Rodda & Savidge, 2007), but this outlier snake indicates that this pattern could change as the age since invasion gets longer. We did find that the invasive snakes were 23% heavier for the top decile, and the heaviest invasive snake was 35% larger than the heaviest snake from the California trap study (Table 1). Increased weight in invasive snakes is most likely tied to their increased predation success on naïve prey.

We observed a higher percentage of tail breaks and scarring of the snakes in the Canary Islands. This could be due to incomplete predation from cats (*Felis catus*) or other predators, from defensive wounds of their prey (e.g. *Gallotia stehlini*), or possibly some other unknown process (Medina & Nogales, 2009; Santos, et al., 2011). Increased frequency of tail breaks does not necessarily affect body condition, for some species (Pleguezuelos, et al., 2013). Within the snakes' native range, predators may be more efficient resulting more often in complete predation, especially by raptors, leaving fewer individuals with incomplete predation scars.

Trophic cascades

A major concern with novel invasive species is that their removal of highly specialised endemic species with unique roles in the island ecosystems may result in unexpected downstream changes in biodiversity and in the landscape. The Canary Islands have a small but unique and ancient biodiversity that could be highly susceptible to perturbations from invasive species (Fernandez-Palacios, et al., 2011). One example is the endemic *Gallotia* lizard which is an essential part of the trophic cascade/feedback loop that enables the dispersal of trees on the Canary Islands (Valido, et al., 2003). The lizards eat the fruit off the trees and shrubs, effectively spreading the seeds of the endemic flora. The invasive CKS are consuming these lizards at a high rate, with complete removal of juveniles in areas where snakes have invaded, and over time will impede the proliferation of these native trees and shrubs, altering the biodiversity and native habitat (Cabrera- Pérez, et al., 2012; Monzón-Arguello, et al., 2015). Published examples of trophic cascades tied to snake invasions include the relationship between spiders and birds in Guam now caused by the snake irruption, and the dynamics of python and mid-sized mammals in Florida (Rogers, et al., 2012; Willson, 2017).

The CKS has a varied diet in its native range, including venomous snakes and juvenile birds (Morrison & Bolger, 2002). Because there are currently no birds recorded in the diet of the invasive snakes (Monzón-Arguello, et al., 2015), initiating intensive sampling of birds in areas with and without snakes to get an assessment of bird density and recruitment may be valuable. From the literature it seems clear that these snakes could target birds, many of which are endemic and some are currently endangered, as prey as they exhaust the lizards and rodents present (Morrison & Bolger, 2002; Carrascal, et al., 2017). This may also be valuable because the published diet data are five years old, and there might already be a change in their diet if there is a depletion of the main reptile and rodent prey.

If it looks like the snakes are going to achieve an island-wide distribution, then one approach is to pre-emptively safeguard various biologically intact areas around the island at different elevations. This approach could preserve biodiversity and create reservoirs of native animals in the event that the snake control/eradication fails.

Pet trade and captive breeding/selection and then released into wild

The invasive CKS has a unique history as it came from several generations of selection in captivity for various colour morphs and albinism, in addition to rapid growth and reproduction. Their release to the wild in the Canary Islands is concerning as this selection might provide some reproductive advantage versus the release of wild animals not subjected to selection in captivity. This trade of potential invasive species is concerning as more and more reptile species become bred for sale globally in the pet trade (Robinson, et al., 2015).

Considerations for snake management in the Canary Islands

Looking at CKS published movement data suggests that placing snake traps with sterile female snakes, or proxies, less than every 150 m apart may be effective for snake management. This distance may be appropriate because the literature indicates that 98% of the males and 100% of the females radio-tracked do not move farther than this (Anguiano & Diffendorfer, 2015). Having a grid of traps in closer proximity across the snake-occupied parts of the island would be optimal for a snake removal programme.

There are large ecological and monetary costs to invasive animals, and costs of control and/or eradication often exceed the available funding. We suggest (1) stronger controls on snakes in the pet trade, (2) rapid response to prevent spread when detection first occurs, and (3) use of citizen science as a tool to detect early invasions.

CONCLUSION

Our results show that data from the native range of the snake can inform management and control for CKS within their invasive range. Also, we found that they flourish within a diverse native snake community; they have a high natural abundance, both historically (Klauber, 1931) and currently (Fig. 1).

We suggest that the continued use of a variety of traps in addition to active surveys be used to maximise detection of snakes of all sizes, especially within the months of March through July. We also suggest that managers consider protection of natural areas with critical biodiversity on Gran Canaria from invasion by CKS. In addition, managers may wish to consider increased controls to prevent spread to other areas in the Canary Islands.

There is no literature on where the CKS lays its eggs in its natural habitat or in the Canary Islands. A comparison of this and other reproductive characteristics may be important as well as a better understanding of how to detect juveniles within the invasive range. Greater support for risk assessments of species, within the pet trade in particular, could help to identify species of greatest concern which would help reduce these types of invasions elsewhere.

ACKNOWLEDGEMENTS

We thank the following museum collections and curators for their support of our research on these snakes: LACM (Greg Pauly, Nefty Camacho), UCSB CCBER (Sam Sweet, Mireia Beas-Moix), California Academy of Sciences (Jens Vindum), San Diego Natural History Museum (Brad Hollingsworth, Laura Williams). United States Geological Survey, San Diego Zoo (Kim Lovich), and Brian Hinds provided unpublished records. Data were provided by HerpMapper (<www.HerpMapper.org>) and its network of citizen contributors. Stephen Goldberg provided invaluable training and Tim Felton, Christine and Herk Alcaraz, and Marie Fisher provided other support. We thank Miguel Ángel Cabrera- Pérez, Miguel Ángel Peña, José Miguel Sánchez, Alejandro Ramírez, Jorge Fernando Saavedra, Francisco Alarcón for all the help with the snakes and the research in the Canary Islands. Funding was provided by the European Project LIFE10 NAT/ES/000565 LAMPROPELTIS and the USGS Ecosystems Mission Area. Any use of trade, firm, or product names is for descriptive purposes only and does not imply endorsement by the U.S. Government.

Control of the ladder snake (*Rhinechis scalaris*) on Formentera using experimental live-traps

Abstract The ladder snake (*Rhinechis scalaris*) is a recent alien invasive species found on Formentera (83 km^2), in the Balearic Archipelago (4,492 km^2). It has been introduced in the last decade as cargo stowaway hidden within ornamental olive trees from the Iberian Peninsula, causing negative impacts on native fauna. This paper describes the methodology used to reduce the ladder snake population as a first attempt since it was detected in 2006. For this purpose, an experimental live-trap was designed by the wildlife management team of the Consorci per a la Recuperació de la Fauna de les Illes Balears (COFIB) during the 2016 campaign. As a result, 314 *R. scalaris* were trapped in an area of 472 ha, achieving an efficiency of up to 0.167 captures per trap and night, and 0.040 captures per unit effort on average. This outcome encourages the use of the live-trap as a cost-effective method for reducing the snake population in Formentera. Nonetheless, this method should be considered a starting point toward *R. scalaris* control.

Keywords: alien species, Balearic Islands, ophidian, population

INTRODUCTION

The accidental transportation of invasive alien species to new locations is a major cause of biodiversity loss worldwide. This is of special concern in island ecosystems, where native species are especially vulnerable to biological invasions (Quammen, 1996). In this regard, the presence of reptiles in the Balearic Islands is a paradigmatic case, with a greater number of alien species (19) than native ones (2), namely, the Lilford's wall lizard (*Podarcis lilfordi*) and the Ibiza wall lizard (*Podarcis pityusensis*) (Silva-Rocha, et al., 2015). The ladder snake (*Rhinechis scalaris*) is a Mediterranean species which is present in most of the Iberian Peninsula (just missing on the Cantabric ledge), in the south-east of France and the north-east of Italy (Pleguezuelos & Honrubia, 2002). This ophidian is also considered an introduced species on other Spanish islands, namely, Ons, Aurosa (in Pontevedra), Mallorca, Menorca, Ibiza and Formentera (in the Balearic Islands) (Pinya & Carretero, 2011), but fortunately not on any of the surrounding islets (Carretero & Silva-Rocha, 2015). However, in Menorca *R. scalaris* has a wide distribution and is catalogued as a protected species in the Catàleg Balear d'Espècies Amenaçades (Decret, 2005) due to its presence on the island dating from the pre-Roman period (Vigne & Alcover, 1985). Conversely, on Mallorca, Ibiza and Formentera *R. scalaris* is a recent introduction (Álvarez, et al., 2010; Mateo & Ayllón, 2012), so its presence is still isolated to particular locations and its range is expanding. In fact, in Ibiza and Formentera this ophidian is catalogued as an invasive alien species (Real Decreto, 2013).

Until 2006 Formentera was considered snake-free. The first *R. scalaris* was detected on 25 May 2008, followed by another sighting on 17 July 2008; both located near La Mola. Then, a third specimen, not identified, was recorded the 20 May 2009 (Álvarez, et al., 2010; Mateo & Ayllón, 2012). It is presumed that the first ophidian was introduced to the Pityusic islands through the trade of ornamental olive trees originating from the Iberian Peninsula (Álvarez, et al., 2010; Carretero & Silva-Rocha, 2015; Montes, et al., 2015), and genetic studies suggest that the whole *R. scalaris* population comes from one introduction event (Silva-Rocha, et al., 2015). Nonetheless, it would be expected that all the snakes spotted in Formentera during the first years could come from Ibiza, since direct connections between Formentera and the mainland are rather limited (Álvarez, et al., 2010; Mateo & Ayllón, 2012).

The naturalisation of this ophidian could result in important consequences for the Pityusic ecosystem and also for the demographic stability of the endemic Ibiza wall lizard (Rodríguez-Pérez, 2009; Álvarez, et al., 2010). Previous cases of introduction of snakes to island ecosystems have been terrible in terms of ecological balance as experienced by the ancient settlement of ophidians on the neighbouring islands of Mallorca and Menorca (SPE, 2007), the deliberate release of the Californian kingsnake (*Lampropeltis getula californiae*) on Gran Canaria (Cabrera-Pérez, et al., 2012) and the accidental introduction of the brown treesnake (*Boiga irregularis*) to the island of Guam (Savidge, 1987; Rodda, et al., 1997; Fritts & Rodda, 1998; Wiles, et al., 2003).

In the last decade, sightings from local people have increased and as Carretero & Silva-Rocha (2015) stated, "the area of Formentera where ladder snakes were spotted in the past, should be checked thoroughly and regularly". So, the need to monitor the presence of *R. scalaris* on Formentera is a real concern.

The present paper reports the first experience of trying to catch and reduce the presumed population of *R. scalaris* in the vicinity of La Mola in Formentera during the 2016 campaign. For this purpose, an experimental live-trap was designed by the wildlife management team of the Consorci per a la Recuperació de la Fauna de les Illes Balears (COFIB), along with the Government of the Balearic Islands. Budget constraints restricted the scope of this first campaign to confirming and mapping the presence of the ladder snake in the vicinity of La Mola. So, the aim was to determine the effectiveness of the trap, as defined by captures per unit effort (CPUE), in order to establish a starting point for future campaigns.

MATERIALS AND METHODS

Study area

This study was conducted on Formentera, the smallest (83 km^2) and southernmost island of the Balearic archipelago

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 332–336. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

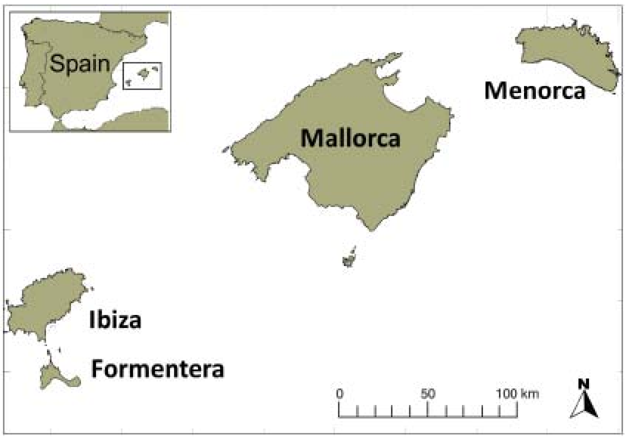

Fig. 1 Map of the Balearic Islands, showing the name of the main islands.

(Fig. 1). A channel of 3.6 km separates Formentera from the other Pityusic Island, Ibiza, and it is 100 km away from the Iberian Peninsula. Vegetation consists of sand dunes with pine forest, oak groves and brushwood. It is considered a flat island, with the highest point being La Mola, at 192 m above sea level, in the south-east of the island. This is where the *R. scalaris* population seems to be concentrated, thus, the study focuses on this area

The live-trap

To conduct this study, live-traps were designed by the COFIB for the purpose of capturing colubrid snakes. The trap used on Formentera was the same as those used in the project "Análisis de la efectividad de métodos de control de especies exóticas invasoras de la familia *colubridae* en islas" (COFIB, 2016) that took place simultaneously in a parallel campaign on Ibiza.

The trap measures 50.0 × 35.5 × 17.0 cm and is made of marine plank (1 cm thick) in order to endure inclement weather conditions (Fig. 2). The box consists of two compartments separated by a galvanised steel mesh of 5 × 5 mm, with two large doors on top to allow snake removal and bait maintenance. These doors are secured with a bolt in order to prevent escapes. The front side is also made of a galvanized steel mesh, allowing air flow through the mesh

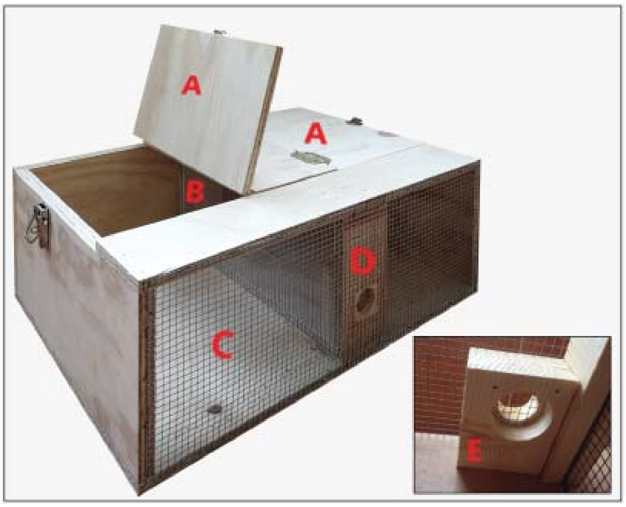

Fig. 2 Model of the live-trap designed by the COFIB. A: the two doors of the top, B: galvanized steel mesh that separates the two compartments, C: galvanized steel mesh of the front side, D: one-way flap door, E: detail of the trapping door viewed from the inside.

and the opportunity to glimpse the animals. Therefore, the trap is not completely opaque. There is just one entrance with a one-way flap door positioned on the mesh front of the trap, with a diameter of 3.5 cm. The flap only opens inwards, falling closed behind the snake to prevent escape and allowing multiple captures. This one-way flap entrance design has been used on a number of snake trap designs (reviewed by Rodda, et al., 1999a). Inside the snake compartment a hide is placed: a 300 mm length of 100 mm diameter plastic bottle, covered with 40 mm of water to prevent snake dehydration.

A live mouse, with enough water and food for optimal welfare, is used as attractant. In this trap, the bait is contained in a separate compartment to prevent the snake from ingesting the mouse.

Trapping method

In the 2016 campaign, trap boxes were placed in the area near La Mola (Fig. 3), mostly at the limit of pine forests, near stone walls or at the base of vegetation (Montes, et al., 2015), all of them at ground-level. We covered a total area of 472 ha with 64 traps. Fourteen extra traps were placed in different locations on the island where no snakes had been spotted in the past, as snake indicators. All the traps located in the field were georeferenced.

Every effort was made to keep the mice alive during the whole project, as they are the basis for the operation of the trap (Mateo & Ayllón, 2012). During the coldest months of the year dry grass or similar materials were provided and the boxes were placed in the sunlight, avoiding hypothermia. Conversely, in summer the boxes were moved slightly towards the shade, helping the mice to endure the suffocating heat. Also, for the duration of the rainy season, traps were placed on stones and covered with plastic, preventing contact between the bottom of the box and a waterlogged ground. These measures were taken not just for humane and economic reasons but also because they allowed a longer period between inspections. All traps were checked and bait replaced every nine days, on average.

Capture and data gathering

When an ophidian was captured, it was identified to ensure it was a *R. scalaris* (as opposed to an unknown and possibly venomous snake), so handling did not require

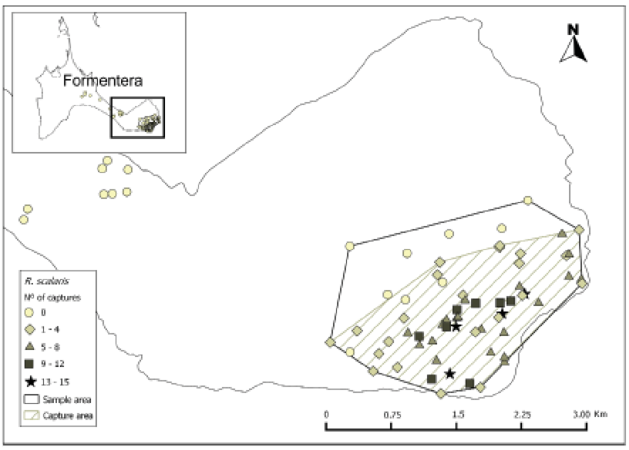

Fig. 3 Distribution of the ladder snake (*Rhinechis scalaris*) in Formentera in 2016. The number of captures per trap is represented with different shapes (see the key). The sample area and the capture area are determined by applying the minimum convex polygon method. All traps on the field are represented on the map but none of the indicator traps are included in the sample area.

Fig. 4 Two specimens of ladder snake (*Rhinechis scalaris*), a juvenile on the left and an adult on the right, caught with the same live-trap in the field on Formentera.

anything special other than a pair of gardening gloves (Fig. 4). We euthanised the snakes using pentobarbital (the approximate dose was 0.1 ml per 100 g) and all injections were performed by an experienced veterinarian, who was the main field technician. Once the specimen was lifeless, it was placed in a 'zip' bag with an identification label including trap number, species, and date. Each captured specimen was stored in a freezer for further investigation; no morphological data was collected on the field. Afterward, all captures were mapped in order to estimate the abundance of *R. scalaris* in La Mola, using the minimum convex polygons tool of Quantum GIS (1.8.0).

RESULTS

A total of 64 traps where placed on La Mola, remaining in the same location for the entire sampling period (Fig. 3). The trapping was conducted between May and late November. The team was based on Ibiza and, for this reason, both sea conditions and vehicle availability restricted the number of possible surveys to 19. The number of traps increased in nearly every survey till the end of July and August, when we had the total number of traps placed in the field. The capture area comprised 321 ha from a sampling area of 472 ha. No indicator trap had any capture.

By the end of the campaign, 314 ladder snakes had been caught, with a total of 7,906 trap-nights (Table 1). It is evident that this was a grass-roots effort, using the best available knowledge to catch as many snakes as possible while keeping costs as low as possible. Therefore, we did not have the time to estimate the density of snakes prior to the trapping. Instead of this, we evaluated the trap effectiveness as defined by captures per unit effort (CPUE). By the end of the project we had an average of 0.040 CPUE.

In May, the first month of trapping, we obtained a trap efficiency of 0.108 captures per trap and night. Next month, June, we got 0.075 captures per unit effort (CPUE), even though the number of traps in the field was more than double. A similar pattern occurred in the following months: the captures per unit effort continued dropping, until we got 0.006 CPUE in November. Therefore, preliminary data seems to indicate an encouraging trap capture decay rate, with a high CPUE at the beginning and a declining recovery from traps as the local supply of snakes depleted. However, seasonal changes in capture success need to be evaluated.

DISCUSSION

The 2016 trapping campaign is the first attempt to remove large numbers of snakes as a step towards controlling the invasion of *R. scalaris* on the island of Formentera. Previous attempts on the neighbouring islands of Ibiza (Montes, et al., 2015) and Mallorca (Mateo, 2015) have tested different methods to capture *R. scalaris* and *Hemorrhois hippocrepis*. After a thorough review of these documents, we decided to use a passive method to trap as many snakes as possible, continuing the work of Montes, et al. (2015) by adapting the wooden box they used. In this regard, we followed the advice and recommendations of previous snake trapping studies. As Rodda, et al. (1999a) showed, it is possible to have higher capture rates using live mice as lures, opaque chambers and flap entrances. Firstly, flap traps have a lower entry rate than open funnel traps, but the former have a higher capture rate. For this reason, we replaced the two open-funnels used by Montes, et al. (2015), with a single frontal flap door, as these are considered to have a negligible escape rate (Rodda, et al., 1999a).

Secondly, in contrast with the lack of a mouse's chamber in the wooden box by Montes, et al. (2015) and the small one that housed the mouse inside the funnel trap described by Mateo & Ayllón (2012), our trap had a proper shelter for the mouse, which was the second big compartment of the cage. With this modification we avoided snake ingestion of the lure and contributed to reducing mouse mortality.

Finally, in order to enhance capture success, refugium bottles were placed inside the snake's compartment as it has been observed that there is a significantly higher number of entries into traps having hiding places, even if the possibility of escape is unlikely (Rodda, et al., 1999a).

Our trap optimises previous designs and the positive capture rates seem to be the result of using both a flap door and a bottle refuge, as these contribute to reducing the number of snakes escaping, along with the separate compartments, which keeps the trap active after a first successful capture. Indeed, our results (0.040 CPUE) confirm a higher efficiency when compared with the study by Montes, et al. (2015) (0.007 CPUE).

All data could have been more accurate had we had a technician exclusively dedicated to checking the traps every other day. Then, not only the number of traps per hectare would have been greater, but the capture rate probably higher. In this case, re-check intervals were determined in relation to care and maintenance of live lures (as the snakes had enough water to avoid death by dehydration during these intervals) instead of capture rate increase. This allowed optimising labour and maximising cost-effectiveness. Even so, trap captures are hypothesised to be higher if the area of trapping is not disturbed (Rodda, et al., 1999a), suggesting normal entrance rates if checks are done within longer intervals. In this study, traps were checked weekly during the summer season but checks were done every 12 days in autumn.

Regarding trap location, Rodda, et al. (1999a), argue that traps should be widely spaced in order to maximise the capture rate when traps are infrequently checked. However, there is still a lack of a mathematic equation describing the relationship between capture rate and trap spacing, as well as a poorly understood interaction between trap design and the environment in which it is used. Taking into account that *R. scalaris* is an active forager (Pleguezuelos, et al., 2007), traps were placed as far apart as it was practical for revisits considering the topography, the trapping area and the number of traps available, resulting in a wide range from 50 m to 600 m apart.

Table 1. Data on ladder snakes (*Rhinechis scalaris*) caught during the 2016 campaign on Formentera.

Survey	Month	No. Traps	No. Captures	Trap/night	CPUE

		TOTAL	**314**	**7,906**	**0.040**

The first traps distributed on the ground were placed within view of neighbours (on the south of the road to the lighthouse of La Mola), and then a consecutive radial expansion was drawn. As can be seen in Fig. 3, there is a clear ‘hot spot’ to the south of La Mola, with the highest number of captures close to the southern coast. The number of captures decreases the further we move from this high-density area and the traps on the north and west boundaries are characterised by no captures (except for two traps on the west). Considering that the sea is a natural barrier, potential expansion is only possible to the north or to the west of the sample area. As mentioned above, no indicator traps in other parts of the island had any captures. Therefore, our trap array gives an initial indication about the range of *R. scalaris* on Formentera, having a higher density of snakes in the core of the invasion zone than at the edges. Still, a larger array of traps around La Mola, especially on the west boundary, would depict the range of *R. scalaris* more accurately.

It is clear that a population of *R. scalaris* is naturalised in Formentera. Previous extinctions of endemic birds and lizards have been documented as a result of the introduction of an alien snake, such as the well-known case of the *B. irregularis* in the Island of Guam (Savidge, 1987; Rodda, et al., 1997; Fritts & Rodda, 1998). Therefore, the Guam experience should made us wary of the invasive potential that *R. scalaris* could have on the native fauna of the Pityusic islands. It has the potential to affect a wide range of animals, such as the emblematic Ibiza wall lizard, the Balearic shearwater (*Puffinus maruritanicus*), the Scopoli's shearwater (*Calonectris diomedea*), the storm petrel (*Hydrobates pelagicus*) or the garden dormouse of Formentera (*Eliomys quercinus ophiusae*) (Hinckley, et al., 2016), as few predators are present on Formentera and the abundant endemic fauna is an easy and vulnerable target because prey species lack co-evolutionary experience with snakes (Rodda, et al. 1999b).

Successful control of *R. scalaris* is Formentera’s highest conservancy priority (Pleguezuelos, et al., 2015). This is an early invasion, in chronological terms, and the area of invasion seems to be relatively small. The use of this wooden box trap seems to be a useful starting point towards *R. scalaris* control. However, more comprehensive research is required to determine whether the ladder snake’s expansion on Formentera can be stopped by using this capture method. In order to assess this question, the study will continue in future years with a greater trap array.

ACKNOWLEDGEMENTS

This work was supported by the Consell Insular de Formentera and Eivissa, Agents de Medi Ambient and IBANAT. The wooden trap would not have been possible without the help of the Escola d’Arts i Oficis d’Eivissa in making the first prototype. This project has been funded by the FEADER (Fondo Europeo Agrario de Desarrollo Rural) through the Desenvolupament Rural de les Illes Balears Programme.

Abstract The endemic-rich amphibian fauna of the Philippine Archipelago (ca. 350,000 km^2) includes six alien frogs: the American bullfrog (*Lithobates catesbeianus*), Asiatic painted toad (*Kaloula pulchra*), cane toad (*Rhinella marina*), Chinese bullfrog (*Hoplobatrachus rugulosus*), green paddy frog (*Hylarana erythraea*), and greenhouse frog (*Eleutherodactylus planirostris*). The chronological history of their invasion across the Philippines was reconstructed based on historical and geographic data. Subsequently, we estimated their current and potential distribution through species distribution modelling and Gaussian kernel density smoothing species distribution data. Seven known and potential pathways of introduction into and spread throughout the Philippines were identified, namely, intentional introduction as a (1) biocontrol agent and (2) food source; contamination of (3) agriculture trade, (4) aquaculture trade, and (5) ornamental plant trade; (6) stowaway of cargo; and (7) through the exotic pet trade. Spatio-temporal patterns of distribution showed a stratified diffusion process of spread wherein human-mediated jum dispersal is the primary mode followed by diffusion dispersal. The status of the American bullfrog in the Philippines is unresolved, whether it has successfully established. Meanwhile, the other five alien frogs have established populations in the wild, typically the dominant species in both artificial and disturbed habitats, and are continuously spreading throughout the Philippines. Estimates of current and potential distribution indicate that none of the alien frogs has realised its full potential distribution and that the cane toad is the most widespread, occurring in almost all major islands of the Philippines (ca. 85%), while the greenhouse frog is the least distributed, being found so far in eight provinces and on seven islands. In light of these findings, we provide policy and management recommendations for responding to current and future alien frog invasions.

Keywords: frogs, geographic risk assessment, invasion history, invasive alien species, policy and management

INTRODUCTION

The Philippines (Fig. 1) is the second largest archipelago in the world, with ca. 7,641 islands, and is recognised as a megadiverse nation and a global biodiversity conservation hotspot (Heaney & Mittermeier, 1997; Heaney, et al., 1999; Myers, et al., 2000a). A compelling example of its rich biodiversity is exhibited by the country's amphibian assemblage, which is among the most important faunas in the Indomalayan Region in terms of diversity and endemism (Bain, et al., 2008; Diesmos, et al., 2014). Currently, there are 110 native species of amphibians known from the Philippines, 97 of which (ca. 91%) are endemics (Diesmos, et al., 2015). However, ca. 45% of Philippine amphibians are threatened with extinction: the major threats include habitat loss and deforestation, invasive alien species, emerging infectious diseases, and climate change (Alcala, et al., 2012; Brown, et al., 2012; Diesmos, et al., 2014).

Included in the Philippine amphibian fauna are six introduced frogs, namely, the American bullfrog (*Lithobates catesbeianus* [Shaw, 1802]), the Asiatic painted toad (*Kaloula pulchra* Gray, 1831), the cane toad (*Rhinella marina* [Linnaeus, 1758]), the Chinese bullfrog (*Hoplobatrachus rugulosus* [Wiegmann, 1834]), the green paddy frog (*Hylarana erythraea* [Schlegel, 1837]), and the greenhouse frog (*Eleutherodactylus planirostris* [Cope, 1862]) (Fig. 2; Diesmos, et al., 2006; Diesmos, et al., 2014; Olson, et al., 2014; Diesmos, et al., 2015). Preliminary studies and anecdotal reports indicated that these introduced species, particularly the cane toad and the Chinese bullfrog, are harmful invasives, threatening Philippine wildlife through competitive exclusion and direct predation (Rabor, 1952; Alcala, 1957; Soriano, 1964; Espiritu, 1985; Adraneda, et al., 2005; Diesmos, et al., 2006). Diesmos, et al., (2006) provided the first review on the status and distribution of alien frogs in the Philippines (then only five alien frogs were present). However, there remains a large knowledge gap on their history of invasion and no recent attempts have been made to synthesise the growing body of knowledge on their geographic distribution. By assembling and analysing historical and geographical data of the six alien frogs in the Philippines, we reconstructed the chronological history of invasion and updated their status and distribution. We then estimated their current and potential distribution by projecting suitable areas based on two separate species distribution models ("native range models" and "Philippine models") and, subsequently, Gaussian kernel density smoothing distribution data to delineate occupied suitable areas ("current distribution") and unoccupied suitable areas ("potential distribution").

METHODS

Reconstructing history of invasion

We reconstructed the chronological history of invasion of the six alien frog species in the Philippines based on historical and geographical data ("species distribution data") obtained from the following sources: (1) Natural history collections (NHC): data obtained directly from collections managers of local and international institutions or through the Global Biodiversity Information Facility (GBIF); (2) published and (3) unpublished scientific literature; and (4) personal observations of authors and fellow experts.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 337–347. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Species distribution modelling

Species Distribution Modelling (SDM) involves the quantification of species-environment relationships to define a species' ecological niche. The ecological niche models are then projected into geographic space to visualise and yield an estimate of geographic range or suitable areas where a species can or cannot persist (Guisan & Zimmermann, 2000; Guisan & Thuiller, 2005; Elith & Leathwick, 2009). In studies dealing with invasive alien species, predictions of suitable areas are typically made by extrapolating models fitted with data from the species' native range onto areas that could be invaded (Peterson & Vieglais, 2001; Venette, et al., 2010; Araújo & Peterson, 2012). However, empirical studies have shown evident niche shift in invasive populations, suggesting that species can occupy climatically distinct niche spaces following their introduction into a new area (Broennimann, et al., 2007; Beaumont, et al., 2009).

Here, we developed two separate projections of Philippine-suitable areas for the alien frogs based on models fitted with species distribution data and environmental data (1) from the invaded range in the Philippines (hereafter called "*Philippine models*") and (2) from the alien frogs' native ranges (hereafter called "*Native models*"). Because of the limited amount of species distribution data, we did not develop *Philippine models* for the American bullfrog and the greenhouse frog.

Data collection and calibration. The *Philippine models* were fitted using species distribution data from the Philippines (data used in reconstructing history of invasion). Meanwhile, *Native models* were fitted using species distribution data obtained from the GBIF. Sampling bias was corrected through systematic subsampling neighbouring species distribution data to a resolution of one distribution point per five square kilometres or 2.5 arcminutes and by developing bias files (Elith, et al., 2010; Fourcade, et al., 2014).

The original set of environmental variables includes 19 bioclimatic datasets (Worldclim – Hijmans, et al., 2005) and Global Land Cover 2000 (GLC2000) (Fritz, et al., 2003)

Table 1 Calibration of ecological niche models. Shown are the species distribution data used for model training and testing, model validation approach, number of replicates, and the Maxent features (L – linear; Q – quadratic; P – product) used in fitting *Philippine models* (A) and *Native range models* (B) of the alien frogs. Due to the limited amount of species distribution data viable for model fitting, Philippine models of the American bullfrog and the greenhouse frog were not developed.

Species	Training data	Testing data	Validation	Replication	Maxent Features

with a spatial resolution of 30 arc seconds. Environmental variables used for fitting the *Philippine models* had a spatial coverage from the Philippines only. Meanwhile, *Native model*s had a spatial coverage equivalent to the native range of the species, based on a convex hull polygon of species distribution data. For both *Philippine* and *Native models* of each species, the environmental variables used for model fitting were pre-selected to only include those that are ecologically relevant (Austin, 2002; Wells, 2007) to the species and are not highly inter-correlated (Dormann, et al., 2013). Correlation between variables were assessed using pair-wise Pearson's correlation coefficient (*stats* R version v.3.3.0 by R Core Team, 2016) and, subsequently, we selected only the putatively ecologically most relevant variable from each group of highly inter-correlated variables ($|r| \geq 0.7$) (Dormann, et al., 2013). The final set of environmental variables used for model fitting included (1) diurnal temperature, (2) temperature seasonality, (3) maximum temperature of warmest month, (4) minimum temperature of coldest month, (5) annual precipitation, (6) precipitation seasonality, (7) precipitation of wettest quarter, and (8) Global Land Cover 2000.

Model fitting. Species distribution modelling was performed using Maximum Entropy Modelling (Maxent v.3.3.3k) (Phillips, et al., 2004; Phillips, et al., 2006a). Maxent is a general-purpose machine learning method premised on the principle of maximum entropy and with a simple and precise mathematical formulation for presence only (i.e., species distribution data) modelling of species distributions from incomplete information (Phillips, et al., 2004; Phillips, et al., 2006a). Maxent has been found to outperform other statistical approaches based on predictive accuracy (Jeschke & Strayer, 2008; Elith & Graham, 2009). Maxent settings used for fitting species distribution models are shown in Table 2. The Maxent features (i.e. linear, quadratic, product) used for each species' models were selected following Phillips (2005), Phillips, et al. (2006b) and Phillips & Dudik (2008) suggestions and were based on the number of species distribution points after systematic subsampling. Developed *bias files* were incorporated in the bias function of Maxent (Table 1). A logistic output was selected to represent the predicted suitable habitats of the species. Pseudo-absence data or background data were generated at random within the Philippines for *Philippine model*s and within the native geographic range of each species for *Native model*s. All other Maxent settings were set to default.

Model evaluation. Model performance of the *Philippine models* of the cane toad, Chinese bullfrog, and green paddy frog, and *Native Models* of all alien frogs except the greenhouse frog was evaluated using the area under receiver operating characteristic (ROC) curve (AUC) by subsampling (randomly splitting presence/pseudo-absences into two subsets with 70% of the records used for model fitting and the remaining 30% to evaluate the models) and was repeated 10 times (Table 1, Pearce & Ferrier, 2000; Allouche et al., 2006; Araújo & Guisan, 2006). Meanwhile, due to the limited amount of species distribution data, model performance of the *Philippine models* of the Asiatic painted toad and *Native Models* of the greenhouse frog was evaluated using the AUC values by 10-fold cross-validation and was repeated five to 10 times (Pearce & Ferrier, 2000; Allouche, et al., 2006; Araújo & Guisan, 2006) (Table 1). The AUC values were interpreted based on Swets (1988) recommendation where 0.5–0.6 = fail, 0.61–0.7 = poor; 0.71–0.8= fair, 0.81–0.9 = good, and 0.91–1.0 = excellent.

Projection. The models were projected to Philippine geographic space to predict suitable areas for the species. The projections were transformed into binary maps of suitable/unsuitable areas, wherein areas above a minimum training presence threshold (no omission) are referred to as "suitable" areas (Liu, et al., 2005).

Table 2 History of invasion and current status and distribution of alien frogs in the Philippines.

Species	Origin of introduced populations	Year and locality of introduction or first detection	Pathway of introduction and spread	Islands Present	Provinces Present
American bullfrog	Louisiana, USA	1966 in Luzon Island	Food source	5	12
Asiatic painted toad	Unknown	2003 in Luzon Island	Cargo Stowaway, Exotic Pet Trade, Ornamental Plant Trade	6	16
Cane toad	Hawaii, USA	1934 in Luzon Island	Biocontrol agent	36	53
Chinese bullfrog	Unknown	1993 in Luzon Island	Food source, Aquaculture trade	7	26
Green paddy frog	Borneo Island[b]	1800s (unknown locality); 1908 Panay Is	Agricultural trade	20	38
Greenhouse frog	Hawaii, USA[b]	2014 in Mindanao Is	Exotic plant trade	8	7

Estimating current and potential distribution

We define the current and potential distribution of invasive alien species as respectively areas occupied and unoccupied by the alien species conditional on areas of suitable habitat (Gormley, et al., 2011). The geographic ranges of the alien frogs in the Philippines were estimated by two-dimensional Gaussian kernel smoothing assembled species distribution data (*kde2d* function of *MASS* v.7.45 R package; Ripley, et al., 2015). This method applies a two-dimensional Gaussian kernel to compute distribution of an animal within its home range/geographic range (Worton, 1989; Venables & Ripley, 2002; Gaston & Fuller, 2009). The solve-the-equation method (*width.SJ* function *MASS* R package; Sheather & Jones, 1991), was used to select the bandwidth for kernel smoothing, and was defined to include 99.5% of species' distribution data. Estimated geographic ranges were then used to delineate the occupied suitable areas ("current distribution") and unoccupied suitable areas ("potential distribution"). Because of the limited amount of species distribution data, we did not estimate the geographic range of the American bullfrog and the greenhouse frog in the Philippines, and, consequently, we did not delineate their current and potential distribution.

RESULTS

History of invasion

A comprehensive review of the history of invasion, including an assembled species distribution database, of the six alien frogs in the Philippines is prepared in a separate study for future publication. The review provided below will suffice as a general overview of their history of invasion.

The American bullfrog

Individuals of the American bullfrog were imported from Louisiana, United States in 1966 and were first reared on Luzon Island (Ugale, 1976; Pascual, 1987b). Frogs were initially bred for the export production of scientific specimens for biomolecular and medical research and other educational activities (Pascual, 1987a; Urbanes, 1988; Urbanes, 1990; Matienzo, 1990). Subsequently, in 1980, through government efforts to boost food security, the American bullfrog breeding shifted to food production. Another eight American bullfrog breeding centres were established across the Philippines (Table 2; Fig 3a; Ministry of Natural Resources, 1981; Buenviaje, 1983; Inovejas, 1985). Breeding centres ceased operation in 1985. The current status of the American bullfrog in the Philippines, whether they were able to successfully establish populations in the wild, is unknown.

The Asiatic painted toad

The Asiatic painted toad was first reported in the Philippines in 2003 on Luzon Island (Diesmos, et al., 2006). It was earlier suggested that the initial introduction of the Asiatic painted toad was through the exotic pet trade (Diesmos, et al., 2006). Introduction as a contaminant of ornamental plant trade or as cargo stowaway is also plausible. From localities of its initial introduction, the Asiatic painted toad has spread in all directions throughout the Philippines and is now recorded in 16 provinces on six islands (Table 2; Fig. 3b). It is likely that the identified introduction pathways may have mediated its spread throughout the Philippines.

The cane toad

The cane toad was intentionally introduced in the Philippines as a part of a national pest control programme (Merino, 1936). Cane toads were secured from the Hawaiian Sugar Planters Association and were brought to the Philippines in 1934 (Merino, 1936). The toads were initially reared on Luzon Island. Since then, they have spread in all directions across islands and onto different islands throughout the Philippines. Their spread is primarily mediated by human movement (deliberate release for biocontrol), as a cargo stowaway, and neighbourhood diffusion dispersal (Rabor, 1952). Today, the cane toad can

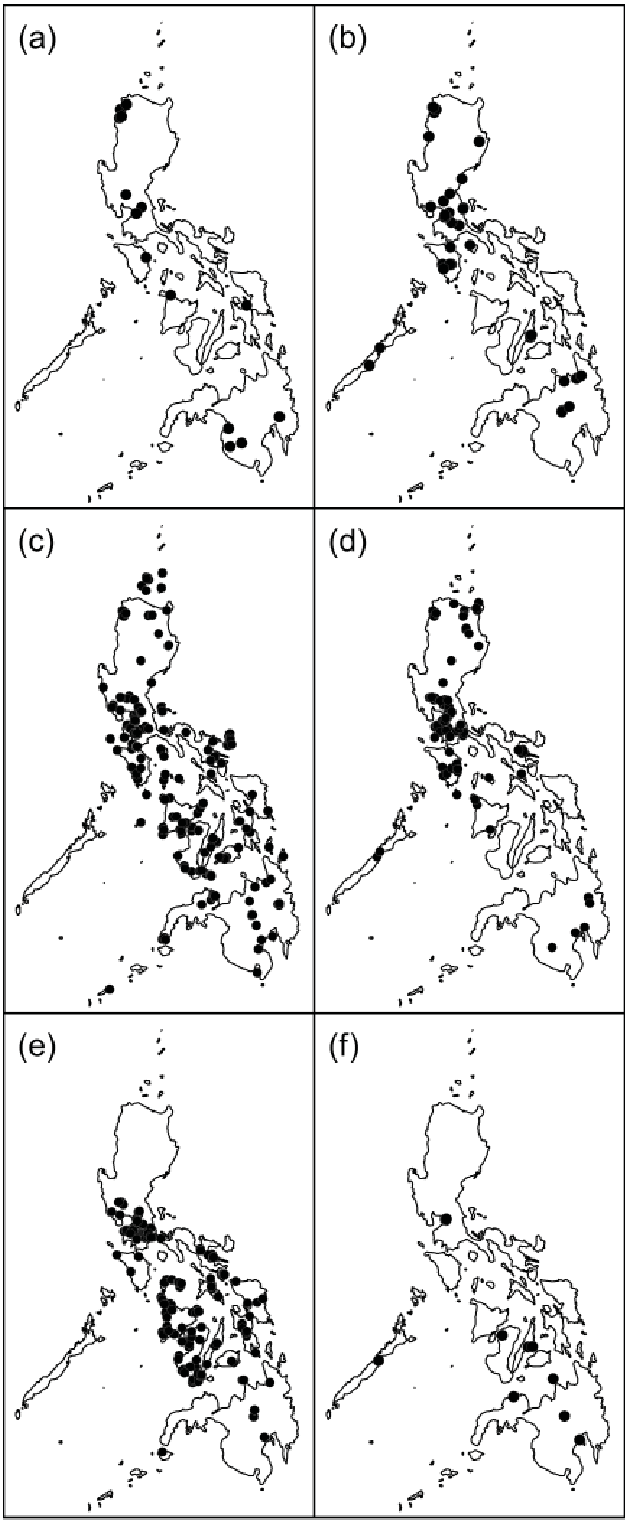

Fig. 3 Geographic distribution of the alien frogs in the Philippines, (a) American bullfrog, (b) Asiatic painted toad, (c) cane toad, (d) Chinese bullfrog, (e) green paddy frog, and (f) greenhouse frog. Points indicate areas where alien frogs were reported present (release sites or areas where bullfrog breeding centres were formerly established for the case of the American bullfrog).

be found on almost all major islands of the Philippines, where it is usually the dominant amphibian species in invaded areas (Table 2; Fig. 3c; Alcala, 1986; Alcala & Brown, 1998; Diesmos, et al., 2006; Diesmos, et al., 2015).

The Chinese bullfrog

The Chinese bullfrog was first reported in the Philippines in 1993 on Luzon Island (Diesmos, 1998; Diesmos et al., 2006). It was speculated that this species was introduced into and spread throughout the Philippines along with American bullfrog breeding in the 1980s (Diesmos, et al., 2006). Other potential pathways of introduction and spread of the Chinese bullfrog throughout the Philippines are contamination of agricultural trade, as for the case of co-occurring alien and native frogs in the Philippines (Inger, 1954; Kuraishi, et al., 2009), and contamination of aquaculture trade, as was the case of its congeneric (Indian bullfrog *Hoplobatrachus tigerinus*) on Andaman Islands, India (Surendran & Vasudevan, 2013). The Chinese bullfrog is now found in 26 provinces on seven islands in the Philippines (Table 2; Fig. 3d).

The green paddy frog

The earliest valid records of the green paddy frog, overlooked in previous discussions regarding its history of invasion (e.g., Inger, 1954), were collections from Panay Island in 1908 (Orrell & Hollowell, 2017). In the early 1900s, the green paddy frog was initially thought to be native to the Philippines with restricted distribution on the islands of Negros, Panay, Sibuyan and Tablas (Taylor, 1920; Taylor, 1922; Inger, 1954). Inger (1954) suggested that the green paddy frog was introduced as a contaminant of agricultural trade owing to its disjunct distribution from the nearest extra-Philippine populations on Borneo Island. The green paddy frog is now found in 38 provinces on 20 islands (Table 2; Fig. 3e). Contamination of agricultural and aquaculture trade may be implicated for its spread throughout the Philippines.

The greenhouse frog

The greenhouse frog was first detected on Mindanao Island in 2013 (Olson, et al., 2014). the propensity of the greenhouse frog to thrive in human-modified environments, especially in gardens (Olson et al., 2014; Sy & Salgo, 2015; Sy, et al., 2015a, b; Sy, 2017a,b), suggests that the trade in exotic ornamental plants is the most plausible pathway of its introduction into and spread throughout the Philippines, as was documented in Hawaii (Kraus, et al., 1999). The greenhouse frog has so far been recorded in eight provinces on seven islands (Table 2; Fig. 3f).

Philippine-suitable areas

Models of the alien frogs indicate fair to excellent training-AUC values (≥70) (Table 3). Based on projections of Philippine-suitable areas of both the *Philippine models* (except American bullfrog and greenhouse frog) and *Native models*, the alien frogs are, to varying extents, suitable to the Philippines. It should be noted that the *Native models* consistently projected a broader range of Philippine-suitable areas (Figs 4 & 5; Table 4). Moreover, both the *Philippine* and *Native models* consistently projected human-modified and disturbed areas to exhibit typical to high probability of suitable conditions for these alien species.

Current and potential distribution

Maps show that the Asiatic painted toad has occupied ca. 30–40% of projected suitable areas (or ca. 20–30% of total Philippine land area), particularly most of central and northern Luzon Island, north-western islands of central Philippines (Cebu, Marinduque, Mindoro, and Palawan Islands), and central Mindanao Island. Potential distribution of the Asiatic painted toad includes islands north of Luzon Island (Babuyanes and Batanes group of islands) areas in north-central (Cordillera Administrative Region), southern (Bicol Region) and most of central Luzon Island, western Mindanao Island, and Sulu Archipelago (Table 5; Fig. 6). The cane toad has occupied almost all projected suitable areas (ca.98–100%) except those on the islands of Batanes Province (northernmost group of islands of the Philippines), islands of Palawan Province (westernmost group of islands), and most of Sulu Archipelago (southernmost islands) (Table 5; Fig. 6). Maps showed that Chinese bullfrog has a disjunct distribution throughout the Philippines, having occupied ca. 40–50% of suitable areas (or ca. 35–40% of total Philippine land area), specifically most of Luzon Island, islands of central

Table 3 Evaluation of the prediction of Species Distribution Models of the six alien frogs. *Philippine models* (**A**) and *Native range models* (**B**) were evaluated by validation of predictions based on the Area Under the Receiver Operating Characteristic (ROC) Curve (AUC).

Species	Training AUC (mean)	Test AUC (mean)	AUC values interpretation	Minimum training presence threshold
A. Philippine model				
American bullfrog	0.78	-	Fair	0.2886
Asiatic painted toad	0.86	-	Good	0.2663
Cane toad	0.72	0.71	Fair	0.0922
Chinese bullfrog	0.84	0.82	Good	0.0858
Green paddy frog	0.82	0.79	Fair	0.1286
Greenhouse frog	0.97	-	Excellent	0.1527
B. Native range model				
American bullfrog	0.70	0.70	Fair	0.0378
Asiatic painted toad	0.86	0.81	Good	0.1243
Cane toad	0.76	0.75	Fair	0.1091
Chinese bullfrog	0.85	0.83	Good	0.0206
Green paddy frog	0.74	0.69	Fair	0.1225
Greenhouse frog	0.78	-	Fair	0.1823

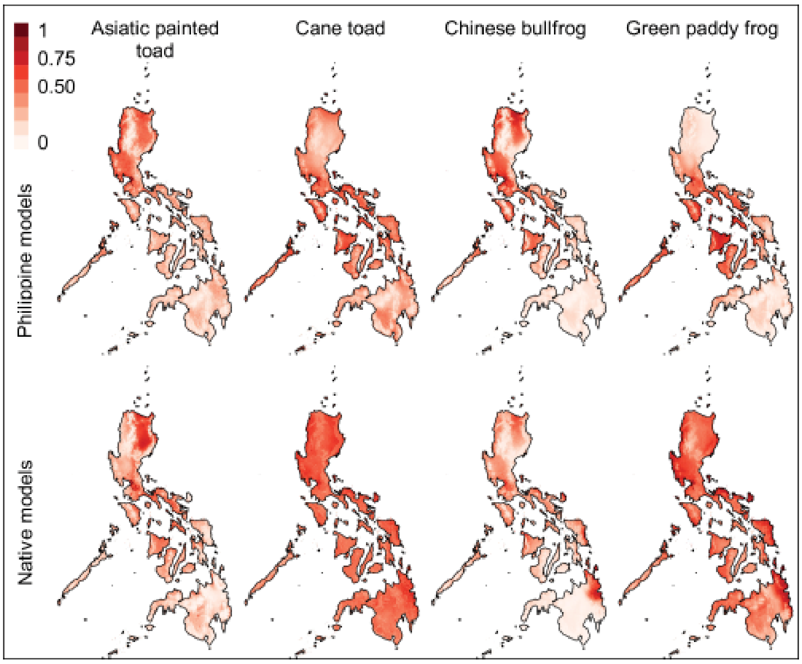

Fig. 4 Projected Philippine-suitable areas for (from left to right) Asiatic painted toad, cane toad, Chinese bullfrog, and green paddy frog, based on (top row) *Philippine model* and (bottom row) *Native model*.

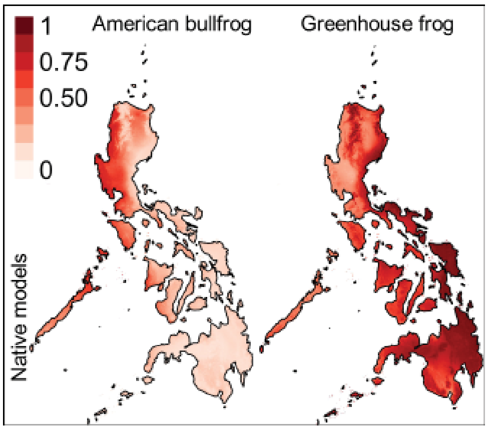

Fig. 5 Projected Philippine-suitable areas for (from left to right) the American bullfrog and the greenhouse frog based on *Native models*.

Philippines (Mindoro and Panay Island), and central and eastern Mindanao Island. Most of its potential distribution are the islands north of Luzon Island (Babuyanes and Batanes group of islands), some areas in central Philippines (Central Visayas Region and Eastern Visayas Region), and most of Mindanao Island including Sulu Archipelago (Table 5; Fig. 6). Despite being present in the Philippines for more than a century, the green paddy frog has only invaded ca. 40–60% of projected suitable areas or 30–40% of the Philippines. The current distribution of the green paddy frog is mainly in Central Philippines, southern and central parts of Luzon Island, disjunct areas in Mindanao Island, and Basilan Island. Potential distribution of the green paddy frog includes most of the islands of Palawan Province, Mindanao Island, and central to northern Luzon Island (Table 5; Fig. 6). Lastly, due to the limited amount of species distribution data, the current and potential distribution of the American bullfrog and the greenhouse frog were not estimated. Interestingly, projections show that almost all of the Philippines is suitable for both species (Fig. 7).

Collectively, maps showed that none of the alien frogs has fully occupied all projected Philippine-suitable areas, and that all alien frogs are on Luzon Island and Mindanao Island, the two largest islands of the Philippines. The islands of Batanes Province (Northernmost group of islands of the Philippines) are the only remaining places in the Philippines with no record of alien frogs.

DISCUSSION

We first discuss here how our study filled knowledge gaps on the invasion history and the status of the alien frogs in the Philippines. At the end of this section, we provide policy and management recommendations.

Invasion history: conceptual background

Our study is the first to reconstruct the invasion history of the six alien frogs in the Philippines. History of invasion refers to the historical, demographical and geographical features of a species' invasion processes. This may include information on the source of propagules and propagule pressure, the dispersal pathways and associated vectors, and the geographical and demographical dynamics of the spread of the adventive populations (Dlugosch & Parker, 2008; Estoup & Guillemaud, 2010). Knowledge of the invasion history forms the foundation of invasion biology by addressing practical and theoretical questions as well as testing different hypotheses concerning the ecology and evolution underlying biological invasions (Estoup & Guillemaud, 2010). More importantly, elucidating invasion history can provide invaluable insights for the

Table 4 Estimates of suitable area in the Philippines (PH) for the six alien frogs. Total area (km²) and percentage (%) of total Philippine land area that is suitable (above minimum training presence threshold) to the alien frogs.

Species	Philippine model		Native range model	
	km²	(%) of total PH	km²	(%) of total PH
American bullfrog	-	-	349,107	99.64

development and implementation of sound strategies and science-based policies for the management of invasive alien species, particularly in preventing future introductions and controlling incursions (Hulme, et al., 2008; Estoup & Guillemaud, 2010; Kulhanek, et al., 2011). Here, we reconstructed the chronological history of invasion, identified known and potential pathways involved in introduction, and updated the current status and distribution of invasive frog species in the Philippines. Below we discuss further the dynamics and mechanisms underlying their spread based on spatio-temporal patterns of species distribution.

Invasion history: pathways of introduction of the alien frogs

Identifying the geographical origin, causative pathways, and associated vectors of past introductions can help guide the development of preventive measures, such as monitoring and quarantine schemes, which are most effective when specifically targeted to ports of entry and trade of commodities associated with identified pathways of introduction (Hulme, 2006; Hulme, 2009; Hulme, et al., 2008). Six principal pathways are involved in the global movement of species into new areas: alien species may be commodities (intentionally released and escapees), contaminants of commodities, stowaways on vectors, opportunists exploiting corridors resulting from transport infrastructures, or they may spread naturally (Hulme, et al., 2008). It is noteworthy that the number of total introductions through each pathway may vary among taxonomic groups. For instance, global alien amphibian introductions are most frequently through intentional release as biocontrol agent and food source, contaminant of ornamental plant trade, stowaway of cargo, and escapees from exotic pet trade (Kraus, 2009). In addition to these, herein we identified two other pathways by which alien frogs were introduced into the Philippines: as a contaminant of agricultural trade and aquaculture trade.

Invasion history: dynamics and mechanisms of spread of the alien frogs

Understanding the pattern and rate of spread of invasions are essential components of risk assessment of invasive alien species (Stohlgren & Schnase, 2006;

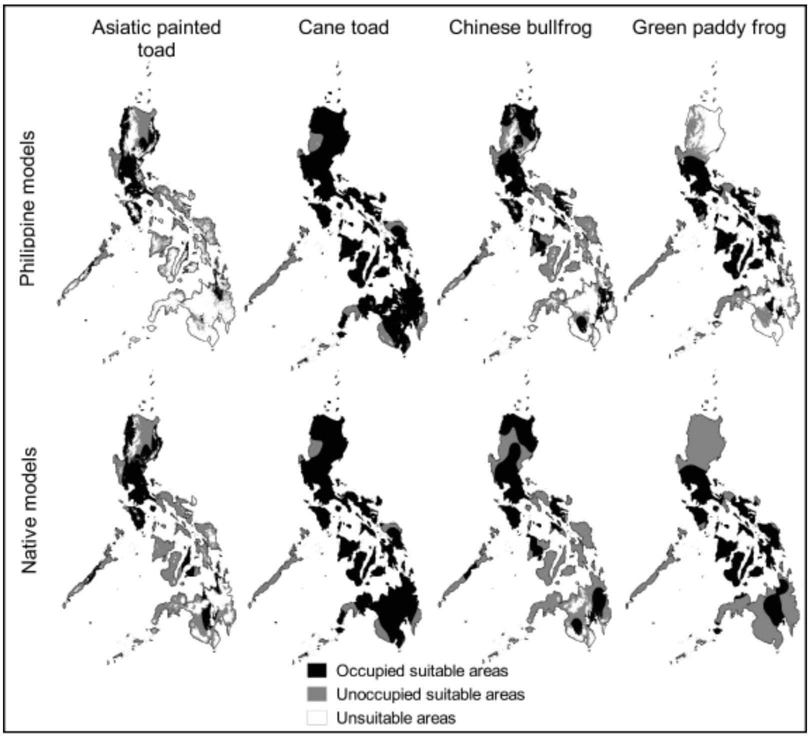

Fig. 6 Current and potential distribution in the Philippines of (from left to right) the Asiatic painted toad, cane toad, Chinese bullfrog, and the green paddy frog based on estimates of geographic range and Philippine-suitable areas projected by (top row) *Philippine models* and (bottom row) *Native models*.

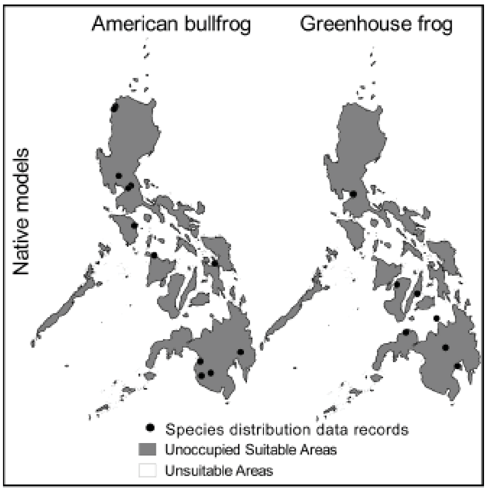

Fig. 7 Current and potential distribution in the Philippines of (from left to right) the American bullfrog and the greenhouse frog based on overlaid species distribution data over Philippine-suitable areas projected by *Native models*. Points indicate areas where alien frogs were reported present (release sites or areas where bullfrog breeding centres were formerly established for the case of the American bullfrog).

Stohlgren & Jarnevich, 2009). For invading organisms, a stratified diffusion process of spread "seems to be the rule rather than the exception" (Higgins & Richardson, 1999). In a stratified diffusion process, initial range expansion occurs though neighbourhood diffusion and new colonies are successively created through jump dispersal events by long-distance migrants, accelerating the rate of overall invasion (Van der Plank, 1967 as cited in Hengeveld, 1989; Shigesada, et al., 1995; Higgins & Richardson, 1999). Jump dispersal events are particularly common for species that are closely associated with humans (Suarez, et al., 2001). For instance, human-mediated jum dispersal has been documented in *Eleutherodactylus* spp. in Hawaii (Kraus & Campbell, 2002), Argentine ants (*Linepithema humile*) in the United States (Suarez, et al., 2001), common ragweed (*Ambrosia artemisiifolia*) in France (Chauvel, et al., 2006).

The reconstructed history of invasion showed that the spread of alien frogs in the Philippines followed a stratified diffusion process wherein human-mediated jump dispersal and neighbourhood diffusion dispersal were the main modes of spread. Given the innate physiological limitations of frogs to cross marine barriers and the close affinity of alien frogs with humans (Wells, 2007), human-mediated jump dispersal is the most plausible primary mode of dispersal of alien frogs inter- and intra-island. Numerous jump dispersal events throughout the course of the invasion of alien frogs in the Philippines can be observed in the spatio-temporal distribution patterns shown in the generated species' distribution maps (Fig. 3). This is particularly evident in the invasion of the cane toad, wherein from founder populations on five islands, it has invaded almost all major islands in the Philippines in a matter of decades (Rabor, 1952). The dispersal of the green paddy frog to Basilan Island, some 300 km from the nearest introduced population in Negros Island in the 1960s and 350 km from nearest native population on Borneo Island, demonstrates a good example of either long-distance jump dispersal or perhaps a secondary introduction event. For the cases of the Asiatic painted toad, the Chinese bullfrog, and the greenhouse frog, it is unclear whether their presence on different islands is caused by jump dispersal events from a single founder population or the result of multiple, independent introduction events.

The same pathways implicated for alien frog introductions may have served as the same pathways that mediated their jump-dispersal throughout the Philippines. Spread of the cane toad was primarily human-mediated, being released deliberately by both government and private individuals with the belief that the frogs would control insect and rodent pests in agricultural fields (Merino, 1936; Rabor, 1952; Soriano, 1964). Observations in the Philippines and on Borneo reported cane toads and the Asiatic painted toads in cargo and vehicles of transport and trade as stowaways (Inger, 1966; A.C. Diesmos personal observation). The greenhouse frog may have spread throughout the Philippines as a contaminant of ornamental plant trade and nursery plants, as happened in Hawaii (Kraus, et al., 1999; Olson, et al., 2012). Similarly, the propensity of the Asiatic painted toad to seek refuge in greenhouse materials (e.g. potted plants, soil, etc.) implicate ornamental plant trade and movement of nursery plants as a potential pathway for its spread (E.Y. Sy personal observation). The American bullfrog, despite having an unresolved status in the Philippines, was dispersed throughout the Philippines as a food source. It was earlier speculated that the Chinese bullfrog may have been introduced and spread throughout the Philippines alongside the proliferation of American bullfrog breeding centres in the 1980s (Diesmos, et al., 2006). Moreover, agricultural trade and aquaculture trade may have served as dispersal pathways for the Chinese bullfrog and as well as the green paddy frog. Agricultural trade has been attributed to recent range expansion of some Philippine native species such as the Philippine common tree frog (*Polpedates leucomystax*), the common mud frog (*Occidozyga laevis*), and the Philippine paddy frog (*Fejervarya vittigera*) (Inger, 1954; Brown, et al., 2010). Meanwhile, the aquaculture trade served as a minor pathway of global introduction for alien frogs and has been well documented in some alien frogs on Guam (Christy, et al., 2007; Kraus, 2007; Kraus, 2009).

Neighbourhood diffusion dispersal also played an invaluable role in the spread of alien frogs within islands. For instance, it was observed that the cane toad has diffused up to 20 km around Dumaguete City, Negros Island in a matter of 15 years (Rabor, 1952). Though this observation was not supported by empirical data, in Australia, the cane toad was observed to travel up to 1.8 km per night, especially during the rainy months (Phillips, et al., 2006b). Moreover, short-distance dispersal may be aided by other "natural" processes such as extensive floods, which are common in most parts of the Philippines.

Policy and management recommendations

Given the potential negative ecological and economic implications of alien frogs (Kraus, 2015), policies and management strategies for alien frog invasions in the Philippines are urgently needed. Our study filled knowledge gaps on the invasion of the alien frogs in the Philippines, which can guide the development and implementation of sound policies and management strategies, particularly the Philippines' National Invasive Species Strategy and Action Plan (NISSAP; DENR-PAWB, 2013).

Prevention of future alien introductions.

Of the six alien frogs currently occurring in the Philippines, three were introduced only in the past three decades, with the greenhouse frog being the most recently reported. Given the lack of measures to prevent invasions in the Philippines, future alien frog introductions seem inevitable. In fact, a recent survey conducted by the authors reported a seventh alien frog is now present (A.C. Diesmos, *for future publication*). A useful preventive measure are early-warning systems (i.e., black-white lists, watch lists, etc.). These systems direct border preventive measures, such as inspection, quarantine, and policies banning entry, by identifying alien species with the potential to threaten native biodiversity (Heger & Trepl, 2003; Hulme, 2006; Maynard & Nowell, 2009). A separate study conducted by the authors for future publication identified alien amphibians that can potentially threaten Philippine biodiversity based on three factors of invasion success, namely history of invasion elsewhere, climate match, and propagule pressure.

To prevent future alien frog introductions, preventive measures are best focused on potential pathways and associated vectors (Perrings, et al., 2005; Hulme, 2006; Hulme, 2009; Hulme, et al., 2008). Some examples of preventive measures include (1) prohibition or developing stricter regulations and standards for the breeding, trading, and keeping of exotic pets (e.g., Taiwan, Australia, and New Zealand) and animals for food production (e.g., European Union States), (2) post-border inspection, quarantine, and treatment of imported commodities such as ornamental plants (e.g., Hawaii and Guam), fish fingerlings, and agricultural products, standardising risk assessment of candidate biocontrol species, and (3) early detection and rapid eradication schemes at ports of entry such as seaports and airports (reviewed in Hulme, 2009; preventive measures focusing on alien amphibians and reptiles are reviewed in Kraus, 2009).

Management of spread between islands

Developing measures to control the inter-island spread of alien frogs is critical in archipelagic systems, such as the Philippines. Like prevention, measures to control the inter-island spread of alien species are best focused on the identified potential pathways of spread and their associated vectors (Hulme, 2006; Hulme, 2009; Hulme, et al., 2008). Some examples of control measures include: for the American bullfrog, Asiatic painted toad, and the Chinese bullfrog, prohibition of release and implementation of standards and regulations for possession or breeding either as pets or for farming (although no bullfrog breeding centres are operational to date); for the Asiatic painted toad and greenhouse frog, quarantine, inspection, and treatment of traded and transported ornamental plants, nursery plants, and greenhouse material; for the Asiatic painted toad and cane toad, early detection and rapid eradication schemes on ports of entry such as seaports and airports and inspection of cargo; for the Chinese bullfrog and green paddy frog, inspection of products of agricultural trade and prohibition of fish fingerling collection for release in novel areas. These control measures should be focused on unoccupied but suitable islands (Leung, et al., 2005), especially in the Batanes Island Group.

It is noteworthy that the Philippines has perhaps the moral responsibility to contain these exotics from spreading into neighboring foreign areas. For example, the southernmost extent of invasion of the cane toad in the Philippines is on Basilan Island, which is about 100 kilometers from Borneo Island (Malaysia) and where the species is alien. The spread of the alien frogs to foreign countries can be prevented by inspection of commodities for export, especially those associated with pathways of introduction and spread. In fact, the Philippine common treefrog was introduced into Ryukyu Archipelago, Japan by contaminated traded agricultural commodities (Kuraishi, et al., 2009).

Maps of current and potential distribution as a guide for management schemes.

Estimating and delineating the potential and current geographical range of alien species is a critical component of risk assessment by providing science-based information that can help guide the strategic allocation of limited resources for the management of invasive alien species (Stohlgren & Schnase, 2006; Stohlgren & Jarnevich, 2009; Venette, et al., 2010). For instance, surveys and monitoring schemes should be focused in areas with no information on the status of the alien frogs or areas of high conservation concern (Wittenberg & Cock, 2001; McGeoch & Squires, 2015), such as in most Protected Areas in the Philippines, on central Luzon Island (Cordillera Administrative Region), western Mindanao Island, and islands in the Batanes Province. More importantly, field surveys are warranted in areas where bullfrog breeding centers were formerly established as well as in release sites, so to confirm the status of the American bullfrog in the Philippines (Fig. 3a). Control and containment of incursions and mitigation of impacts should be focused on invaded areas, especially in areas of high conservation value such as protected areas and nature reserves (Myers, et al., 2000b; Wittenberg & Cock, 2001; Parrish, et al., 2003). Early detection and rapid eradication schemes are best focused on the interface between the potential and current distribution (Hulme, 2006), such as the invasion front of the green paddy frog on central Luzon Island (Fig. 3e).

Recognizing the variability in projected suitable areas between the *Philippine* and *Native models*, and that different modelling techniques yield different results even if calibrated with same set of data, we developed in a separate study for future publication projections of suitable areas based on ensembles of models fitted with data from the entire range (native range and all invaded range/s) and using different statistical techniques. Moreover, evaluation of the accuracy of projections and estimates through ground truthing are underway.

Recommendations for future research

The following recommendations for future research on alien amphibian invasions in the Philippines are suggested: data mining grey literature, conducting interviews, and targeted field work to populate the assembled species distribution database and improve reconstructed invasion history; vector analysis of the pathways so as to understand their importance to current and future alien amphibian invasions; identify 'native exotics' and understand their invasion histories (e.g. dynamics and mechanisms involved in their spatial spread) and impact to ecosystems; comprehensive risk analysis of the alien frogs, specifically research on their ecological and socio-economic impacts; test different hypothesis on the evolution and ecology of alien species invasions.

ACKNOWLEDGEMENTS

We sincerely thank all museums, both local and international, that shared their data on the six alien frogs either directly or through the Global Biodiversity Information Facility (GBIF); namely, the National Museum of the Philippines, California Academy of Sciences, Florida Museum of Natural History, National Museum of Natural History, University of Kansas Biodiversity Institute, and the University of Texas at Austin Biodiversity Collections. In addition, we thank the Agriculture & Fisheries Information Division (AFID)/ Library Section of the Department of Agriculture, the Library Section of the Science and Education Institute of the Department of Science and Technology, the Library Section of the Environmental Research and Development Bureau of the Department of Environment and Natural Resources for allowing us to access their information facilities. We are truly grateful for all the institutions that provided financial support for fieldwork, including support for ANP from the Department of Science and Technology Science Education Institute (Accelerated Science and Technology Human Resource Development Program) and National Geographic Science and Exploration Asia Young Explorers Grant (ASIA 57-16), ACD from the National Museum of the Philippines, ANP and MLD from the University of Santo Tomas, ANP, CES, MLD, and ACD from the Department of Environment and Natural Resources and GEF-UNEP Project 0515 "Removing Barriers to Invasive Species Management in Production and Protection Forests in Southeast Asia" (FORIS Project).

Abstract After decades of biodiversity loss and economic burden caused by the brown treesnake invasion on the Pacific island of Guam, relief hovers on the horizon. Previous work by USDA Wildlife Services (WS) and its National Wildlife Research Center (NWRC) demonstrated that brown treesnake numbers in forested habitats can be dramatically suppressed by aerial delivery of dead newborn mouse (DNM) baits treated with 80 mg of acetaminophen. However, manual bait preparation and application is impractical for landscape-scale treatment. WS, NWRC, and the US Department of the Interior have collaborated with Applied Design Corporation to engineer an automated bait manufacturing and delivery system. The core technology is an aerially delivered biodegradable "bait cartridge" designed to tangle in the tree canopy, making the acetaminophen bait available to treesnakes and out of reach of terrestrial non-target organisms. When mounted on a rotary- or fixed-wing airframe, the automated dispensing module (ADM) unit can broadcast 3,600 bait cartridges at a rate of four per second and can treat 30 hectares of forest at a density of 120 acetaminophen baits per hectare within 15 minutes of firing time. We conducted the first *in situ* evaluation of the ADM in July 2016. Initial acetaminophen bait deployment rates (proper opening of the bait cartridge for canopy entanglement) were low, and mechanism jams were frequent due to internal friction and wind forces; on-site remedial engineering improved these performance measures. Bait cartridge placement and spacing were accurate (average 8.9 m along 9 m swaths) under various flight heights and speeds. Canopy entanglement of properly-deployed acetaminophen baits was high (66.6%). Although only a small proportion (5.9%) of radio transmitter-equipped acetaminophen baits were confirmed to have been taken by brown treesnakes, the baiting density was high enough to make it likely that a significant proportion of brown treesnakes in the area had taken acetaminophen baits. With subsequent improvements in system reliability, the automated bait cartridge manufacturing and delivery system is poised to transition from research and development to operational field implementation. Applications include reduction of brown treesnake numbers around transportation infrastructure and within core habitats for the reintroduction of native birds extirpated by this troublesome invasive predator.

Keywords: invasive species suppression, invasive vertebrate predator, public-private partnership, scaling up, technical innovation, toxic baits

INTRODUCTION

The brown treesnake (*Boiga irregularis*) is a nocturnal, arboreal predator that was probably introduced on the island of Guam after World War II as a passive stowaway in cargo from the Admiralty Islands north of New Guinea (Rodda & Savidge, 2007; Richmond, et al., 2014). Lacking natural predators on Guam, the population of brown treesnakes irrupted, reaching as many as 50–100 brown treesnakes per hectare in some areas (Rodda, et al., 1999). Brown treesnakes colonised the entire island of Guam (54,930 ha) in about 20–30 years (Savidge, 1987). The brown treesnake has been – and continues to be – a threat to the economy and ecology of Guam, and is currently the subject of a cooperative programme to control brown treesnake populations on the island and prevent its spread throughout the Pacific Basin and other vulnerable locations (Clark, et al., 2018). Owing to the significant ecological and economic damages caused by the brown treesnake on Guam, the potential for the brown treesnake to be spread to other Pacific Islands, including Hawai`i, is of great concern (Shwiff, et al., 2010).

Landscape-scale suppression of brown treesnakes is desirable in habitats adjacent to transportation network infrastructure (e.g., cargo terminals), to reduce the risk of accidental transport to other vulnerable ecosystems, and within key habitats for the recovery of Guam's native wildlife. Because of the great amount of inaccessible and topographically challenging forest habitat on Guam, aerial delivery of brown treesnake suppression tools is key to the management of this species on a landscape scale. Dead newborn mice (DNM) dosed with 80 mg of acetaminophen have proven to be safe and effective baits for lethal control of brown treesnakes (Savarie, et al., 2001; Johnston, et al., 2002; Clark, et al., 2012) and are registered with the US Environmental Protection Agency (EPA) as an approved pesticide (Registration No. 56228-24, Revised 06/2018). To be effectively delivered to the forest canopy where they are available to foraging brown treesnakes and inaccessible by terrestrial non-targets, the baits must be coupled with a 'flotation device' intended to entangle in foliage (Savarie & Tope, 2004).

Through a previous project, the US Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) Wildlife Services National Wildlife Research Center (NWRC) has demonstrated that brown treesnake abundance in Guam's forests can be suppressed via the aerial application of DNM baits adhered to paper streamers (Dorr, et al., 2016). During this prior study, baits were hand-prepared and hand-broadcast from a helicopter. While this method of treatment proved effective on a small scale (two 55 ha plots), manual bait preparation and application is economically impractical for larger landscape-scale treatments. In scaling up to meet the challenge of landscape-scale control of brown treesnakes, one of the principal logistical concerns is the obvious need to automate both bait production and the aerial dispensing of baits. In response to this need, NWRC, primarily funded by the US Department of the Interior Office of Insular Affairs, has partnered with a private, small business engineering company (Applied Design Corporation, Boulder, Colorado) to develop a brown treesnake suppression system that offers the capability to achieve precise distribution of thousands of baits in a matter of minutes, through a fully-integrated

solution that encompasses bait cartridge production, an aerial bait cartridge dispensing system, and supporting infrastructure and logistics for practical manufacturing, storing, and flight-line handling of bait cartridges.

Automated Bait Manufacturing System (ABMS)

Many of the functional details of the three-stage ABMS are currently considered proprietary information pending application for US and foreign patent protection. The descriptions provided below will suffice as a basic functional explanation.

The first of three bait cartridge manufacturing stations is the Gluer/Placer Station (Station 1) where the DNM are distributed on moulded pulp paper trays and an 80 mg acetaminophen tablet is adhered to the DNM via a hot-melt adhesive. At the final stage of Station 1, the individual capsules containing the acetaminophen tablet and DNM are cut from the paper trays and fed into a transport cassette for transfer to the Assembly/Winder Station (Station 2). Hereafter, a DNM with an adhered acetaminophen tablet will be referred to as an “acetaminophen bait”.

At Station 2, the capsule is folded and held closed by pinching at the paper hinge between the two capsule halves. This pinched paper hinge, hereafter referred to as the ‘tang,’ is inserted into a slotted pressed pulp paper end cap. One end of a biodegradable plastic ribbon is adhered to the endcap and the entire assembly is rotated until the ribbon is wound around the length of the capsule in a ‘barber pole’ fashion. The terminal end of the ribbon is then adhered to the paper capsule. An exterior cardboard tube is placed over the wound assembly, with the end cap tightly pressed into the tube; this entire resulting assembly, comprised of the acetaminophen bait, capsule, streamer, and end cap, enclosed within the external tube, is referred to as a “bait cartridge”. The entire bait cartridge (Fig. 1) is biodegradable.

The final manufacturing station is Packaging (Station 3). Completed bait cartridges are automatically fed to the packaging station, where they are gathered and placed into a corrugated plastic case (900 bait cartridges per case). Filled cases are shrink wrapped, placed on a shipping pallet, and frozen. A complete pallet of 40 cases holds 36,000 bait cartridges, enough to treat 300 ha at the current EPA-approved maximum application rate of 120 acetaminophen baits/ha.

Fig. 1 When deployed, the bait capsule and outer bait cartridge tube are joined by a length of unfurled ribbon intended to entangle in the forest canopy when applied aerially.

Automated Dispensing Module (ADM)

The Automated Dispensing Module (ADM; Fig. 2) is comprised of three main components: 1) four magazines; 2) an electro-mechanical firing unit on a tilt-plate; and 3) a frame, which holds the power supply battery, the computer control module, and integrates the other components into a single functional ADM. The frame is mounted within the hold of the aircraft.

Each magazine is comprised of a body with two halves hinged at the back, allowing the payload area to be fully exposed, and a faceplate. The opened magazine receives the contents of one case (900 bait cartridges). Upon loading, the bait cartridges receive a final inspection for manufacturing imperfections or shipping damage which may adversely affect smooth feeding through the magazine and into the firing unit (Fig. 3).

Fig. 2 The ADM is comprised of four firing units and four 900-cartridge magazines along with an onboard battery and control electronics (not visible).

Fig. 3 Bait cartridges are inspected for manufacturing imperfections or shipping damage that might impede smooth feeding and ejection.

A magazine can be loaded with a case of bait cartridges and prepared for flight in two to three minutes. Once four magazines are prepared, they are loaded into the aircraft-mounted ADM frame (Figs. 4 and 5). The bait cartridge exit door on each magazine is then opened, allowing bait cartridges to flow into the firing unit feed chute. A full payload of 3,600 bait cartridges is sufficient to treat 30 ha of forest at the maximum application rate. At full performance, this area can be treated at 120 acetaminophen baits/ha within 15 minutes of firing time (Fig. 6). An additional set of magazines allows for the next payload to be prepared while the current payload is being applied.

A payload manager and the pilot are the only personnel aboard the aircraft. As directed by the payload management software, the computer control module engages the firing units within the ADM to fire bait cartridges at the proper rate to match the aircraft's current ground speed and intended acetaminophen bait application rate. The payload management software detects when a port is jammed or a magazine is empty and increases the firing rate of the other three ports to maintain the desired bait cartridge delivery rate.

Fig. 4 Magazines are loaded into the helicopter-mounted ADM frame.

Fig. 5 Complete ADM with loaded magazines mounted in a McDonnell-Douglass MD 500D helicopter.

Aerial navigation is achieved by following a preprogrammed mission plan in the payload management software, which details the transects to be flown. The pilot is provided with an LCD display, a "virtual lightbar," that provides realtime feedback as to whether the aircraft is on the prescribed flight path and what corrective movements are needed to return to the path. The payload manager manually toggles on bait cartridge firing when over the treatment area, and toggles it off when the flight path is complete. After an 'ag turn' (an aerial maneuver to quickly reverse directions) the next flight path is flown in the opposite direction. This is repeated until the payload is expended or the treatment area has been fully covered.

Objectives

This report describes the first *in situ* evaluation of this system through the experimental treatment of 110 hectares of forest on Guam. The major objectives were to evaluate: 1) the ground support work flow and performance of the automated dispensing module in-flight; 2) the precision of spatial coverage of the treatment area; and 3) the proper deployment of bait cartridges into the forest canopy and the fate of acetaminophen baits once distributed into the environment.

MATERIALS AND METHODS

Study site

The evaluation was conducted over 110 ha of secondary forest on the Marbo Annex of Andersen Air Force Base (typically referred to as "Andy South") in Yigo, Guam, at approximately 13.508°N, 144.873°E. This site was selected because: 1) there is low risk to threatened or endangered species; 2) the habitat is representative of much of Guam's forests; and 3) it is on a closed military facility with restricted public access.

ADM performance

We assessed the performance of the ADM through two trial applications of acetaminophen baits, simulating operational applications for brown treesnake control. The first application was initially scheduled to be completed on 19 July 2016, during which 13,200 acetaminophen

Fig. 6 Bait cartridges dispensed in flight.

baits would be applied over the 110 ha treatment area (120/ha). A second application was scheduled to occur three days later. For the purposes of this report, we define an "application" as a treatment of an area with aerially-distributed acetaminophen baits within the usage restrictions described in the EPA label.

A McDonnell-Douglas MD 500D (Fig. 5) and pilot were contracted from Hansen Helicopters (Tamuning, Guam) to perform aerial bait cartridge delivery. GoPro video cameras (GoPro, Inc., San Mateo, California) were positioned at various locations on the helicopter to document and evaluate bait cartridge ejection and deployment success.

On the night prior to flight operations, bait cartridge cases required for the next day's application were removed from the freezer to thaw and were stored overnight in an air-conditioned workspace to minimise condensation. The plastic wrapping on the cases were left intact to ensure that all condensation would occur on the external surface of the plastic wrap rather than on the paper-based bait cartridges themselves.

Bait cartridge coverage

Bait cartridge spacing trials were conducted to determine the accuracy and evenness of bait cartridge distribution at varying flight heights and airspeeds. Three lanes of approximately 200 m were delineated with orange traffic cones within an open grassy area at the treatment site. The helicopter, traveling at 50 knots, distributed bait cartridges along each flight line at heights of 25 m, 50 m, and 100 m above ground level. A ground crew attempted to locate all bait cartridges and measured their distance from the ideal flight path and the distance to the next bait cartridge along that path. A second round of transects was flown, this time at 60 knots, to determine the effect of airspeed on accuracy and spacing.

The completeness and the evenness of the spatial coverage of the treatment area was determined by recording the GPS flight paths in the payload management software, and generating coverage maps. Flight path segments were highlighted where the ADM unit was firing.

Acetaminophen bait fate

Methods for monitoring of radio transmitter-equipped baits were modified from procedures established by Dorr, et al. (2016). During each treatment, a subset of baits was prepared containing small 1.0 g VHF radio transmitters (Holohil BD-2H with internal helical antennae, Holohil Systems Ltd., Carp, Ontario, Canada) implanted in the acetaminophen bait DNM. Transmitter-equipped bait cartridges were placed directly in the ADM firing port unit so that they would be deployed simultaneously at the beginning of the flight path, to be followed by bait cartridges without transmitters.

An acetaminophen bait is considered properly "deployed" when the inner capsule assembly slides out of the outer cardboard tube, unfurling the ribbon to allow entanglement in the forest canopy. While some acetaminophen baits may deploy on impact with treetops, the system is designed for the acetaminophen bait to deploy in the air immediately upon ejection of the bait cartridge from the ADM.

Immediately after being aerially distributed, field technicians with handheld VHF receivers located the transmitter-equipped baits and recorded: bait cartridge location, position (in tree/vegetation or on ground), type of vegetation the bait cartridge was suspended from, height above ground, whether the bait cartridge was actually seen or its location was estimated, whether the acetaminophen bait was properly deployed and the DNM available for take by a brown treesnake, whether the acetaminophen tablet was still adhered to the mouse, and other notes about the circumstances of the condition and location of the acetaminophen bait and its availability for take by a brown treesnake.

If a DNM became separated from the bait cartridge and was on the ground but still had the acetaminophen tablet attached, it was considered intact and available for take by a brown treesnake. If the acetaminophen bait did not deploy properly and the DNM was not available to be taken, the bait cartridge and transmitter were recovered and that trial was ended. After deployment-day data were collected, the transmitter-equipped baits were left to determine the fate of acetaminophen baits over the next 48–72 hours. On each day following the application, each transmitter was re-located and the following data were recorded: whether the acetaminophen bait was still present and viable, whether the acetaminophen tablet was still attached, whether the acetaminophen bait was consumed by a brown treesnake or a non-target, whether the brown treesnake or non-target was alive or dead, whether the transmitter had moved to a new location, and other notes about acetaminophen bait location and condition.

If acetaminophen baits were unconsumed and still viable, they were left for another night and located again the next day. If acetaminophen baits had been consumed by a brown treesnake or non-target that was still alive, it was left undisturbed and relocated daily to establish survival or time to death. While tracking transmitters, technicians were alert for carcasses of any dead organisms, including those that had ingested transmitter-equipped baits. Global Positioning System (GPS) locations and notes on the location and condition of carcasses were recorded. Carcasses were collected and stored frozen for future analytical chemistry to verify acetaminophen exposure.

RESULTS

ADM performance

The first application of bait cartridges commenced on schedule on 19 July 2016. Ground operations and logistical support proceeded according to plan. However, crew and video observations indicated poor ADM performance in two primary categories: 1) bait cartridge feed/ejection reliability and 2) percentage of bait cartridges properly deploying in flight. These problems with system performance resulted in frequent flight stoppages to resolve bait cartridge jams and address other engineering challenges. As a result, additional flight days on 20, 22, 23, 25, and 26 July were required to achieve the first complete coverage of the treatment area.

Reliable bait cartridge ejection was hampered in three primary manners: 1) mechanical jams in the firing unit; 2) "starvation" of the firing unit feed ramp (bait cartridges not arriving at the firing position from the magazine); and 3) impediment of ejection by aerodynamic forces. These are not distinct processes, with multiple possible interactions among them. These issues were resolved with a variety of on-the-fly field improvements, with the causes and effects noted for future ADM design improvements.

Acetaminophen baits that do not deploy from the bait cartridge constitute a waste of resources (because the toxicant is inaccessible to snakes) and a fruitless toxic input into the environment. While we did not expect 100% deployment, observations by ground crew and video camera evidence indicated that initial acetaminophen bait deployment rates were unacceptably low at far less than 50%. Acetaminophen bait deployment issues generally fell into two categories: inadequate rotational energy imparted by the firing unit to overcome external air resistance effects and internal friction between the sliding components of the bait cartridge.

Air resistance effects were largely mitigated by employing adjustable baffles near the firing unit ejection ports to disrupt ejection-inhibiting air currents. Internal friction effects were traced to excessive friction between the bait cartridge capsule 'tang' and end cap. As manufactured, the tang (folded paper hinge) of the interior clamshell is seated in the slot of the end cap to prevent rotation of the internal assembly during manufacturing and unwinding of the ribbon during shipping and handling. However, it was discovered that the tension of the ribbon wound around the clamshell capsule caused the inner assembly to rotate slightly and the tang to twist against the sides of the slot in the end cap. This friction, along with the taut wind of the ribbon, created a 'locking' force, holding the entire assembly together and resisting the available centrifugal force which would otherwise deploy the acetaminophen bait properly. We determined that tearing off the paper tang would relieve the friction against the end cap slot, greatly increasing the deployment rate. For the second application, all bait cartridges were prepared by manual removal of the paper tang.

After system modifications were made, the second application was re-scheduled for 29 July 2016 (three days after the completion of the first application in accordance with EPA label restrictions). During this application, bait cartridge ejection and acetaminophen bait deployment were far more reliable. Bait cartridge jams in firing ports were less frequent and were promptly cleared. The only significant delay occurred when an ejector unit bearing broke; a temporary bushing replacement was fabricated and the ADM was returned to service within a few hours. Aside from this stoppage, the entire second application was completed within 2.5 hours.

Even after the above-mentioned modifications, only 37.3% of acetaminophen baits (571 out of a sample of 1,528 bait cartridge ejections observed on video) deployed immediately, as intended. Bait cartridges could only reliably be observed for about a third of their trajectory to the canopy, and some certainly deployed lower in the airstream. Still more would have deployed upon impact with the canopy or the ground. Nonetheless, we determined that improvement is needed in the reliability of aerial deployment of acetaminophen baits. Though there is no way to be certain of the actual deployment rates, we presume the realised acetaminophen bait deployment rate to be <50% for the overall acetaminophen bait application period.

Bait coverage

Bait cartridge placement and spacing was tested on 28 July 2016. Wind conditions during all flights were recorded at 0 to 1 on the Beaufort scale (0 = < 1 km/h, calm, smoke rises vertically; 1 = 1–5 km/h, light air, wind motion visible in smoke). When air movement was detectable, it was moving north to north-northwest. Flight direction was west to east or east to west. Bait cartridge distributions over trial flight paths are depicted in Fig. 7.

Placement along target flight paths and within 9-m swaths was very accurate and consistent. The one exception was the run at 100 m flight height at 50 knots airspeed; these results are inconsistent with the other five, and we consider this to be an anomalous lapse in pilot flight accuracy. Results do not appear to be influenced by the difference between 50 and 60 knots airspeed. Likewise, accuracy of placement along paths did not appear to be influenced by flight height. The most challenging combination of higher flight speed (60 knots) and highest flight height (100 m) resulted in an acceptable distribution pattern. Spacing between bait cartridges along a given flight path was highly variable, but the mean overall spacing of 8.9 m was virtually identical to the target spacing of 9 m.

Due to frequent flight stoppages during the first application, the full site coverage was achieved piecemeal over several days, with the entire area being treated by the 6th flight day. While the appropriate number of bait cartridges was deployed, the evenness of transect spacing was of reduced importance compared to overcoming the engineering challenges. The second application of acetaminophen baits was relatively uninterrupted. Flight paths were flown as planned which, along with increased pilot and payload manager experience, resulted in a much more even treatment (Fig. 8).

Acetaminophen bait fate

On 26 July 2016, 28 transmitter-equipped baits were broadcast over the treatment site. On 29 July 2016, an additional 23 were broadcast, for a total of 51 transmitter-equipped baits. The conditions of acetaminophen baits on the day of deployment are summarised in Table 1. Of the

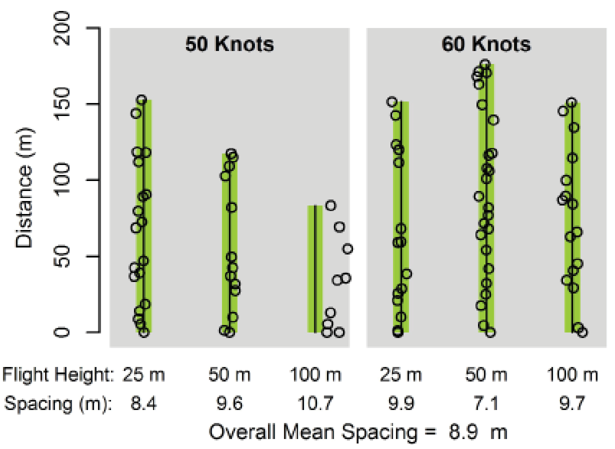

Fig. 7 Bait cartridge spacing and placement results. The centre line for each flight path indicates the target line, over which the pilot flew and bait cartridges were dispensed. Green boxes around the centre lines indicate 4.5 m on each side of the centre line, for a 9 m swath (the ideal flight path spacing for applications at 120 baits/ha). "Spacing" is the average distance from one bait cartridge to the next one along the flight path (target spacing was 9 m).

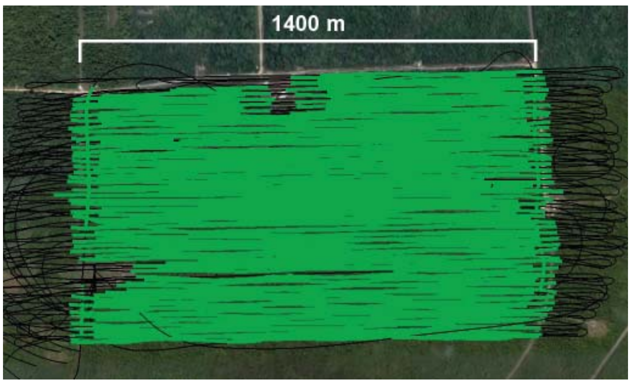

Fig. 8 Flight paths from the second bait application. Green swaths (portion of the flight paths where bait firing was actuated) are depicted at 9 m width, the optimal bait cartridge spacing for the 120 acetaminophen baits/ha application rate.

51 transmitter-equipped baits, 92.2% deployed from the bait cartridges, with the acetaminophen baits available to brown treesnakes.

Thirty-four bait cartridges (66.6%) tangled in the canopy as intended (Fig. 9). Thirteen (25.5%) were on the ground, but open and available to be taken by ground-foraging brown treesnakes. Four (7.8%) were not deployed (closed) on the ground, making the bait and toxicant unavailable to the brown treesnake. During each application, one transmitter-equipped cartridge was in the canopy but could not be confirmed to have deployed; we consider it unlikely that an unopened bait cartridge would be caught in the canopy, so assumed that these acetaminophen baits deployed.

Fig. 9 Desired canopy entanglement and acetaminophen bait exposure.

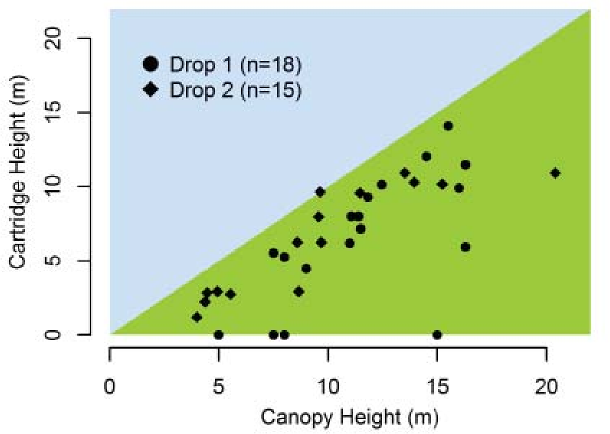

Fig. 10 Hanging height of the bait cartridge (y-axis) in relation to the height of the canopy at that location (x-axis).

Of the 47 opened bait cartridges, two from each application had the acetaminophen tablet detached from the DNM, making it an ineffective acetaminophen bait. In total, 41 of the 51 acetaminophen baits (80.4%) had acetaminophen tablets attached to the DNM and were available for take by a brown treesnake. This should be viewed as the overall successful bait deployment rate for this sample of baits.

Of the 51 transmitter-equipped baits, canopy height and acetaminophen bait height data were available on 33 acetaminophen baits that successfully deployed (18 from Application 1 and 15 from Application 2). The hanging height of the acetaminophen bait with respect to the canopy height is represented graphically in Fig. 10. In a linear regression, canopy height and acetaminophen bait height were significantly correlated ($p << 0.001$, adjusted $R^2 = 0.694$; the four bait cartridges on the ground were not included in the regression). These results show that the majority of deployed acetaminophen baits were entangled within a few metres of the top of the canopy.

Deployed and intact acetaminophen baits were re-checked daily, with very few confirmed takes by brown treesnakes or non-target organisms (Table 2). Of the 51 transmitter-equipped baits, three (5.9%) were confirmed by visual sighting to have been taken by brown treesnakes, or 7.3% of the 41 transmitter-equipped baits known to be available and intact. The 95% binomial confidence interval (logit parameterisation) for the estimated take rate of 5.9% is 1.9% to 16.7%; given the small number

Table 1 Status of transmitter-equipped bait cartridges following ejection from ADM. "Deployed" means the inner capsule completely exited the outer tube and the acetaminophen bait was available for take by a brown tree snake. "Intact" means the acetaminophen tablet was still attached to the bait mouse and available to be taken by a brown treesnake.

Bait cartridge status	Application 1 (n=28)	Application 2 (n=23)	TOTAL (n=51)
Opened in canopy*	19 (67.9%)	15 (65.2%)	34 (66.6%)
Opened on ground	7 (25.0%)	6 (26.1%)	13 (25.5%)
Not deployed	2 (7.1%)	2 (8.7%)	4 (7.8%)
Unknown	1 (3.6%)	1 (4.3%)	2 (3.9%)
Total deployed*	26 (92.3%)	21 (91.3%)	47 (92.2%)
Total known deployed and intact**	23 (82.1%)	18 (78.3%)	41 (80.4%)

*Assumes that "unknown" bait cartridges in canopy were deployed; **Does not assume "unknown" baits were intact.

Table 2 Transmitter-equipped acetaminophen baits taken by target (brown treesnake) or non-target species.

Species	Application 1	Application 2	Total
Brown tree snake	1	2	3
Monitor lizard	1*	0	1
Marine toad	0	2*	2
Unknown	0	1	1

*Transmitter recovered in faeces

of acetaminophen baits equipped with transmitters, the actual rate of acetaminophen bait take by brown treesnakes could vary widely. All three transmitters were regurgitated prior to death, so no transmitters were recovered in brown treesnake carcasses. All three transmitters taken by non-targets were later found in faeces; it is unclear whether any of these animals succumbed to acetaminophen toxicosis.

All vertebrate carcasses encountered during field activities were collected. This included three brown treesnakes and one marine toad (*Rhinella marina*).

DISCUSSION

ADM performance

Future improvements to the ADM will focus on: baffling of the airstream around the ejector ports to prevent interference with ejection; improved feeding of bait cartridges from redesigned magazines and; increased energetic impact imparted to the bait cartridge at the instant of firing in order to improve ejection and deployment reliability. Engineering modifications to the ABMS will further address the non-deployment issue through tighter quality control on bait cartridge imperfections and abatement of tang friction through a redesigned end cap.

Bait cartridge coverage

The accuracy of bait cartridge placement along flight lines was encouraging. There was very little air movement during these trials; under windier conditions, bait cartridges distributed from greater heights will be more likely to drift further from the intended flight path.

We attribute high variability in bait cartridge spacing along the flight lines to variability in the times at which acetaminophen baits deployed after being ejected from the ADM. When the acetaminophen bait deploys, wind drag increases greatly and the forward momentum is quickly attenuated, causing the bait cartridge to drop straight down. Acetaminophen baits that deploy later maintain forward momentum longer and will move farther along the flight path before landing. It is expected that bait cartridge modifications that improve acetaminophen bait deployment will also result in less variability in time of deployment, leading to more consistent spacing along flight paths.

Variability in spacing along the flight path does have the potential to affect bait cartridge placement accuracy at the edges of treatment areas where bait cartridge application begins and ends, potentially leading to a small number of bait cartridges landing outside of the desired treatment area. To make up for the inconsistency of bait cartridge density at these edges, it is advisable that another application flight should occur along these edges, perpendicular to the original flight paths, ensuring that the edges get a full treatment in a more controlled fashion, similar to coastal aerial rodenticide applications during island rodent eradications.

Variability in bait cartridge placement along and perpendicular to the flight path will add apparently random "noise" to the locations, as opposed to placing bait cartridges precisely on an idealised 9 x 9 m grid. This variability will not affect the ability to get acetaminophen baits into the movement areas of every brown treesnake. The greatest risk of gaps in coverage might arise from strong changes in wind direction, which might introduce strong biases in bait cartridge drift patterns. This will likely factor in with other considerations leading to recommendations not to apply baits during high wind conditions.

Wind effects at bait cartridge ejection ports and direct sunlight on the bait cartridge counter photogates resulted in unreliable bait cartridge counts as tabulated by the ADM onboard software. We ensured that EPA label application rate restrictions were not exceeded by confirming that no more than 14.66 cases (13,200 bait cartridges) were applied throughout the treatment area during each application period.

Acetaminophen bait fate

The proportion of transmitter-equipped baits taken by brown treesnakes was low (5.9%); however, only a very small portion of the bait cartridges distributed (0.19%) were equipped with transmitters. If we assume that half of the acetaminophen baits applied during both applications properly deployed and were viable, then there were 13,200 acetaminophen baits available for take by brown treesnakes. If 5.9% of those acetaminophen baits were taken by brown treesnakes, we would expect approximately 779 brown treesnakes to have taken an acetaminophen bait. If we assume a density of 25 brown treesnakes per hectare in this area (a conservative estimate based on the 25-50/ha range reported by Rodda, et al. 1999), 2,750 brown treesnakes would have been exposed to the treatment. If 779 brown treesnakes took acetaminophen baits and were killed, this would be a brown treesnake mortality of approximately 28% in what was effectively a single treatment (given the low deployment rate). The three acetaminophen baits visually confirmed to have been taken by brown treesnakes were found on the ground, apparently regurgitated. In previous NWRC lab efficacy trials of acetaminophen baits with acetaminophen tablets internally-implanted in the DNM (rather than glued to the exterior), 26% were regurgitated, but 100% of the caged brown treesnakes that regurgitated the acetaminophen bait died within 12 to 36 hours (Savarie, 2002). Based on that result, it is reasonable to assume that the brown treesnakes that had taken and regurgitated acetaminophen baits with transmitters in this study also died.

With respect to deployment and entanglement rates, caution should be taken in considering transmitter-equipped cartridges to be representative of the standard bait cartridges distributed during this evaluation. Machine-assembled bait cartridges were manually unwound and rewound by hand after the implantation of the radio transmitter; this may explain why transmitter-equipped cartridges deployed at a higher rate than those observed on video. The added mass of the transmitter may also have an effect on the forces exerted on various parts of the bait cartridge and acetaminophen bait assembly. However, it is also possible that unopened bait cartridges without transmitters actually did deploy lower in the air column (out of view of the video cameras) or upon impact with the canopy.

The overall reduction of brown treesnake abundance in the treatment area – as inferred from a foraging activity index based on take rates of non-toxic DNM from bait stations – is currently being monitored as a separate study for future publication.

CONCLUSION

Upon firing from the ADM, bait cartridge ejection and acetaminophen bait deployment reliability was initially low. Performance was improved dramatically with field-improvised remedial measures. It is estimated that <50% of acetaminophen baits deployed from the bait cartridges, resulting in an under-treatment compared to the target application rate of 120/ha. Canopy entanglement of acetaminophen baits that properly deployed was high. Aerial bait cartridge placement and spacing were satisfactorily accurate. Reliability of bait cartridge ejection and acetaminophen bait deployment will be a critical focus of bait manufacturing and delivery system improvements, increasing per-cartridge effectiveness. Future advancements of this technology may include adaptation for payload management by the pilot alone, incorporation of a longer-lasting artificial bait to replace the DNM, and increases in ejector unit and magazine capacity for greater payloADM.

With this evaluation – and subsequent improvements in system reliability – we consider the concept of automated bait production and aerial delivery to be fundamentally sound. For the first time in the decades-long saga of the brown treesnake invasion of Guam, the prospect of landscape-scale suppression hovers on the horizon.

DISCLAIMER

ACKNOWLEDGEMENTS

We wish to thank the DOI Office of Insular Affairs for funding the development of the ABMS and ADM technologies, and for funding this evaluation. Additional funding for this evaluation was provided by US Navy, Joint Region Marianas. The ABMS and ADM systems were conceived and built by ADC engineers Jonathan Fragoso, Shane Vogt, Grady Barfoot, and Michael Messaros. Bill Coon engineered the ADM software and flew as the navigator and payload manager. Hansen Helicopters general manager (Rufus Crowe), pilot (Dan O'Brien), and service shop staff were instrumental in the success of this evaluation. Methodology for acetaminophen bait fate via radio transmitters was established by Brian Dorr (Dorr, et al., 2016). Logistics and field support were provided by Francine Chlarson, Derek Hendricks, Jerome Larimer, Joe Rabon, Anthony Thompson, and Rachel Volsteadt. Additional site support on flight days was provided by Ray Quichocho, Rico Terrazas, and Marc Hall. Regulatory and permitting assistance were provided by Shannon Hebert, James Watkins, Earl Campbell, Diane Vice, Jim McConnell, and the Guam Environmental Protection Agency.

AUTHOR CONTRIBUTIONS

S. Siers was the principal investigator for the field evaluation, establishing the study design, coordinating site access and environmental compliance, curating data, executing analyses and data visualisation, and writing the original draft of the manuscript. S. Siers, M. Messaros, C. Clark, and R. Gosnell supervised field evaluation activities. W. Pitt and M. Messaros conceptualised the automated bait cartridge manufacturing and delivery systems. M. Messaros was the chief engineer and developer of the intellectual property associated with the bait cartridge and associated manufacturing and delivery systems. W. Pitt, L. Clark, A. Shiels, J. Eisemann, and S. Siers contributed to programme administration, funding acquisition, and other matters associated with research and development of the automated systems. J. Eisemann coordinated pesticide registration and technology transfer matters, and contributed to on-site coordination of evaluation activities. All authors contributed to review and editing of the manuscript.

The potential detrimental impact of the New Zealand flatworm to Scottish islands

B. Boag and R. Neilson

The James Hutton Institute, Invergowrie, Dundee, Scotland, DD2 5DA, UK. <brian.boag@hutton.ac.uk>.

Abstract: The New Zealand flatworm, *Arthurdendyus triangulatus*, is an alien invasive species in The British Isles and the Faroes. It was probably first introduced after WWII and is an obligate predator of our native earthworms. It was initially considered a curiosity until observations in the 1990s in Northern Ireland found it could significantly reduce earthworm numbers. In 1992, it was scheduled under the Countryside and Wildlife Act 1981 then transferred to the Wildlife and Natural Environment (Scotland) Act in 2011 which makes it an offence to knowingly distribute the flatworm. A retrospective survey in Scotland showed that it was detected in botanic gardens, nurseries and garden centres in the 1960s but then spread to domestic gardens then finally to farms in the 1990s. Although the geographical distribution of *A. triangulatus* was initially confined to mainland Scotland it was subsequently found established on 30 Scottish Islands. Most of the islands are to the north and west of Scotland and have cool damp climates which are favoured by the New Zealand flatworm. These islands also generally have relatively poor soils that support grassland farming systems. Evidence from both Northern Ireland and Scotland suggests anecic species of earthworm which occur predominantly in grassland, which help drainage and are a source of food for both animals and birds are at particular risk from the flatworm. The detrimental impact of the flatworm on soil processes and wildlife has yet to be quantitatively evaluated but unlike many other invasive species there is currently no known means of control. The precautionary principle must be therefore applied wherever possible and every opportunity taken to stop its further spread.

Keywords: *Arthurdendyus triangulatus*, earthworms, invasive alien species, predator, Scotland

INTRODUCTION

Many of the Scottish islands have impoverished acidic soils (Boyd, 1957; Glentworth, 1979; Hudson, et al., 1982) which have been improved in the past by the addition of seaweed, lime or occasionally imported soil (Magnusson, 1997; Entwhistle, et al., 2000). Wind-blown calcareous sandy soils with a high shell content occurring in the north and west of Scotland, known as "machair" (Angus, 2001), are characterised with a defined flora and low input agriculture (Hudson, et al., 1982) and is a fragile ecosystem listed under the EU Habitats Directive Annex 1. Earthworms prefer soils with a near neutral pH and are therefore typically found in improved soils compared with those with a pH levels< 4 (Guild, 1951; Edwards & Bohlen, 1996). Boyd (1956, 1957) surveyed earthworms in the Hebrides and recorded a complex of 15 species from the machair, dominated by *Lumbricus rubellus, Aporrectodea caliginosa* and *Dendrobaena octaedra*. This contrasted with only six species under acidic heather soils, the dominant species being *L. rubellus and D. octaedra.* The genus of one of the recorded species, *Bimastos,* has since been removed from the British list (Sims & Gerard, 1985).

Stop-Bowitz (1968), suggested that in Norway some species e.g. *D. octaedra* and *L. rubellus* could have survived the Quaternary ice age and this may also have occurred in Scotland. However, many of the other recorded earthworm species were probably introduced by man to enhance the productivity of the land as occurred in New Zealand where productivity was increased significantly by the addition of European earthworm species (Stockdill, 1982). The only other place in the world where the New Zealand flatworm has become established is the Faroe Islands where earthworms have been found in closed association with human settlements possibly due to the inhabited areas being on fertile land (Enckell & Rundgren, 1988).

The New Zealand flatworm (*Arthurdendyus triangulatus*) was probably first accidentally introduced into the British Isles just after WWII but not officially recorded in Scotland until 1965 when it was considered a curiosity (Wakeman & Vickerman, 1979). However, Blackshaw (1990) reported that the presence of the New Zealand flatworm was associated with a decline in earthworm populations to below detectable levels in Northern Ireland. The results of a survey undertaken in Scotland during 1991–1992 (Boag, et al., 1994) indicated that the New Zealand flatworm was initially confined to botanic gardens, garden centres and nurseries but then spread to domestic gardens in the 1970s and finally to farms in the 1980s. It also showed that by 1992 it had spread to many parts of Scotland including the islands of Skye and Orkney. In the last 30 years the flatworm has been recorded from several other islands off the west and north coast of Scotland.

Further research indicated that the presence of the New Zealand flatworm reduced the abundance of anecic earthworm species (Jones, et al., 2001), populations of which were unlikely to fully recover (Murchie & Gordon, 2013). Anecic earthworm species are those which make vertical burrows and consume dead organic matter on the soil surface (Fraser and Boag, 1998), thus play a key role in soil nutrient processes and are considered ecosystem engineers (Lavelle, et al., 1997; Blouin, et al., 2013). Furthermore, they are also a major component of food for some mammals and birds (Boag & Neilson, 2006).

The New Zealand flatworm prefers cool damp conditions to survive (Boag, et al., 1998a) and this may have contributed to it being a problem predominantly in the north and west of Scotland, Ireland and the Faroe Islands compared with the east of Scotland and England (Jones & Boag, 1996). The flatworm is also dependent on the presence of earthworms which potentially restricts its distribution in Scotland as earthworms rarely occur in soils with a pH < 4 (Boag, et al., 1998b).

The aim of the present paper is to document the extent to which the New Zealand flatworm has become established in the Scottish islands and to consider the detrimental impact its presence might, in the future, have on island agriculture and wildlife.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 356–359. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

MATERIAL AND METHODS

The data used for this paper were the records of where the New Zealand flatworms were found by the general public in their gardens, parks etc. and these records over time have also shown how it spread. The New Zealand flatworm can easily be recognised by the general public as different from earthworms as it is flat, covered by a sticky mucus and pointed at both ends. Initially the records were collated by the National Museum of Scotland until this was taken over by the senior author after a survey financed by the Scottish Government (Boag, et al., 1994) and a 1995 BBC TV survey (Jones & Boag, 1996). Subsequent records have continued to be collected by staff at the James Hutton Institute and submitted to and curated by the National Biodiversity Network from where three additional island records were gleaned for this paper. More recently The Open Air Laboratory (OPAL) has run a citizen science survey for the New Zealand flatworm (<https://www.opalexplorenature.org>). The records are stored by the National Biodiversity Network and the senior author is the national expert on this species and verifies all records.

RESULTS

Most flatworm records were from individual households with a few from farms, garden centres and schools. Scotland has 790 offshore islands of which 95 are inhabited of which 30 islands recorded New Zealand flatworm (Table 1). These were distributed from Arran in the south of Scotland to Shetland in the north. Many of the infested islands had few inhabitants, but in general the number of flatworm records reflected the population size (Table 1).

This was demonstrated across the Orkney archipelago (Fig. 1) where there were 41 flatworm records, from a population > 17,000 on mainland Orkney compared with the outlying islands of Burray, Egilsay, Hoy, North Ronaldsay, Rousay and South Ronaldsay which had a combined population of > 1,700 and had only seven flatworm records. The Orkney mainland had the most records of all Scottish Islands even though it has a smaller land area than Skye, Shetland, Mull or Lewis. Of these larger islands Orkney is by far the most fertile with a large proportion covered with arable crops or permanent pasture (Dry & Robertson, 1982). Most island records only reported the presence of the flatworm but others reported a reduction or absence of native earthworms while others reported that large numbers of flatworms had been collected e.g. a householder from Baleshare killed 1,445 flatworms over a period between May 2015 and January 2016. Another householder from Skye regularly killed 20-40 flatworms daily with a reported maximum of 150, and an estimated total kill of 15,000 over a period of one year.

DISCUSSION

The records received over the last 25 years show that the New Zealand flatworm is now widely distributed in the Scottish islands. Since it is an obligate feeder on earthworms, the presence of the flatworm also indicates that these islands must have had an abundance of earthworms. A possible reason for Orkney having a disproportionately greater number of New Zealand flatworm records compared with Lewis, Skye, Mull or Shetland is probably the fact that Orkney is formed from sedimentary rock while the others are igneous or metamorphic in origin (Dry & Robertson, 1982) thus more conducive to earthworm establishment and survival.

The New Zealand flatworm is known to have a deleterious impact on earthworms in mainland Scotland and Ireland (Jones, et al., 2001; Murchie & Gordon, 2013) and it can probably be assumed that is also the case on these islands. Apart from earthworms playing an important role in delivering soil function and ecosystem services (Lavelle, et al., 1997; Blouin, et al., 2013) they are an important constituent of the diets of some mammals and birds which live in the islands and are, in some cases, declining in number e.g. the lapwing (*Vanellus vanellus*). To help revive the decrease in lapwing numbers it has been proposed that lime should be added to increase the soil pH and hence encourage the build-up of earthworms upon which lapwing feed (McCallum, et al., 2015). Studies have also shown that earthworms are a major constituent of the diet of chough (*Pyrrhocorax pyrrhocorax*) (Meyer, 1990), a rare breeding corvid found on Islay and Colonsay with an estimate of c. 50 breeding pairs in 2014 (https://scotlandsnature.wordpress.com/2014/09/25/good-news-from-islay-as-population-grows/). It is therefore concerning that flatworms have been recorded from Islay as this may confound the conservation of chough on the island.

Apart from the direct impact of New Zealand flatworm on wildlife it has been estimated that it could have a potential detrimental economic effect on agriculture (Boag & Neilson, 2006). This is particularly relevant to small holdings with tight farm unit margins such as crofts. Circumstantial evidence from an area north of Dunoon infested with flatworm suggested that in addition to an accumulation of dead organic matter on the soil surface, undesirable plants such as rushes became established as a result of frequent flooding after rainfall events. The New Zealand flatworm may also become a problem where there are large amounts of arable land and permanent grassland which occurs in mainland Orkney. Agricultural land in Scotland can have a wide range of earthworm species including the anecic species which would be particularly at risk (Boag, et al., 1997).

No investigations have been undertaken to ascertain the actual impact of the New Zealand flatworm on either wildlife or agricultural production in the Scottish islands. Assumptions on the detrimental impact of the New Zealand flatworm must therefore be made based on the knowledge gleaned from the literature on the benefits that earthworms have on agricultural production and wildlife (Schmidt & Curry, 1999; Bartlett, et al., 2010). Unlike many other invasive plants and animals which have been successfully removed from Scottish islands e.g. mink from the Uists and rats from Canna (Bell, et al., 2011; Roy, et al., 2015) there are no prospects of the New Zealand flatworm being controlled on the Scottish islands once it has become established. Given the only mechanism known to spread the New Zealand flatworm is the human mediated movement of plant material every effort must be made to stop infested material reaching the islands by informing the general public of the threat that New Zealand flatworm poses.

ACKNOWLEDGEMENTS

The authors thank members of the general public who have contacted the senior author and, in some cases, sent photographs and specimens. We also thank Scottish Natural Heritage and especially Colin MacLeod for submitting the flatworm records onto the National Biodiversity Network. The James Hutton Institute receives financial support from the Scottish Government, Rural and Environment Science and Analytical Services Division.

Management of an invasive avian parasitic fly in the Galapagos Islands: is biological control a viable option?

R.A. Boulton[1,2], M. Bulgarella[3], I.E. Ramirez[1], C.E. Causton[4] and G.E. Heimpel[1]

[1]University of Minnesota, Department of Entomology, St Paul, Minnesota, USA. [2]University of Exeter, College of Life and Environmental Sciences, Penryn Campus, Cornwall, UK. <R.Boulton@exeter.ac.uk>. [3]Victoria University of Wellington, School of Biological Sciences, Wellington, New Zealand. [4]Charles Darwin Foundation, Puerto Ayora, Santa Cruz, Galápagos, Ecuador.

Abstract The bird-parasitic fly, *Philornis downsi*, was first recorded in the Galápagos Islands in 1964 where it likely invaded from mainland Ecuador. This muscid fly is now the leading cause of recent declines in endemic landbird populations as its larvae feed on the nestlings of at least 19 bird species in the Galápagos, including many species of Darwin's finches. As yet, no long-term control method has been implemented for *P. downsi*, but importation (also known as classical) biological control may be a viable option. Due to historically high-profile examples of biological control agents attacking non-target species, some consider biological control to be too risky to be compatible with conservation aims. However, since biosafety practices were implemented beginning in the 1990s, these risks have been drastically reduced, and biological control is now an important tool for suppressing invasive species that are difficult to control using other means. We investigated the safety of a potential biological control agent, the parasitoid wasp, *Conura annulifera,* that attacks *P. downsi* in its native range. Here we summarise the results of a series of field, laboratory and comparative studies on *C. annulifera* (methods and results are not reported here) and outline future directions. We used a field experimental paradigm involving nest boxes baited with non-target hosts, and quarantine laboratory no-choice trials in which non-target hosts were exposed to *C. annulifera.* Our work to-date suggests that *C. annulifera* is restricted to attacking species within the genus *Philornis*. Furthermore, a phylogenetically controlled comparative study suggests that *C. annulifera* is evolutionarily constrained in its host range. These results lead us to conclude that *C. annulifera* demonstrates promise as an ecologically safe agent for the long-term biological control of *P. downsi.* Studies will now focus on an evaluation of risks to endemic and native species in the Galápagos.

Keywords: biological control, conservation, *Conura annulifera*, invasive species, *Philornis downsi*

THE HISTORY OF BIOLOGICAL CONTROL

When non-native species invade novel ecosystems, the consequences can be extreme. Anthropogenic change has increased the frequency and the success of such invasions; increased traffic to previously isolated sites increases the chance that non-native species will arrive, and the chances of colonisation are often increased in areas that are altered by human activity (Sax, et al., 2002). When colonisation occurs, non-native species are often far more successful than in their native range. Although the reasons for this are likely complex, one often-cited reason is the 'enemy release' hypothesis (ERH) (Liu & Stiling, 2006). Enemy release occurs when invaders colonise a new area, free from the natural enemies (predators, parasites and pathogens) with which they co-evolved, and are released from the effects that these enemies have on population suppression. Importation (also known as classical) biological control involves reconstructing (at least in part) the assemblage of co-evolved natural enemies present in the native range of the problematic species in order to control it (Heimpel & Mills, 2017). Although more commonly known from agricultural systems, importation biological control for conservation is a developing sub-discipline and shows promise as a long-term strategy for dealing with harmful invasive species (Van Driesche, et al., 2010; Van Driesche & Reardon, 2017). One noteworthy example is the introduction of the specialised ladybeetle, *Rodolia cardinalis,* which effectively controlled populations of the cottonycushion scale, *Icerya purchasi*, in the Galápagos archipelago. This particular introduction has more than likely been the saviour of endemic plant species that are attacked by *I. purchasi* (Hoddle, et al., 2013).

Unfortunately, historically high-profile cases of biological control failures that led to non-target effects on threatened species have received significant media attention and these examples have hampered progress in the sub-discipline of conservation-focused biological control (Van Driesche & Reardon, 2017). In order for importation biological control to be safe and successful, it is paramount that we understand the ecology, in particular the host specificity of the putative natural enemy set for release. A majority of examples of biological control, for conservation or for agriculture, have demonstrated both its success and its safety, particularly since the 1990s when concerns over biosafety gained momentum (Barratt, et al., 2010; Van Driesche, et al., 2010; Van Driesche, 2012; Heimpel & Mills, 2017; Van Driesche & Reardon, 2017; Heimpel & Cock 2018). However, the negative reputation of biological control persists due to the memorable nature of failures that have caused detrimental effects on native fauna (see Clarke, et al., 1984; Howarth 1991). Sadly, it is these examples that are more publicly well-known due to the strong emotions that they elicit (Van Driesche, & Reardon, 2017). Yet there is still hope for the discipline, and conservation-focused biological control has initiated a paradigm shift, demonstrating that biological control can be more than just compatible with conservation aims, it can actually promote them (Van Driesche, et al., 2010; Heimpel & Cock, 2018). In order for these techniques to be incorporated into the conservation 'tool box' it is imperative that we build trust between practitioners of biological control, conservationists and the public. To do so, the biological control community must demonstrate the pragmatism and caution that go into designing safe and effective biological control programmes.

Philornis downsi

Philornis downsi (Dodge & Aitken) is a bird-parasitic muscid fly that is native to mainland South America but is invasive in the Galápagos Islands where it likely invaded from mainland Ecuador (Bulgarella, et al., 2015). It was first reported in the archipelago in 1964 and, in the last 15–20 years has become a major threat to the persistence of many passerine bird species in the Galápagos, including

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 360–363. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

the majority of species of Darwin's finches (Fessl, et al., 2018). This threat occurs because of the way the larvae of *P. downsi* feed: the adults are free-living but the larvae are obligate ectoparasitic blood-feeders on young nestlings, leading to blood loss and death (Fessl, et al., 2006; O'Connor, et al., 2010; Kleindorfer, et al., 2014; Koop, et al., 2016; Heimpel, et al., 2017). *P. downsi* is considered the greatest threat to the persistence of many land-bird species in Galápagos. The critically endangered mangrove finch (*Camarhynchus heliobates*) and medium tree finch (*C. pauper)* are particularly at risk, with any nestlings of the former now being protected by 'head-starting' (hand-rearing any eggs collected in the wild; Cunninghame, et al., 2012). The ramifications of any such extinction would be extensive. Not only would this represent a tragic loss of iconic species in a well-protected environment, it would also be a terrible loss of evolutionary history and the opportunity to study it. Rosemary and Peter Grant spent the last forty years studying the evolution of Darwin's finches and have commented on the importance and uniqueness of Darwin's finches for work of this nature:

'A final reason that makes them (Darwin's finches) *so suitable* (for studying evolution) *is that none of the species has become extinct as a result of human intervention. This cannot be said for many other radiations elsewhere in the world.'* Grant & Grant (2009)

The Grants' work has demonstrated the power of evolution and speciation and the underlying mechanisms, but much more remains to be discovered (e.g. Abzhanov, 2010 and articles therein). Losing even a single species of Darwin's finch would represent a terrible loss for evolutionary biology and could have a profound impact on future phenomena that the species' radiation may reveal to us. Moreover, losing large numbers of individuals of any of these species will have considerable impacts on the functioning of Galápagos ecosystems due to the critical roles that they play in pollination and seed dispersal (Causton, et al., 2013; Traveset, et al., 2015; Nogales, et al., 2017).

Need and potential for biological control of *Philornis downsi*

Infestation by *P. downsi* results in extreme nestling mortality in Galápagos, which has not been observed in the native range of the fly (Fessl, et al., 2018). The ERH (Liu & Stiling, 2006) – a paucity of co-evolved natural enemies in the invaded compared to the native range – is one likely reason for the increased abundance of *P. downsi* in Galápagos compared to the mainland (Bulgarella, et al., 2015; 2017; Boulton & Heimpel, 2017). The ERH serves as the theoretical underpinning of modern importation biological control, whereby one or a suite of co-evolved natural enemies is liberated into the invasive range to control the target species (Heimpel & Mills, 2017). The scarcity of natural enemies of *Philornis* spp. in the Galápagos compared to the mainland suggests that importation biological control may be a valuable tool to control *P. downsi* (Bulgarella, et al., 2017).

Although several control strategies are currently being explored and considered, importation biological control may be critical in protecting Darwin's finches and other endemic bird species in Galápagos from *P. downsi.* Other possible control methods include short-term strategies, such as nest treatment with insecticide and mass trapping using lures (Fessl, et al., 2018). The short-term approaches are considered mainly as stop-gap measures, whilst long-term measures, such as biological control and sterile male release, are developed and implemented. Of the long-term measures considered so far, biological control using natural enemies from the native range is currently the most promising solution. The release of sterile males is another potential long-term solution but this is currently hampered by difficulties in laboratory breeding of *P. downsi* (Lahuatte, et al., 2016; Fessl, et al., 2018).

In 2012, a workshop was organised by the Charles Darwin Foundation and the Galápagos National Park Directorate in order to form an action plan for conservation of Darwin's finches and other small land birds due to the ever-increasing threat from *P. downsi* (Causton, et al., 2013). One priority research goal recognised at this workshop was to identify natural enemies in the fly's native range and investigate the potential for biological control (Causton, et al., 2013). Over the last four years, we have discovered several parasitoid wasp species attacking species of *Philornis* in mainland Ecuador (Bulgarella, et al., 2015; 2017). Before any of these parasitoids can be considered as suitable biocontrol agents, in-depth studies of their host range need to be conducted. To address this question, we have been using a holistic approach consisting of a novel field experimental paradigm, comprehensive literature review, detailed study of the physiology and evolutionary ecology of the putative biological control agents, and traditional laboratory host range tests. In this manuscript we review and summarise our published work so far and outline future directions.

FIELD OBSERVATIONS AND EXPERIMENTS

Field work at two field sites in western mainland Ecuador between 2013 and 2017 has revealed a number of parasitoid species attacking *Philornis* spp. pupae collected from nest boxes (Bulgarella, et al., 2015; 2017). In addition, we have developed a novel field experimental paradigm over the last two years that can be used as a preliminary assay to test whether the parasitoid wasp species that we have recovered are specific to *Philornis* spp. in the field.

The experimental set-up was as follows. Nest boxes that we monitor throughout the bird breeding season for *P. downsi* pupae and their parasitoid wasps were paired with bait boxes. These bait boxes contained a number of non-target host species that had been reared from the local area. We also placed pupae of non-target species inside active bird nests. Any parasitoid wasp species that attacked *Philornis* spp. in the nest boxes and nests also had the opportunity to attack non-target hosts in the adjacent bait boxes and inside active nests. Using this experimental paradigm, we were able to determine which (if any) species of parasitoid wasp did not exclusively attack *Philornis* spp. We have concentrated our further efforts on *Conura annulifera* (Hymenoptera: Chalcididae), a parasitoid that has been recorded attacking only *Philornis* spp. in these field experiments. We will concentrate on this species for the remainder of the manuscript but note that we are also considering other species for biological control of *P. downsi*, such as an unidentified species of *Trichopria* (see Bulgarella, et al. (2017) and Boulton & Heimpel (2017) for details). This study is in progress at the time of writing and the results will be published elsewhere.

Life history and evolutionary ecology of *Conura annulifera*

Previous work on the natural host range of *C. annulifera* supports our assertion that it is a specialist on the genus *Philornis*. It has been recorded in previous studies throughout South and Central America where is has been reported as parasitising only *Philornis* spp. (including *P. downsi* and *P. deceptivus;* Burks, 1960; De Santis, 1979; Delvare, 1992; Couri, et al., 2006). Moreover, studies where pupae were reared from other Diptera (Muscidae, Calliphoridae and Sarcophagidae) in regions where *C. annulifera* has been reported never yielded this parasitoid

(Bulgarella, et al., 2017). However, only five studies have reported finding *C. annulifera* in the field (Burks, 1960; De Santis, 1979; Delvare, 1992; Couri, et al., 2006; Bulgarella, et al., 2017), and so more data were needed in order to determine whether this species might constitute a *Philornis*-specific biological control agent. In the sections below, we present the evidence that we have accumulated so far in support of the possibility that *C. annulfiera* is a *Philornis* genus specialist.

Conura annulifera is a solitary pupal ectoparasitoid (Bulgarella, et al., 2017). It attacks pupae of *Philornis* spp., laying a single egg on the outside of the developing pupa. More specifically, *C. annulifera* is a 'gap-layer', a parasitoid that deposits its egg between the hard external puparium and the soft body of the developing pupa. We hypothesised that the specificity of this oviposition site is likely to restrict the range of suitable hosts that *C. annulifera* can parasitise to the cyclorrhaphan Diptera, an unranked taxon that contains families such as the Muscidae, Calliphoridae, Sarcophagidae and Syrphidae (Griffiths, 1972; Boulton & Heimpel, 2017). The Cyclorrhapha are the only group of holometabolous insects that exhibit this gap (Whitten, 1957), and so it is unlikely that species outside this taxon are physiologically viable hosts for *C. annulifera*. We tested this possibility using phylogenetically controlled comparative studies for all known species of gap-layers in the superfamily Chalcidoidea and the results support our hypothesis: gap-laying species exhibit narrower host ranges than 'true' ectoparasitoids (Boulton & Heimpel, 2018). Moreover, these analyses revealed that gap-laying as a strategy may constitute an evolutionary dead-end. Compared to endoparasitoids and other ectoparasitoids, evolutionary transitions towards gap-laying were more likely than transitions away from it (Boulton & Heimpel, 2018).

This comparative work has implications for biological control in general and for the specific case of control outlined here. Our findings suggest that (1) gap-layers such as *C. annulifera* are likely to be more host specific, and so safer putative biological control agents, than 'true' ectoparasitoids, and (2) gap-layers including *C. annulifera* may represent particularly useful agents for importation biological control as they are less likely to transition, or diversify, to attack novel hosts after release outside their native range. With regards to the specific case of using *C. annulifera* to control *P. downsi* in the Galápagos, this work improves our understanding of the most at-risk non-target organisms were a release to be attempted, but it does not explicitly tell us whether *C. annulifera* is likely to be a safe species for importation biological control. To test this, more traditional host range studies were conducted, the results of which we outline in the section below.

Laboratory host range studies

Bulgarella, et al. (2017) exposed a range of non-target host pupae to *C. annulifera* that were maintained in the laboratory. This included five cyclorrhaphan Diptera (*Musca domestica, M. autumnalis, Stomoxys calcitrans* (Muscidae), *Sarcophaga bullata* (Sarcophagidae), *Calliphora vicina* (Calliphoridae)), three Lepidoptera (*Epiphyas postvittana* (Tortricidae), *Manduca sexta* (Sphingidae), *Plodia interpunctella* (Pyralidae)) and a hymenopteran (*Habrobracon hebetor* (Braconidae)). These species were chosen due to their likely physiological compatibility with parasitism by *C. annulifera* (Diptera) and because other species in the genus *Conura* have been shown to attack various Lepidoptera and Hymenoptera (see Bulgarella, et al., 2017).

In no case did the wasp produce offspring on any of these non-target species: in these lab studies, *C. annulifera* only reproduced successfully on *P. downsi*. This suggests that, of the species presented so far, only *P. downsi* represents a viable host for *C. annulifera* (Bulgarella, et al., 2017). However, this experimental design did not allow us to address the mechanism underlying this apparent specificity. It could either be that *C. annulifera* does not attempt to attack any species other than *Philornis* (i.e., behavioural specificity) or the wasp attempts to parasitise these species but their offspring fail to develop and emerge (i.e., only physiological specificity; see Desneux, et al., 2009). For an importation biological control programme with *C. annulifera* to be truly considered safe, it is important that we rule out the possibility that *C. annulifera* would attack non-target hosts, and cause their mortality by envenomation or oviposition.

To do this, we carried out additional analyses to test whether exposure to *C. annulifera* had any influence on the successful emergence of non-target pupae compared with controls. We found no evidence that exposure to *C. annulifera* resulted in elevated mortality for non-target hosts (see Bulgarella, et al., 2017). In contrast, when *P. downsi* pupae were exposed to the wasp, mortality increased independently of successful parasitism (i.e. more unparasitised fly pupae failed to emerge in the exposed treatment than in the control), perhaps as a result of host-feeding or envenomation/attempted parasitism. This finding, plus behavioural observations, suggests that *C. annulifera* does not attempt to sting or probe any potential host other than *Philornis* spp. pupae (Boulton & Heimpel, 2017; Bulgarella, et al., 2017).

FUTURE DIRECTIONS

Although all the evidence accumulated so far suggests that *C. annulifera* is a specialist parasitoid of *Philornis* spp. and should be seriously considered as a potential agent for the biological control of *P. downsi* in the Galápagos, one crucial question regarding the host range remains. It is critical to know whether *C. annulifera* is able to attack and develop on native or endemic non-target species present in the archipelago. As is common for most oceanic islands, the Galápagos exhibits high rates of endemism in insects (Peck, 1996). Island endemics may be particularly vulnerable to the introduction of a non-native parasitoid due to their lack of shared co-evolutionary history and the necessary adaptations to evade or resist parasitism. Before we can consider biological control in the Galápagos using any natural enemy, we must evaluate the host specificity of the putative biological control agent in the context under which it is intended for use. The studies that we have conducted using *C. annulifera* thus far represent a vital first step, suggesting that importation of *C. annulifera* into a quarantine facility in the Galápagos for further host range testing is justifiable. The results of these studies also allow us to narrow down the list of most at-risk non-target organisms in the Galápagos, due to the limitations imposed by its evolutionary and behavioural ecology.

Importation biological control of *P. downsi* in the Galápagos constitutes a promising means of population suppression that may ultimately serve to protect the extremely vulnerable bird species that the fly attacks (Boulton & Heimpel, 2017). Establishment of a biological control agent such as *C. annulifera*, may, in addition to ameliorating the current situation, serve as a preventative measure from future invasions of *P. downsi* and other bird parasitic species in the genus *Philornis* that are found in Ecuador. Preventative measures such as this may be deemed particularly judicious given the probability of further invasions under the high tourism pressure that the islands currently face (Toral-Granda, et al., 2017).

ACKNOWLEDGEMENTS

We would like to thank Paola Lahuatte and Andrea Cahuana for providing *Philornis downsi* from Galápagos; Mauricio Torres for assistance with field work supporting the reviewed studies; Jonathan Dregni, Carleigh Windhoerst, Ashleigh Sampedro, Justine Bleick, Leah Vaugn and Melisa Rodriguez for assistance with bird, fly and wasp husbandry supporting this work; Stephanie Dahl and Nik Prenevost for assistance with logistics in the quarantine facility; Bradley Sinclair for assistance with insect identifications; and the Ecuadorian Ministry of Environment and Galapagos National Park Directorate (Projects PC 10-15 and 18-16) for permission to import samples and conduct our research. This work is funded by the Galápagos Conservancy, the International Community Foundation (with a grant awarded by the Leona M. and Harry B. Helmsley Charitable Trust). This is contribution number 2202 of the Charles Darwin Foundation for the Galapagos Islands.

Abstract *Pieris brassicae*, large white butterfly, was first found in New Zealand in Nelson in May 2010. The Ministry for Primary Industries (MPI) responded with a monitoring programme until November 2012 when the Department of Conservation (DOC) commenced an eradication programme. DOC was highly motivated to eradicate *P. brassicae* by the risk it posed to New Zealand endemic cress species, some of which are already nearly extinct. DOC eliminated the butterfly from Nelson in less than four years at a cost of ca. NZ$5 million. This is the first time globally that a butterfly has been purposefully eradicated. Variation in estimates of benefits, costs, the efficacy of detection and control tools, and the probability of eradication success all contributed to uncertainty about the feasibility. Cost benefit analyses can contribute to assessing feasibility but are prone to inaccurate assumptions when data are limited, and other feasibility questions are equally important in considering the best course of action. Uncertainty does not equate to risk and reducing uncertainty through data gathering can inform feasibility and decision making while increasing the probability of eradication success.

Keywords: biodiversity, cost-benefit analysis, eradication success, extinction risk, invasive species, non-native species

INTRODUCTION

Biological invasions by insects, including Lepidoptera, are increasing worldwide (Liebhold, et al., 2016; Suckling, et al., 2017). Insect invaders can cause significant biodiversity, economic, social and health impacts, which makes eradication an attractive management strategy (Liebhold, et al., 2016). Expanding international trade and travel have increased the numbers of exotic organisms entering New Zealand (Biosecurity Council, 2003; MPI, 2016).

Pieris brassicae (Lepidoptera: Pieridae), a Northern Hemisphere species native to Eurasia, was first found in the wild in New Zealand in Nelson (41°27′S, 173°28′E), a coastal city at the north of the South Island, in May 2010 (Toft, et al., 2012). An Unwanted Organism under the Biosecurity Act 1993, and a known pest of cultivated brassicas, it was referred to locally as 'great white butterfly' (GWB), or 'great white cabbage butterfly' (GWCB'). In this paper we use the scientific name *Pieris brassicae*.

Pieris brassicae can migrate hundreds of kilometres to new locations within a season (Spieth & Cordes, 2012). Together with the species' cold tolerance, its dispersal ability would put most New Zealand endemic brassica populations at risk (Kean & Phillips, 2013). However, the rate of *P. brassicae* spread in Nelson was uncertain. It was found at eight sites spread over 10–12 km in urban Nelson five months after the initial detection, but its distribution appeared not to have changed significantly after a further two years (Phillips, et al., 2016). This suggested unexpectedly slow dispersal for this species, perhaps impeded by parasitic wasps, predation or other factors.

DOC considered that *P. brassicae* had potential to cause extinctions of New Zealand endemic cresses, many of which occur in isolated, small populations; this makes them vulnerable to a wide range of threats and expensive to protect. New Zealand has 79 native cress species within the Brassicaceae family, most of them endemic and two already presumed extinct. Fifty-five species are currently threatened by extinction: 18 listed as nationally critical (the closest ranking to extinction), four nationally endangered, five nationally vulnerable, one declining, eight naturally uncommon, and 19 threatened though not yet ranked (Townsend, et al., 2008; de Lange, et al., 2013; S. Courtney, DOC, pers. comm.).

After mating, a *P. brassicae* female lays a cluster of 50–150 eggs on a host plant, and can lay a total of ca. 500 eggs (Gardiner, 1963; Spieth & Schwarzer, 2001). After hatching, larvae feed together and can wander up to 350 m in search of food plants. *Pieris brassicae* develop through five larval stages, usually defoliating several host plants in the process. Larvae at the fifth stage crawl away from their host plants to form pupae. The time required for *P. brassicae* to complete its lifecycle depends both on temperature and day length. It had two to three generations per year in Nelson (Kean & Phillips, 2013).

The Ministry for Primary Industries (MPI) is New Zealand's lead biosecurity agency with responsibilities to protect New Zealand's environment, economy, health and socio-cultural values under the Biosecurity Act 1993. MPI responded quickly to the 2010 detection of *P. brassicae* in Nelson by alerting the public and establishing a monitoring and surveillance programme. However, they terminated their response in November 2012 based on the results of the final of several cost benefit analyses (CBA) (Dustow, 2010; Dustow & van Eyndhoven, 2012; Manning, 2012). MPI predicted costs would outweigh benefits and that the probability of success was low (Manning, 2012).

The Department of Conservation (DOC) has a responsibility to protect native biodiversity under the Conservation Act 1987. DOC has a strong track record of pest management and successful eradication of (mostly) vertebrate pests from islands (Diamond, 1990; Simberloff, 2002; Howald, et al., 2007). On 19 November 2012, DOC initiated an eradication attempt to eliminate the risk that *P. brassicae* posed to New Zealand endemic cresses, primarily using systematic ground-based searching (Phillips, et al., 2016). The attempt succeeded: the last *P. brassicae* was captured near central Nelson on 16 December 2014, and the eradication programme closed on 4 June 2016. MPI and DOC declared *P. brassicae* eradicated from New Zealand on 23 November 2016, at a cost of NZ$4.97 million (€3.22 million).

DOC and MPI both had very pressing competing priorities and were acutely aware that spending money on an eradication attempt would take resources from other high priority work. To spend limited taxpayer dollars wisely, MPI responds to incursions according to carefully

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 364–369. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

considered priorities using CBA to prioritise management responses. When considering eradication, MPI calculates a Benefit Cost Ratio (BCR) by estimating: the pest's impact over 20 years, the predicted cost of the eradication attempt, and the probability of eradication success. A BCR over 3:1 is required for MPI to initiate an eradication attempt.

Unfortunately, elements of a CBA can be difficult to quantify. Accurately predicting the impacts of invasive species can be difficult (Andersen, et al., 2004; Paterson, et al., 2015; Simberloff, et al., 2013; Simberloff, 2015). There is no universally accepted way of quantifying the benefit of conserving biodiversity in dollar terms (Spash, 2008; Parks & Gowdy, 2013; Barkowski, et al., 2015). Predicting eradication costs (Donlan & Wilcox, 2007; Holmes, et al., 2015) and the probability of eradication success also pose challenges, especially when there are few precedents and limited field data (Pluess, et al., 2012; Brown & Brown, 2015; Phillips, et al., this publication).

A feasibility study that considers eradication costs and benefits is a routinely used decision support tool in DOC (Broome, et al., 2005). Before starting the *P. brassicae* eradication attempt, DOC also considered costs, benefits and probability of success, though in a proposed eradication strategy rather than a CBA (Toft, et al., 2012). After commencing it, DOC revised costings, procured an independent CBA (East, 2013a) and developed additional feasibility criteria (Phillips, et al., this publication)

In this paper we explore uncertainties in the feasibility and economics of eradicating *P. brassicae* and suggest ways of reducing them to help inform future decision-making.

METHODS

We examined the question of when to attempt or abandon eradication when faced with high uncertainty and discuss ways to assist future decisions in such circumstances.

Cost Benefit Analysis

Four CBAs were developed, three by MPI and one by the University of New England for DOC. CBA is a systematic process for calculating and comparing the costs and benefits of a decision. Written as a formula it would read: (discounted benefits × probability of success)/ discounted costs. Costs and benefits were discounted at a rate of 8% for 20 years based on New Zealand Treasury advice (NZ Treasury, 2005).

The costs of aerial and ground-based eradication were predicted using known or estimated costs of service providers. Predictions also drew on experience with previous eradication operations regarding the activities required and their likely timeframes. Costs were included for active surveillance, passive surveillance (media, public), organism management (insecticide spraying, etc.), vegetation (host plant) movement controls, host plant removal and science support (developing a lure, augmenting natural enemy populations by releasing parasitic wasps, developing the sterile insect technique, data analysis, genetics and modelling).

The benefits of eradication are the avoided impacts. The impacts on brassica seed production, vegetable growing, and livestock forage production were calculated based on the cost of applying additional insecticide to control *P. brassicae*. These purely monetary impacts were estimated using several assumed rates of *P. brassicae* dispersal that were based on previous observations of *P. brassicae* spread in Chile (400 km in seven years), South Africa (350 km in two years) and Japan (400 km in five years or less) (Manning, 2012).

The biodiversity impacts (i.e. the cost of applying insecticide to endemic cresses to control *P. brassicae*) were considered by two CBAs (Dustow & van Eyndhoven, 2012; East, 2013a). In both analyses, 'willingness to pay' – a non-market valuation method which is based on a New Zealand community's willingness to avoid local extinction of a native plant – was also used to estimate biodiversity impacts (Dustow & van Eyndhoven, 2012; East, 2013a: East, 2013b). However, neither Dustow (2010) nor Manning (2012) used the cost of applying insecticide to endemic cresses for controlling *P. brassicae* in their 'willingness to pay' calculations.

Criteria used to evaluate eradication feasibility

Feasibility analysis aims to scope the size of the project, decide if eradication is possible and identify issues that require resolution to maximise the chance of eradication success (Pacific Invasives Initiative, 2013) and thereby estimate the probability of eradication success. MPI estimated the probability of success of ground-based eradication at approximately 30% based on overseas examples and expert opinion (Manning, 2012). The feasibility criteria used by MPI when considering eradication probability are based on Bomford & O'Brien (1995). They are:

- Rate of removal exceeds rate of increase at all population densities
- Immigration is zero
- All reproductive pests must be at risk
- Target pest can be detected at low densities
- Cost benefit analysis must favour eradication
- Suitable socio-political environment.

DOC assembled a Technical Advisory Group (TAG) to support the eradication attempt. The TAG developed a modified set of nine criteria, which built on the six criteria above, to evaluate feasibility (including the probability of success) and guide the eradication attempt (Phillips, et al., this publication). The criteria used by MPI are discussed below.

Technical advice and decision making

Both MPI and DOC used in-house and external expertise to inform decision making. DOC's TAG comprised three senior animal pest technical advisors from DOC including an entomologist, three senior scientists from two government research institutes (AgResearch and Plant and Food Research), and a private insect ecology consultancy (Entecol Ltd). DOC's TAG had considerable experience in ground-based eradication having advised or been directly involved in multiple animal and weed pest eradications nationally and worldwide. MPI consulted in-house technical staff, some of whom had been involved in previous insect eradication programmes, and also held a day-long meeting to consult with an external group of insect ecologists and industry stakeholders about the feasibility of eradicating *P. brassicae*. An MPI Governance Group reviewed the evidence provided by technical staff and decided not to attempt eradication in September 2012. DOC senior managers decided in November 2012 to attempt eradication based on the technical advice they received (Toft, et al., 2012).

RESULTS

The greatest variation between the four CBAs is in the predicted costs of eradication and discounted benefits (Table 1). The former due to differences in method and labour unit cost, and the latter due to the presence or absence of biodiversity benefit. Probability of success estimates were relatively similar, although the Manning CBA, which MPI ultimately used in their decision to abandon eradication, was somewhat less optimistic.

Eradication feasibility and cost benefit uncertainty

There was uncertainty about *P. brassicae*'s New Zealand distribution, reproductive rate, seasonality, rate of emigration, and host plant range. Similarly, it was difficult to predict the response of the public to control measures, efficacy of control measures, efficacy of detection methods, ability to monitor progress towards eradication, eradication costs, eradication benefits and probability of success.

Technical assessment of eradication feasibility criteria

Rate of removal exceeds rate of increase at all population densities

This was unknown at the outset given the potentially high reproductive capacity. No pheromones or other chemical attractants were available for *P. brassicae*, therefore trapping could not be used as a control tool, nor as a surveillance tool to monitor changes in population density. Aerial insecticide application was considered a potential method of maximising *P. brassicae* mortality at all population densities but was not pursued due to its likely unacceptability to Nelson residents (see criterion 6) and some uncertainty over just how vulnerable eggs and larvae would be to aerial spraying of large-leaved host plants. The large, conspicuous larvae feeding in groups on the same host plant did, however, suggest ground-based searching may be effective if the scale of operation could match the scale of infestation. Also, most *P. brassicae* host plants were likely to be low-growing, which would facilitate ground-based searching.

Immigration is zero

There was concern that the high dispersal potential of *P. brassicae* would make delimiting the population expensive and unreliable (given the unavailability of effective lures) and could result in undetected populations occurring outside the operational area that could reinvade. However, large commercial brassica crops on arable land near Nelson city were routinely monitored and by 2012 were still not showing evidence of *P. brassicae*.

All reproductive pests must be at risk

As described in more detail below, most potential control methods depended on visually detecting *P. brassicae*, but search efficacy was initially unknown. Thus, the possibility that some individuals would evade detection and avoid control was a major concern.

If *P. brassicae* populations occurred outside the operational area and remained undetected, those individuals would not be at risk, therefore violating criteria 2 and 3 above. *Pieris brassicae* adults are highly mobile and can cover long distances in search of larval food plants and nectar sources. Individuals are known to fly up to 5 km a day searching for host plants for egg-laying (Schutte, 1966, cited in Feltwell, 1982). Given the high dispersal potential of *P. brassicae* and the observed rapid spread of the closely related *P. rapae* when it appeared in New Zealand (at least 160–190 km within two years of detection) (Muggeridge, 1942), it was assumed *P. brassicae* would be widespread in Nelson and that undetected populations existed. It was considered that *P. brassicae* was capable of moving outside Nelson city's boundaries in the first season post-detection. There was also the risk that *P. brassicae* could escape Nelson in association with human transport, perhaps as larvae on infested vegetation or as pupae on inanimate objects including vehicles. However, despite the potential for rapid dispersal beyond Nelson, by 2012 there was still no evidence that it had occurred. Possibly dispersal was density-dependent (Toft, et al., 2012).

There was concern that wild brassicas and other food hosts in less accessible places would act as refugia if they could not be found and searched.

There was also concern that some life stages would not be susceptible to control. For example, eggs can occur under leaves making them difficult to see and less vulnerable to insecticide sprays. The cryptically coloured pupae can attach to man-made structures such as fences and it seemed they would often be difficult to find. However, every individual could be put at risk during one or more stages of its lifecycle through human search effort.

In addition, not all tools depended on people detecting *P. brassicae.* There was published evidence that eggs and larvae were vulnerable to storm events, and eggs, larvae and pupae would be susceptible to parasitism or predation by various species of parasitic wasps and paper wasps that were already present in New Zealand (Muggeridge, 1943; Bonnemaison, 1965; Gould & Jeanne, 1984; Richards, et al., 2016). Moreover, detection was not an essential prerequisite for applying control measures such as insecticides and destroying host plants (e.g. garden brassicas).

Target pest can be detected at low densities

There was concern that visually searching for *P. brassicae* without a lure would be costly, labour intensive and ineffective at detecting all individuals at low population densities. All previously successful eradications of Lepidoptera used pheromone lures (Tobin, et al., 2014). Pheromones can be used to detect and monitor populations, and also to disrupt mating, which can be a particularly effective control method at low pest densities. However, pheromones and other chemical attractants were unavailable for *P. brassicae*. Detection probabilities could be calculated but only through data gathering and analysis during an eradication attempt (Phillips, et al., 2014a).

Cost benefit analysis must favour eradication

Four separate CBAs were carried out, three before the eradication attempt commenced and one a year after the

Table 1 Eradication method, cost, benefit and probability of success.

Reference	Method	Discounted cost (NZ$ m)	Discounted benefit (NZ$ m)	Benefit: cost ratio	Probability of success (%)
Dustow (2010)	Aerial	25–73	21.7–60.9	0.3–2.44	50–75%
Dustow & van Eyndhoven (2012)	Aerial	25–73	21.7–123.2	0.3–4.93	50–65%
	Ground	13.3		1.64–9.28	
Manning (2012)	Ground	8.9	13.2–26.5	1.5–3	30–60%
East (2013a)	Ground	3.9	17.4–70.8	4.8–19.7	56–76%

eradication attempt started. All used different estimates of costs, benefits and probability of success and, therefore, all obtained different BCRs and reached different conclusions (Table 1).

Dustow (2010) concluded that "the analysis strongly suggests that it is not economically beneficial to attempt to eradicate great white butterfly [using the aerial application of insecticide]". Dustow & van Eyndhoven (2012) concluded that "the CBA analysis indicates favourable benefit cost ratios for all but the most conservative ground-based eradication when biodiversity values are excluded", and "relatively low biodiversity values are required to generate favourable benefit cost ratios for many scenarios". Manning (2012) concluded that "given the level of uncertainty surrounding the development of effective control tools, low probabilities of successfully eradicating the GWCB, and the uncertainty surrounding biodiversity benefits, it is unlikely to be technically or economically feasible to eradicate the GWCB". Subsequently, East (2013a) concluded that "The high expected impacts of the GWB on New Zealand's native brassicas, the agricultural industry and home gardeners result in high net present values and benefit cost ratios [which suggests] that a GWB eradication programme in Nelson is warranted".

Manning (2012) stated that 'the ground-based eradication option is considered to have a probability of success of approximately 30% based on overseas examples and expert opinion". MPI used the probability of 30% when decision making. The probability of success value (mean 56%; range 50–60%) used in the fourth CBA (East 2013a) a year after eradication commenced was determined by DOC's TAG who had the benefit of some hard data on which to make their estimate.

Cost estimates varied greatly among the four CBAs (Table 1). Aerial spraying costs were based on previous experience of using this method against white tussock moth (*Orgyia leucostigma*) and painted apple moth (*Orgyia anartoides*) in Auckland (Ashcroft, et al., 2010) and assumed substantial social mitigation costs for affected residents of Nelson. Ground-based cost estimates were little more than guesses given uncertainty around method efficacy, delimitation boundaries and detection probabilities (which strongly influence the length of time ground crews must remain operational beyond the last detection to have confidence in declaring eradication success). MPI contractor costs were also estimated at three times higher than DOC staff costs. Again, East (2013a) had some actual data to work with and consequently her cost estimate came closer than the others to the final actual cost.

Suitable socio-political environment

An aerial application of the bio-pesticide bacterium Btk (*Bacillus thuringiensis kurstaki*) was thought likely to raise considerable public opposition as it did in Auckland for white tussock moth and painted apple moth (Ashcroft, et al., 2010). Ground-based control, on the other hand, was assumed likely to gain public and political support. This was evidenced shortly after the initial detection by positive public responses to official requests for reports of *P. brassicae* sightings.

DISCUSSION

When assessing the feasibility of eradication, three basic questions must be answered (Broome, et al., 2005): Why do it? Can it be done? What will it take to succeed?

Why attempt eradication?

It was impossible to precisely predict the impact of *P. brassicae* on New Zealand endemic brassicas (and predicting impacts on cultivated brassicas under different management regimes was also problematic). New Zealand's biodiversity has been geographically isolated for millions of years from Northern Hemisphere plants, herbivores, predators and parasitoids, which makes it hard to predict impacts. This is a generic issue for incursion response management in New Zealand. If the New Zealand native plants that a non-native herbivore will feed on cannot be immediately identified, then estimating impacts can only be achieved either through difficult, expensive and imperfect laboratory testing, or by watching them unfold in the wild. Laboratory testing of the suitability of threatened native cresses for herbivory by *P. brassicae* was impractical as most are not cultivated due either to the difficulty of obtaining seed, or to their complex cultivation requirements.

The risk of extinction to endemic cresses from herbivory by *P. brassicae* was considered significant even without multiple other threats. Other threats to endemic cresses include herbivory and disturbance by a range of pests, viral and fungus attack, weed competition, sea-level rise and the loss of seabird-driven ecosystem processes which all impact on different cresses. As Quammen (1996) pointed out, extinction often results from multiple causes and "to be rare is to have a lower threshold of collective catastrophe".

Preventing extinction of native biodiversity is a core function of DOC and is fundamental to the Department's legislative mandate (Conservation Act 1987). Given the multiple threats facing endemic cresses in addition to *P. brassicae*'s potential to access all endemic brassicas, dietary preference for brassicas, tendency to deposit large numbers of eggs on individual plants and voracious feeding on individual plants by clusters of caterpillars, DOC's senior botanists and entomologist concluded there was a high risk that *P. brassicae* would drive at least some New Zealand endemic cresses to extinction. Knowledge of this risk strongly motivated DOC to attempt eradication, despite the uncertainties, while using a 'learn by doing' approach.

Can it be done?

The value attributed to the probability of success can significantly influence the benefit value obtained (i.e. benefit = discounted benefit × probability of success) and therefore the BCR. Estimating the probability of success is a subjective process based on evidence from previous eradication attempts and expert opinion. This becomes problematic when eradication of the taxon in question has not been attempted before, and where factors including the ecology, physiology and behaviour of the non-native species in the new environment are poorly understood. Accurately estimating the probability of eradication success is impossible without knowledge of the effectiveness of control tools, pest population rate of increase, pest distribution, and risk of immigration (Bomford & O'Brien, 1995; Tobin, et al., 2014; Phillips, et al., this publication). The challenge is to gather enough quality data quickly enough to inform decisions. Choosing a threshold of certainty – where there is enough information to make a decision – can be partly based on an assessment of the consequences of not deciding. As Harvey Cox (1968) puts it "not to decide is to decide".

If the pest can be killed at the same time as it is being surveyed for distribution and abundance, then eradication may gain a 'head start' while critical feasibility information is being collected. Pre-defined stopping rules can be used to trigger reassessments of feasibility, thus limiting the risk of over-investing in eradication attempts that cannot succeed. For example, the DOC TAG defined the following triggers for re-evaluating the *P. brassicae* eradication attempt (Phillips, et al., 2014b):

- If established *P. brassicae* populations are detected outside the residential Nelson operational area
- If the population has expanded outwards after 12 months of being subjected to control
- If *P. brassicae* has not been eradicated by 30 June 2015
- If no *P. brassicae* have been detected for two consecutive years.

Triggers clearly indicate when the objectives in the plan are or are not being achieved. The initial response gathered some information about *P. brassicae*'s distribution prior to commencing the eradication attempt, but not about its rate of increase or the efficacy of visual searching. Once the attempt was underway, however, distribution data and the effectiveness of control tools was gathered in a systematic way that was used to inform management decisions, reduce uncertainty, reassess feasibility through time, measure progress and eventually provide confidence that eradication had been achieved (Phillips, et al., 2016).

What will it take to succeed?

The 'learn by doing' approach informed the technical assessment of the probability of success (described above). It also allowed the level of resourcing and capability that was needed for the eradication to succeed to be accurately quantified and adjusted as the programme progressed. For example, in the early stages of the programme in 2012, the ground control team was limited to a team of four. However, by April 2013 it had become clear that, although the methods might be effective, more resources were needed to achieve success (Table 2). The field team size was increased to 10 (and up to 30 later in the programme) and the consequent increased costs were factored into the final CBA (East, 2013a). By constantly reassessing resource allocations to different aspects of the project, efficiencies were gained without jeopardising the probability of success. Crucial in this decision making was expert analyses of incoming data by DOC's TAG that supported the project.

CONCLUSIONS

Delays in attempting eradication can increase the programme's duration, cost and risk of failure.

Table 2 Sites searched, sites infested with *Pieris brassicae* and proportion infested by financial year (July to June).

Year	Sites searched	Sites infested	Proportion of sites infested
2009–10	3	3	1
2010–11	88	30	0.341
2011–12	76	71	0.934
2012–13	23,923	1,121	0.047
2013–14	80,263	1,490	0.019
2014–15	83,118	170	0.002
2015–16	76,507	0	0
Total	263,978	2,885	0.015

Quick, proactive responses can help to achieve eradication while simultaneously gathering data to inform decision making. Stopping rules can be used to assess if an eradication should cease to minimise the waste of resources.

In the absence of reliable information about costs, biodiversity benefits and probability of success, CBAs should not be relied on as the sole decision making tool.

A TAG can be a powerful tool for providing ongoing well-structured advice to assess feasibility and assist eradication decision making.

Close engagement with research agencies facilitates research support for eradication attempts, which can help to provide critical analyses, information and management tools.

ACKNOWLEDGEMENTS

We thank the many dedicated DOC and MPI staff involved, and the many people from outside these organisations who generously provided their time, advice, support and expertise, including researchers in the Better Border Biosecurity research collaboration, <www.b3nz.org>, particularly from AgResearch and Plant and Food Research. Vegetables NZ, the TR Ellet Agricultural Research Trust, Better Border Biosecurity and Dairy NZ made financial contributions. We also thank Miriam East (University of New England, Armidale, Australia) for her work on *P. brassicae* cost benefit analysis and Shannel Courtney (DOC, Nelson, NZ) for providing up to date information on native cresses at risk and costing the likely *P. brassicae* impacts on native cresses. Peer review that improved the quality of this paper was provided by Shannel Courtney, Bruce Philip (MPI, Wellington, NZ) and Susan Timmins (DOC, Wellington, NZ). Thanks also to the two anonymous referees who challenged our thinking.

Effort required to confirm eradication of an Argentine ant invasion: Tiritiri Matangi Island, New Zealand

C. Green

Department of Conservation, P.B. 68-908, Newton, Auckland, New Zealand. <cgreen@doc.govt.nz>.

Abstract Tiritiri Matangi Island in the Hauraki Gulf, Auckland, New Zealand is a 220 ha restoration island managed by the Department of Conservation as an open sanctuary. Following eradication of the only mammalian predator, the Pacific rat (*Rattus exulans*) in 1993, a variety of threatened birds, lizards and a giant invertebrate have been transferred to the island. In March 2000, Argentine ant (*Linepithema humile*) (Hymenoptera: Formicidae) was discovered and delimiting surveys revealed a 10 ha infestation. Managers were concerned that the ant could have significant negative impacts on invertebrates, birds and lizards. Early surveys confirmed a dramatic decline in all other ant species within the infested area. In February 2001, an eradication programme commenced with paste baits (a.i. 0.01% fipronil) spread manually in a 2 m × 3 m grid over the entire area. The second year employed a 1 m × 3 m spacing. A second incursion part way through the programme extended the area to 11 ha. The same toxic bait was used throughout the programme to kill residual colonies and a non-toxic version was used as a lure to intensively monitor progress. Eradication was declared in 2016. Critical parts of the programme included detection of post treatment survivors and the level of effort required to confirm successful eradication. New treatment techniques were developed to kill the last small nests by placing toxic baits inside vials on the ground to prolong bait life. Such nests exhibited non-invasive behaviour, short foraging distances, and were prone to disturbance leading to foraging cessation. Bait densities and field placement were critical to success. Sites with residual nests were deemed free of Argentine ant once there had been no detections over three consecutive years of ongoing monitoring. With few successful Argentine ant eradications in the world the techniques used here can inform and improve success rates for other ant eradication attempts.

Keywords: *Linepithema humile*, monitoring vials, paste bait, surveillance, toxic baiting

INTRODUCTION

Argentine ant (*Linepithema humile*) is one of the world's worst invasive ant species and an important conservation concern (Holway, et al., 2002) with considerable negative impacts to native biodiversity (Rowles & O'Dowd, 2007; Stringer, et al., 2009). Argentine ant infestations have proven difficult to eradicate with few reports of successful programmes (Silverman & Brightwell, 2008; Hoffmann, et al., 2011; Hoffman, et al., 2016). To date, only around 10% of ant eradications have been greater than 10 ha (Hoffmann, et al., 2016). Detectability of ants in low densities is one of the most critical factors to increase the likelihood of successful eradication (Hoffmann, 2011). Despite a long history of invasive ant management, utilising widely varying approaches, eradication failures are common (Hoffmann, et al., 2016).

A variety of techniques are used to sample Argentine ant such as visual searching, baits placed on the substrate, in vials or in pitfall traps (Stanley, et al., 2008; Casellas, et al., 2009). However, visual detection is less effective in more complex vegetated environments (Ward & Stanley 2013), such as on offshore islands that act as conservation sanctuaries, compared to urban areas. A study by Ward & Stanley (2103) of the detection probability of an Argentine ant population, using vials with honey and sausage meat, found that a site should be surveyed three times to be confident about the presence or absence of ants. Pest eradication programmes on islands are generally considered successful if no detections are found during two years of post-treatment monitoring (Howald, et al., 2007).

Argentine ant was first detected in New Zealand in 1990 (Green, 1990), and subsequently on Tiritiri Matangi Island in March 2000 (Harris, 2002). Following eradication of the only mammalian predator, the Pacific rat (*Rattus exulans*) from Tiritiri Matangi in 1993, a variety of threatened birds, lizards and a giant invertebrate were transferred to the island (Galbraith & Cooper, 2013). Managers were concerned that the ant could have considerable negative impacts on invertebrates (Sanders, et al., 2003), birds (Sockman, 1997; Suarez, et al., 2005) and lizards (Suarez & Case, 2002) through direct predation and competition for invertebrate food sources. Modelling has predicted that sites near Auckland, including Tiritiri Matangi, are hot spots for potential Argentine ant occupancy (Pitt, et al., 2009) with consequent implications for island biosecurity programmes. Two infestations were found on the island, one large area covering ca. 10 ha centred around the wharf and a second, smaller (<0.5 ha) area at Northeast Bay at the northern end of the island (Fig. 1). The latter arose

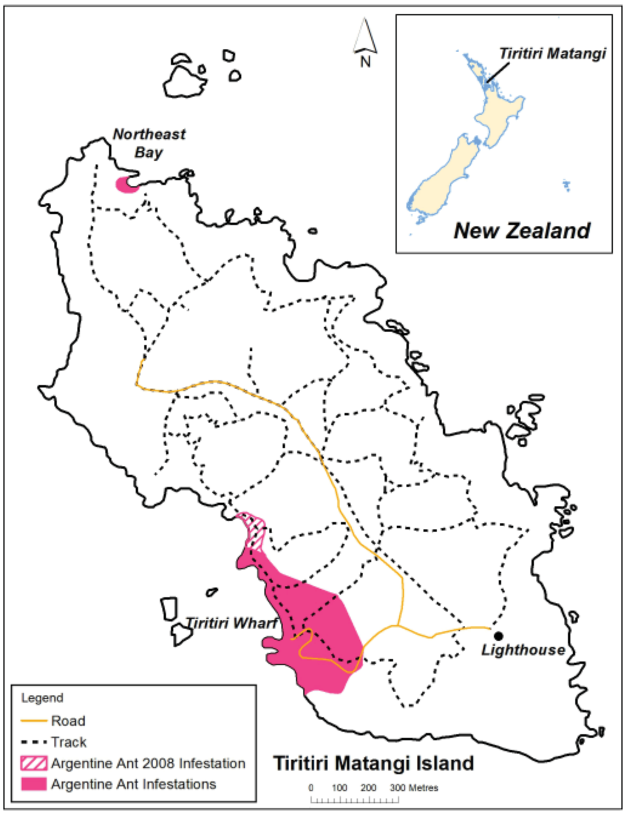

Fig. 1 Tiritiri Matangi Island Argentine ant infestations, tracks and roads.

from the movement of an infested dingy from the wharf area (Harris, 2002). During the eradication programme a second incursion occurred at Hobbs Beach in 2008 at the northern end of the Tiritiri wharf infestation (Fig. 1). The shape of the newly infested ca. 0.5 ha area indicated its likely origin as the south end of Hobbs Beach. This new incursion extended the total infested area on Tiritiri to 11 ha.

Here I outline the programme against Argentine ant on Tiritiri Matangi Island and describe the effort required to confirm eradication.

METHODS

Study area

Tiritiri Matangi Island (Fig. 1) is a 220 ha Scientific Reserve 28 km north of Auckland City in the Hauraki Gulf, New Zealand, managed by the Department of Conservation as an open sanctuary. There are over 38,000 visitors to the island annually (DOC, 2014) with most arriving via commercial ferry to the wharf but the public are free to land on the beaches via private craft. The Supporters of Tiritiri Matangi and the ferry operator facilitate biosecurity measures relating to clean footwear and public awareness messaging on pests including Argentine ant. All freight and goods for island management arrive at the wharf and pest detection operates via inspections for all species, including Argentine ants, plus traps or indicator baits for rodents. The nearest land is the Whangaparaoa Peninsula 3.5 km to the west. The island is low lying and has been the subject of an extensive restoration programme involving the planting of over 280,000 trees over ten years from 1984–1994 (Galbraith & Cooper, 2013). The two areas infested with Argentine ants, Northeast Bay and around the Tiritiri wharf, host a range of plants characteristic of coastal habitats in the region including flax (*Phormium tenax*) (Fig. 2), karamu (*Coprosma robusta*), taupata (*Coprosma repens*), mahoe (*Melicytus ramiflorus*) and the coastal vine pohuehue (*Meulenbeckia complexa*). Typically, the canopy height was up to 6 m with the occasional pohutukawa tree (*Metrosideros excelsa*) exceeding 10 m.

Toxic baiting

Following the discovery of Argentine ant on the island in 2000, the infestation was delimited using visual assessment. A ca. 20 m buffer was added to the boundary of the entire infested area. Bait treatment during the first two years consisted of a single application of Xstinguish™ Argentine ant bait (a.i. 0.01% fipronil) over the 11 ha infestation. The paste baits (2–3 g) were hand laid using a caulking gun to extrude baits on the ground in a grid over the entire area with 2 m × 3 m and 1 m × 3 m spacing in February 2001 and the following season in December 2001, respectively. Where possible, baits were placed under vegetation to avoid exposure to the sun and reduce desiccation. From 2003, all remnant infestations were treated twice a year with toxic bait, four to eight weeks apart. The 2008 incursion (Fig. 1) was double-treated in 2009 with 1 m × 3 m spacing. From 2010, treatment consisted of toxic baits placed inside vials (25 mm × 50 mm) on the ground for five days, repeated two weeks later. Vials were spaced 1 m apart out to 5 m from the remnant colony then extruded baits on the ground out a further 5 m. Vials had netting covers to prevent lizards and larger invertebrates entering. Vials were placed in shade beneath vegetation to reduce desiccation.

Fig. 2 Flax (*Phormium tenax*) (foreground) on beach edge as a typical preferred habitat for Argentine ants on Tiritiri Matangi Island.

All baiting operations were carried out when the ground was dry and weather conditions were warm (air temperature 20–25 ºC) dry, and no rain forecast for at least 24 hours. These conditions were optimal for Argentine ant activity on Tiritiri and thus maximised the chances of bait detection.

Post-treatment monitoring

Intensive post-treatment monitoring commenced from 2003 using ca. 2 g of non-toxic Xstinguish™ Argentine ant monitoring paste lure in vials placed every 2–5 m in a grid over the target area. Although some visual detection was possible for larger remnant infestations during 2003, this was largely ineffective at detecting small infestations. Thus, from 2004 all monitoring used the lure in vials as above. During 2003, baits were left out for approximately four hours. From 2004, this was extended to 24 hours. During collection, the open vials were sealed with a lid and all trapped ants were identified and later verified using a microscope.

During the 16-year programme, the entire treated area was only intensively monitored on two occasions, in 2006 and 2008. Following the 2006 monitoring the whole previously infested 10 ha wharf area was assessed for sites that appeared to be preferred by Argentine ant. Due to limited resources, during years other than 2006 and 2008 varying levels of monitoring focused on these preferred Argentine ant sites. In addition, all detection sites from 2003 onwards were intensively monitored. Due to the initial very high densities of ants and the ongoing survival of a few nests, sites close to the wharf were monitored every year for all 16 years of the programme. Sites where nests remained undetected in alternate years were monitored two or three occasions per year to increase the likelihood of detection.

All lure operations were carried out under the same environmental conditions as described above for baiting, i.e. warm and dry.

RESULTS

Toxic baiting was extremely effective at reducing Argentine ant numbers to very low levels (Fig. 3). No Argentine ants were seen at Northeast Bay after 2001. However, remnant populations persisted at the larger wharf infestation after the initial single treatment per year. Thus, from 2003 toxic treatments were applied on two occasions each year, with a period between treatments sufficient to allow surviving ants to regroup into functioning nests, with foraging ants susceptible to being attracted to baits. This

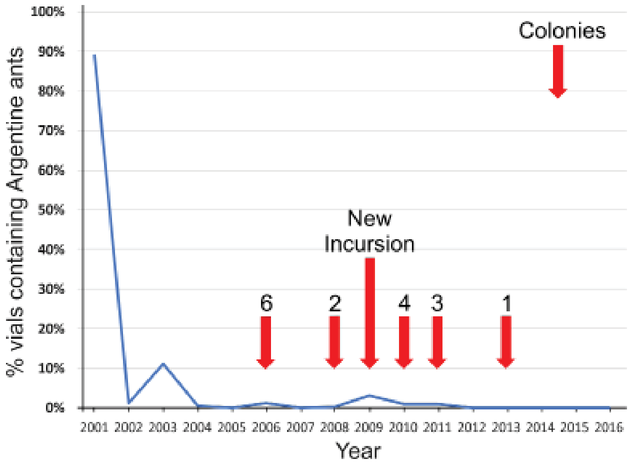

Fig. 3 Percentage of vials with Argentine ants during the 16-year programme. There were zero detections in 2007, 2012, 2014–16.

strategy effectively reduced the infestation to very small colonies, each consisting of a few nests, and sometimes just a single nest.

Argentine ants were detected visually for the first three years of the programme. However, for the remainder of the programme surviving nests could only be detected by using lured vials. This was largely due to the complex nature of the vegetated habitat and the small size of the remnant colonies. As the programme continued, fewer nests were detected (Fig. 3).

The entire treated area was intensively monitored in 2006 and revealed six infestations. Following treatment, no Argentine ants were detected in 2007. Intensive monitoring of the entire treated area again in 2008 detected two residual colonies. However, during these years in the middle of the programme, some small colonies remained undetected in some years. There were at least two sites within the wharf infestation where ants appeared to survive after the 2006 and 2008 treatments as they were re-detected one or two years later in very similar locations. One colony was not detected until 2011, despite the site being monitored annually since 2003. This site was within 5 m of the vehicle and trailer used to transport all arriving baggage and freight to buildings at the top of the island. All these surviving colonies vanished after toxic baited vials were introduced in 2010. Bait inside the vials generally remained moist and palatable to ants for the full five days. No Argentine ants were detected after 2014.

The 2008 incursion (Fig. 1) was discovered and double-treated in 2009. Three surviving colonies were detected in 2010 and two in 2011, with at least one of these being a survivor from 2010. No Argentine ants were detected following treatment in 2011.

The 2006 assessment for preferred Argentine ant sites revealed sites typically characterised by a warm northerly aspect where sun could reach the ground during much of the day. Vegetation was less than 3 m tall and usually had open areas within or adjoining, such as roads, tracks, the coast or exposed banks with just ground cover vegetation. Flax plants (Fig. 2) were often a feature of preferred sites although not a prerequisite.

When Argentine ant was first discovered on the island, the population density was very high close to the wharf, which was assumed to be the entry point. Some of the most problematic nests to destroy were located at sites near the wharf. Thus, these were monitored on two or three occasions per year from 2014. However, this repeated monitoring did not yield any additional detections.

Repeated intensive use of lured vials detected surviving nests. On some occasions, ants were detected in consecutive vials on adjacent lines indicating a larger population, likely to be more than one nest. However, detections were predominantly made in a single vial reflecting the presence of a single nest. Some of these remnant nests appeared to be very small as trails featured few ants and vials contained less than 10 Argentine ants when collected. Much of the lure was still present indicating a lack of substantial feeding activity over the 24 hours. In contrast, lure monitoring early in the programme when large colonies were detected yielded hundreds of ants with little lure remaining after four hours.

DISCUSSION

A single application of toxic bait was not sufficient to eradicate Argentine ant from Tiritiri Matangi Island (Harris, 2002). Although the bait was successful at quickly eradicating the small, recent infestation at Northeast Bay the larger wharf infestation required many years of intensive baiting of small remnant nests to achieve eradication. Increased levels of effort were required throughout the programme to improve both ant detection and treatment techniques to eliminate nests.

Early in the programme when Argentine ant first established on Tiritiri the species' behaviour fitted the usual pattern of being extremely competitive with other ant species for food sources (Human & Gordon, 1999). Foraging Argentine ants recruited to any new food source, including the toxic bait and non-toxic lure, in very large numbers, often within minutes. This behaviour contrasts with that of foraging ants from small, post-treatment, remnant nests that were not necessarily attracted to bait or the lure given the availability of other natural food sources. Detectability of ants in low densities is one of the most critical factors to increase the likelihood of successful eradication (Hoffmann, 2011).

In the latter stages of the programme there were occasions when small nests were detected but not seen again despite there being no toxic treatment in that area during that season. All single nests appeared to be lacking the "invasive" element in their behaviour and were observed foraging over short distances. It is possible that these ants lacked competitiveness to survive with other ant species (Rice & Silverman, 2013). All ants in monitoring vials were identified during the programme and some ant species were in high numbers. Several of those recorded, including *Monomorium antarcticum*, a New Zealand endemic, and *Ochetellus glaber*, a naturalised Australian species, have been shown to be competitive with Argentine ant (Westermann, et al., 2014).

The lack of competitiveness and aggressive behaviour normally seen in invasive species made detection of remnant Argentine ant nests more difficult. It is often true that the last remaining few in an eradication attempt require the greatest effort (Morrison, et al., 2007). As the programme continued, it was necessary to prolong the time that lured vials were available to foraging ants. While a four-hour monitoring period was adequate to measure the level of Argentine ant activity when ants exhibited invasive behaviour, it became clear later that even 24 hours was not adequate so needed to be repeated, as recommended by Ward & Stanley (2013). For the most preferred sites, particularly on coastal banks exposed to the sun most of the day, 24-hour monitoring was repeated three times per season for three seasons to verify eradication.

Ants on trails from small remnant nests often appeared uninterested in lures or baits even when placed next to the trail, despite their known palatability as seen early in the programme. Argentine ants prefer liquid or paste baits/lures (Nyamukondiwa & Addison, 2014), but the disadvantage of such baits/lures is that they have a very short field-life once applied in the environment. This is especially the case when used in warm/hot conditions which are optimal for ant activity. The life of the paste baits when placed on the ground was short (<12 hrs: Harris, 2002), which gave a limited time for ants to be attracted to them and commence feeding. Baits had to compete with other natural food sources for the attention of ants. In addition, on several occasions foraging ceased if the trail was disturbed while placing baits on the ground. This may have contributed to nest survival at some baited sites.

To increase the time of interaction between ants and toxin, baits can be delivered repeatedly through the season, as on Santa Cruz Island (Boser, et al., 2014, Boser, et al., 2017), or the life of each bait can be extended after application by slowing desiccation. Baits placed in vials and shaded under vegetation retained moisture and remained palatable for at least five days. Hoffman, et al. (2001; 2016) highlighted the need for new techniques to eradicate invasive ants. The innovation of placing toxic baits in vials reported here allowed the potential interaction between ants and toxic baits to occur over five days rather than 12 hours. Once toxic baited vials were deployed at detection sites, no further Argentine ants were seen at these sites and eradication was achieved.

During the programme there were at least two sites within the wharf infestation where ants apparently survived the 2006 and 2008 treatments as they were re-detected one or two years later in very similar locations. It is possible that the toxic baiting had sub-lethal effects on either Argentine ants and/or other ant species, such as *M. antarcticum* (Barbieri, et al., 2013), leading to changed interspecific dynamics and subsequent survival of Argentine ant nests. It is also possible that a surviving Argentine ant nest moved away from the monitored area and was not detected until it moved back in a subsequent season. All ant species readily move their nests if disturbed and this was observed with Argentine ants. Trails from surviving small nests were particularly prone to disturbance. The two sites in the wharf infestation were on the edge of Wharf Road in highly preferred locations. They could have moved away from the edge into less preferred locations beyond monitoring lines due to disturbance but returned to the edge and were detected in subsequent seasons.

Toxic vials were used only around the immediate vicinity of remnant nests to restrict the non-target impacts on other invertebrates. Relatively few vials had all the bait removed over the five days. In contrast, non-toxic lured vials used for monitoring often had much of the bait removed by non-target species over just 24 hours. Therefore, it was not worthwhile to leave the monitoring vials out longer than 24 hours.

Since the eradication of Argentine ants from Tiritiri Matangi, the island's biosecurity procedures have altered to include annual surveillance for any new incursions. This study has confirmed that ants from new, expanding populations are readily attracted to baits (Ward & Stanley, 2013), and the level of surveillance monitoring can be less intensive compared to that required to confirm post treatment eradication. Early detection of new incursions through surveillance programmes gives a greater chance of successful eradication (Clout & Williams, 2009; Ward, et al., 2010).

There are very few reported, successful Argentine ant eradications (Silverman & Brightwell, 2008, Hoffmann, et al., 2011, Hoffmann, et al., 2016). The successful Argentine ant eradication programme reported here required considerable effort and improved techniques to achieve eradication. It took 13 years to extirpate the last ants from the main infested area near the wharf, which had areas of very high population density. Problematic remnant nests were mostly found in these high-density areas. With the new monitoring and surveillance techniques developed here, there is confidence that if a new incursion is detected that eradication will be possible within a much shorter timeframe, as demonstrated by the 2008 Hobbs Beach incursion site which took only three years. These techniques would be readily applicable to discrete Argentine ant populations infesting 10 ha or less elsewhere in the world, thus achieving an increased success rate of eradication attempts.

ACKNOWLEDGEMENTS

Thanks to Richard Harris and Jo Rees (Landcare Research) and the island rangers Ray and Barbara Walters, Shaun Dunning, and Ian McLeod for assistance over the early years. Special thanks to Helen Lindsay for supervision of monitoring teams and relentless assistance with all aspects of the field programme during the final 10 years. The advice and support of Viv van Dyk on the bait and lure used is much appreciated. Thanks also to the many volunteers who helped with the toxic baiting during the first two years of the programme – success would not have been possible without your assistance. Suggestions from two anonymous referees have improved the manuscript.

[1]Laboratory of Zoology, Department of Biology, University of the Balearic Islands, Cra. Valldemossa km 7.5, CP: 07122 Palma, Illes Balears, Spain. <mar.leza@uib.es>. [2]Consortium for the Recovery of the Fauna of the Balearic Islands (COFIB), Crta. Sineu km 15, CP: 07142 Santa Eugènia, Illes Balears, Spain.

Abstract The yellow-legged hornet (*Vespa velutina*) was detected for the first time in the north of Spain in 2010, but was not detected in Majorca, Balearic Islands until 2015 and only one secondary nest, with 10 combs, was found in the northwest of the island. During 2016, nine more nests were found in the same region. To better understand the biology of *V. velutina* in isolated conditions, the following objectives were proposed: (I) describe the architecture and structure of nests; (II) analyse the shape of combs and develop a new method to confirm the circular pattern of breeding; (III) determine the colony size and (IV) determine the succession of workers and sexual individuals throughout the season. For these reasons, nests that were removed were frozen for at least 48 days until analysis. Our results show that this species has a high reproductive potential under isolated conditions. Results reveal that parameters such as weight, height, diameter, number of cells and total individual production are directly related. Moreover, each mature nest can produce up to 9,000 individuals and several hundred potential founder queens. All results inform formulation of an efficient control or eradication programme in the Balearic Islands, as we are in the early stages of invasion and intervention is essential to eradicate *V. velutina* on Majorca Island.

Keywords: architecture, breeding provision, caste differentiation, individual production, Latter's formula, Majorca, *Vespa velutina nigrithorax*

INTRODUCTION

The yellow-legged hornet (*Vespa velutina* Lepeletier 1836) is a social Hymenopteran of the family Vespidae. It is native to tropical and subtropical areas of Southeast Asia (Archer, 1994; Martin, 1995; Carpenter & Kojima, 1997). It was reported for the first time in south-west France in 2004 (Haxaire, et al., 2006; Rome, et al., 2009; Villemant, et al., 2011) and rapidly spread to nearby European countries: Spain (Castro & Pagola-Carte, 2010; López, et al., 2011), Portugal (Grosso-Silva & Maia, 2012), Italy (Demichelis, et al., 2014), Belgium (Bruneau, 2011; Rome, et al., 2013) and Germany (Witt, 2015). This species is also established in South Korea (Choi, et al., 2012; Choi, et al., 2013) and Japan (Ueno, 2014). The most recent incursion was in Great Britain in 2016, and Switzerland in 2017 (UK National Bee Unit, 2016; Budge, et al., 2017).

The introduction of *V. velutina* to Europe could lead to important economic and ecological impacts. The main impact of the yellow-legged hornet is the likely decrease in honeybee (*Apis mellifera*) populations (Tan, et al., 2007; Monceau, et al., 2013a; Monceau, et al., 2013b), as wasp larvae feed on the proteins of honeybees. Honeybees are considered one of the most important pollinators for agriculture, so the decrease of *A. mellifera* populations is anticipated to decrease the production of their crops resulting in economic losses for the farmers (Villemant, et al., 2011; Arca, et al., 2014). In addition, it is possible that the yellow-legged hornets attack humans when colonial nests are established in urban areas (Villemant, et al., 2006). In the particular case of Majorca, a yellow-legged hornet invasion could be devastating for the populations of honeybees, the fragility of the ecosystem (typical of the island ecosystems) and the impact on endemic insects.

The life cycle of *Vespa velutina* is annual. In optimal ambient conditions, when the temperature is high and the food resources are abundant, one founder queen will build an embryo nest (Edwards, 1980; Archer, 2010), after that the workers begin to emerge. In spring the workers build combs around the embryo nest; this is called the primary nest. The primary nest has an irregular structure with the embryo nest in the centre (Spradbery, 1973). During summer, the colony increases and the primary nest is left and another nest is built in the same location, if the conditions are favourable (food resources, temperature, humidity, etc.). If the ambient conditions are unfavourable (cold conditions and limited food resources), they build the secondary nest in a different location, normally in large trees. This new nest is named the secondary nest and is larger than the primary nest, with the objective that the colony increases. The nests of this invasive species are classified as a calyptodomus type (concealed nest) (Fig. 1), having an external spherical structure, but the combs are of a conical structure. The upper combs have large diameters and the lower ones smaller diameters, with a slight narrowing in the last comb (Jeanne, 1975). When the reproductive caste emerges in autumn, the nest is

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 375–380. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

called mature, because it is possible to separate males from females by their morphology (Choi, et al., 2012; Rome, et al., 2015). The male hornets fertilise new founder queens, after which the colony dies during the winter. Only new founder queens survive the winter and build new nests the following season and start the annual life cycle (Edwards, 1980; Matsuura & Yamane, 1990).

The yellow-legged hornet is established in the northern regions of Spain (Navarra, Basque Country, Galicia and Cantabria) (Castro & Pagola-Carte, 2010; López, et al., 2011), and in Catalonia (Pujade-Villar, et al., 2012). In 2015 it was reported in Soller (Majorca, Balearic Islands). The hornet was detected by a beekeeper and was identified by the laboratory of Zoology of the University of Balearic Islands. Together with the local authorities, an intensive survey was implemented to detect nests, as is described in Leza, et al. (2017). In 2015 only one nest of *V. velutina* was found in the north-west of the island. However, during 2016 nine more nests were found in the same region. At this moment, the invasion is in its early stages (Leza, et al., 2017), and is the first incursion on an island where eradication through locating and destroying nests can be used to control the spread; a scenario very different to mainland Europe. This immediate intervention plays an important role in the invasion or eradicating the species on the island.

Although the general structure and production of the nests of this species has been previously described in Asia (Spradbery & Kirk, 1978; Matsuura, 1991) and Europe (Rome, et al., 2011), it is important to study the nests in local conditions in order to find out if the adaptation of *V. velutina* is similar to other regions or if they would be unable to breed on the island. For this purpose, the detailed study of the nests found on Majorca (3,667 km^2, situated 176 km from the mainland) can be a useful tool to understand if this invasive species has the same biotic fitness or if they have some problems adapting in an island context. The results could help plan future surveys and possible dedicated control or eradication measures. Therefore, the study's goal was to better understand the biology of *V. velutina* in isolated conditions. For this reason, the following objectives were proposed: (I) describe the architecture and structure of nests; (II) analyse the shape of combs and develop a new method to confirm the circular pattern of breeding; (III) determine the colony size and (IV) determine the succession of workers and sexual individuals throughout the season.

MATERIAL AND METHODS

Nest collection

Nine nests were located from August to November 2016, after an active search for nests using the triangulation method (Leza, et al., 2017). All nests were entirely removed and frozenfor a minimum of 48 hours. Nests were kept frozen at -25°C until dissection.

All nests were located in the ''Serra de Tramuntana'', in the north-west of Majorca (the exact location is shown in Table 1). This region has a meso-Mediterranean climate (Emberger classification), where there is more precipitation than in other parts of the island (mean of 1,400–1,600 mm per annum) and cooler temperatures.

Architecture and structure of nests

External morphology of nests was analysed and described. Weight, height and maximum diameter of each nest was measured and the number of combs was recorded. Total weight was the result of the weight of the structure and its individuals and the total height corresponds to the height of the whole nest with the external envelope.

Shape of combs

In order to check the circular organisation of the combs described in other species of wasps (Spradbery & Kirk, 1978; Matsuura, 1991), a new method was proposed. It follows a similar methodology of comparison between two sequences of DNA (Brudno, et al., 2004). In our study the sequences were the diameters of combs and the nucleotides were the different brood stages, as follows: every developmental stage (empty cell, egg, larvae, prepupae, pupae and teneral adult) in cells across three diameters in each comb was analysed and compared with each other (the first with the second, the second with the third and the first with the third) (Figs. 2 & 3).

Each diameter comparison received an arbitrary categorisation: "2" was assigned if the stage was the same in cells at the same distance from the breeding centre, "1" if one of the stages was before or after the other stage (for example: in one diameter it is a larva and the other a

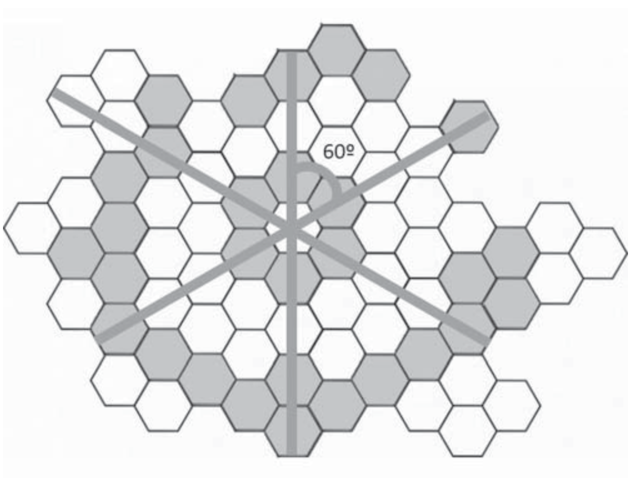

Fig. 2 Diagram of a nest comb. The grey cells represent operculated cells and the lines indicate the three diameters, which pass through the breeding centre and separated by 60º, where the stages of the individuals are determined.

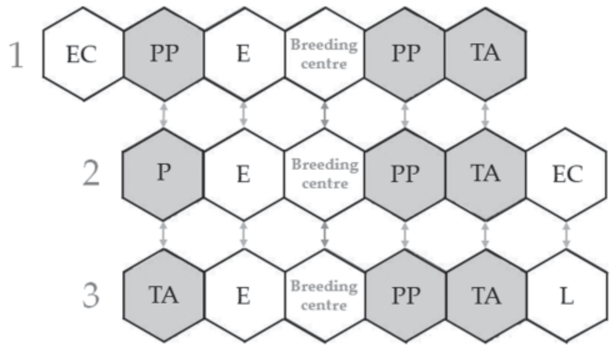

Fig. 3 Example of the three diameters, aligned in the breeding centre, and comparing the development stages at the same distance from the centre. EC = Empty cell, E = Egg, L = Larva, PP = Prepupa, P = Pupa and TA = Teneral adult.

prepupa) and "0" if it does not coincide with any of the previous cases, as long as both cells have some stage or are empty (for example: in one diameter it is an egg and the other a pupa) If one diameter had more cells than the other, those cells in a diameter that did not have their partner in the other would not receive any value. For each diameter comparison the sum of each arbitrary punctuation was divided by the number of cells multiplied by “2”, the maximum arbitrary punctuation, obtaining a coincidence percentage with the circular organisation.

Colony size

The number of cells was estimated with Latter’s formula (Latter, 1935): $N = (3n/2 + 1) \cdot n/2$, where N is the total number of cells in one comb and n is the number of cells counted across its maximum diameter. This formula was extrapolated to estimate the number of eggs, immature stages (larvae and pupae) and meconium pellets (meconium is the gut content eliminated immediately by an individual when moulting from larval to pupal instars and was recorded only as presence or absence, indicating that at least one individual had bred). The number of adults was counted manually.

The estimated total individual production of a nest was defined as the sum of the estimated number of eggs, immature stages and meconium pellets, estimated with Latter’s formula, and adults.

Pearson’s and Spearman’s rank correlations were made between the estimated individual production and the following variables: number of combs, weight, height, diameter, cells, eggs, immature stages or meconium pellets.

Sexual and caste differentiation

Females and males were distinguished by morphological differences (apex of last sternite bilobate in male but sharp in female). For females, founders and workers were distinguished based on their wet weight. Below 593.09 mg individuals can be considered as workers and individuals weighing over 593.09 mg can be considered as potential future queens. The 5% level of uncertainty was reached beyond 525.44 mg for workers and below 664.84 mg for founders. Dry and wet weights are strongly correlated (rho = 0.88, $p < 2.2 \cdot 10^{-16}$) with the following linear regression formula: $y\ (Wwet) = 2.05 \cdot (Wdry) + 80.59$ and dry and wet weights and proved to be useful to discriminate workers and queens (Rome, et al., 2015). Every female was weighed with a precision balance (ADAM NBL 423i: 420 g capacity and precision of 0.001 g).

Statistical analysis

RStudio 3.3.2 software (R core team 2016) was used for analysis. It evaluated the correlation factor and its significance differences between the nest characteristics (Kruskal - Wallis and its Dunn *post-hoc*).

RESULTS

Architecture and structure of nests

Table 1 presents the characteristics of the nine *V. velutina* nests collected from August to November 2016 in Majorca. All the nests found in Majorca analysed in this work were secondary nests (no embryo nests were found inside), presented a calyptodomus typology and had ovoid morphology.

The number of combs within nests analysed ranged from five to nine (the last one, ID9, found in November), except for one nest (ID5, found in September) that had only 2 combs. The weight varied from 136 g (ID5) to 5,090 g (2811,7±482,4), the height from 7 cm (ID5) to 49.3 cm (28.9±5.1) and the maximum diameter from 12 cm (ID5) to 38 cm (26.4±2.7) (Table 1).

Shape of combs

The lower combs had a high coincidence percentage (88.6%) with a circular organisation. However, the coincidence percentage drops in the upper combs to 62.1%. A t-test was applied to observe if the mean of coincidence percentage with a circular organisation of the two upper combs was different from the two lower combs, which produced a $p = 0.0065$, so the circular organisation is lost ascending in the combs because the percentage in upper combs was lower than lower combs (Table 2).

Also, in upper combs there is reduced individual production, in the number of eggs and larvae; lower than in the first lower comb. In lower combs there are more immature stages so the individual production moves to the lower combs. There were significant differences relating to the number of cells between combs ($p = 0.0006$), and also in individual production ($p < 0.0001$). In both cases, cells and individual production, the significant differences were for the first and second lower combs.

Colony size

The evaluation of the total number of cells in the 50 combs of the nine mature nests, using Latter’s formula, revealed that the number of cells ranged from 200 (ID5) to 9,355 (4,073.1±947.5) and the general production (which is the sum of the estimated number of eggs, immature stages, meconium pellets (estimated with Latter’s formula) and adults) varied between 304.5 (ID5) and 9,316 individuals (3,613.08±853.67) (Table 1).

Spearman’s rank correlation test showed that diameter and the general production are highly correlated (rho = 0.895, $p = 0.001$) indicating that diameter is a good parameter for estimating the colony size. The general production follows the exponential function: $y = 0.1778x^{2.8995}$, where y is the

Table 2 Values obtained after applying the arbitrary categorisation. Total = sum of coincidence values between two diameters. Max = sum of the number of paired cells multiplied by the arbitrary categorisation “2”, it corresponds to a 100% coincidence percentage with a circular organisation. Total / Max = index of coincidence to a circular arrangement of breeding.

Mean	0.886			0.684			0.582			0.547			0.621		

general production of the nest and x is the largest diameter of the nest.

Sexual and caste differentiation

Males started to appear during autumn (ID6, ID8 and ID9), except for ID7, which was removed in October and had no males (Table 1). Season starts at 21 of September in north hemisphere and males of these three nests represented 57.9% of the adults found (999 males; 1,724 females in nests ID6, ID8 and ID9). All other nests (ID1-ID5) were found and removed before the first fortnight in September, and had not produced males.

Caste differentiation was determined by weighing all individuals and a weight increase was observed over time. Individuals in the last nests collected, weighed 63 mg more than those in the first nests removed in summer. During the dissection of the nine nests, a total of 5,581 females were weighed. The 97.4% of females found in the first eight nests (ID1-ID8) were workers and only the 1.3% of the females were in the uncertainty interval. However, in the last nest found (ID9) the percentage of females in the uncertainty interval was 48.2%.

DISCUSSION

All the nests found in Majorca during 2016 had a calyptodomus typology, and the number of combs within nests analysed ranged from 5 to 9. In comparison, the general production in mature nests found in France (4,797.75±606.40) revealed that the analysed nest, under isolated conditions, had similar production. So, the nests found in Majorca presented the same morphology as those nests found in other regions of Europe (Rome, et al., 2015).

Here, we suggest that the diameter of the nest is a good parameter to estimate the colony size, and the general production follows the exponential function: $y = 0.1778x^{2.8995}$ where y is the general production of the nest and x is the largest diameter of the nest. This is interesting in order to analyse the fitness of the species, and provide an easy way to analyse it as, by taking only one measurement (the largest diameter), the potential of each nest can be estimated.

Regarding the shape of combs, we provide a new method to check the circular organisation. The lower combs had a high coincidence percentage with a circular organisation and the coincidence percentage drops in the upper combs. The loss of the circular organisation when ascending in the combs and the higher number of immature individuals (such as eggs and larvae), in the lower combs, and pupae and meconium pellets in upper combs, is due to the fact that that this species of genus *Vespa* does not clean the cells after adult emergence (Janet, 1903), limiting each cell to produce between one and four individuals (Archer, 2008). This pattern is similar to the nest structure of *V. crabro* (Nadolski, 2012). Other species of *Vespa* have a higher number of meconium pellets per cell (Yamane & Makino, 1977; Yamane, 1992; Archer, 1993; Makino & Yamane, 1997), with four as the maximum (Archer, 2011) before the queen stops laying eggs inside the combs. Moreover, some authors suggest that un-cleaned combs are the reason the offspring are found in lower combs, which are cleaner than upper combs (Janet 1895). Moreover, the nest analysed presented the lower combs with more immature stages, so the individual production moves to the lower combs, which corresponded with Martin (1991, 1992).

Regarding the sexual and caste differentiation, it is important to note that the method of caste differentiation used in this work, based on the wet weight, was not very useful in our analysis as many individuals were in the error interval, and the increase in weight of 63 mg in workers was observed in autumn. Other authors proposed alternative methods for caste differentiation, such as Perrard, et al. (2012), who used size and nerve structure of the wings to distinguish individuals. Other possible methods are by genitalia differentiation or molecular methods used for other species of Hymenoptera (Barchuk, et al., 2007). So, for future research we will use these other methodologies. The presence of males during autumn is important information for a management plan on the island as it indicates the possibility that new founder queens can mate and create new nests the following season, signifying the beginning of the expansion of the invasive species.

In conclusion, the analysis of the secondary nests of the yellow-legged hornet found in the Balearic Islands reveals the high adaptability of this species to Mediterranean isolated ecosystems, which has important implications for the development of an effective eradication plan.

ACKNOWLEDGEMENTS

The authors would like to thank members of the *Conselleria de Medi Ambient de les Illes Balears,* the *Agents de Medi Ambient* and the field technicians of COFIB for providing the nests used in this study. Thanks to three anonymous reviewers for constructive feedback on an earlier draft of this manuscript.

Methods for monitoring invertebrate response to vertebrate eradication

M. Houghton[1], A. Terauds[2] and J. Shaw[1]

[1]Centre for Biodiversity and Conservation Science, School of Biological Sciences, The University of Queensland, Brisbane, QLD 4072, Australia. <m.houghton@uq.net.au>. [2]Antarctic Conservation and Management, Australian Antarctic Division, Department of the Environment, 203 Channel Highway, Kingston, TAS 7050, Australia.

Abstract Once an island vertebrate eradication is deemed successful, it is typically assumed that ecosystem recovery will follow. To date, most post-eradication monitoring focuses on the recovery of key threatened or charismatic species, such as seabirds. Little attention has been given to monitoring and quantifying the response of invertebrate communities. Rabbits (*Oryctolagus cuniculus*), house mice (*Mus musculus*), and ship rats (*Rattus rattus*) impacted sub-Antarctic Macquarie Island for over 140 years, with wide ranging ecosystem impacts. In 2014, the eradication of rabbits and rodents was officially declared successful. To determine whether management objectives are being met, we are investigating the response of invertebrate communities to pest eradication, using both historic data and contemporary surveys to track changes over space and time. To achieve this, we have developed a survey strategy that is effective and efficient. Here we report on the merits of utilising a variety of invertebrate trapping methodologies to establish current baselines for future invertebrate monitoring. We identify sampling techniques that are most effective for specific groups of taxa, particularly those of interest to post-eradication monitoring, and how the implementation of such methods can improve and facilitate effective post-eradication monitoring of invertebrates.

Keywords: baselines, conservation, insects, island, rabbits, restoration, rodents, sub-Antarctic

INTRODUCTION

Island invertebrates are impacted by invasive species, particularly on remote, unpopulated islands in the Southern Ocean (Chown, et al., 2008; Angel, et al., 2009; St Clair, 2011: Russell, 2012; Thoresen, et al., 2017). Non-native plants and invertebrates have been unintentionally introduced to Southern Ocean Islands (SOI) (Frenot, et al., 2005; Chown, et al., 2008; Convey & Lebouvier, 2009). Non-native vertebrates have also been introduced, both intentionally and inadvertently. For example, rabbits (*Oryctolagus cuniculus*), cats (*Felis catus*), dogs (*Canis lupus familiaris*), sheep (*Ovis aries*), goats (*Capra aegagrus hircus)*, weka (*Gallirallus australis*), pigs (*Sus scrofa domesticus*), brown trout (*Salmo trutta*) and reindeer (*Rangifer tarandus*) were all intentionally introduced to SOI, whereas ship rats (*Rattus rattus*), brown rats *(Rattus norvegicus)* and house mice (*Mus musculus*), were unintentional introductions (Copson & Whinam, 2001; Courchamp, et al., 2003; Convey and Lebouvier 2009; McGeoch, et al., 2015). Grazing by non-native vertebrates on SOI has led to invertebrate habitat modification (Vogel, et al., 1984; Chapuis, et al., 2004), and direct predation by rodents has severely modified and depleted invertebrate populations (Copson, 1986; Chown & Smith, 1993; Angel, et al., 2009; St Clair, et al., 2011; Russell, 2012; Treasure, et al., 2014).

Macquarie Island (54.6208° S, 158.8556° E) lies 1,500 km south-east of Tasmania, Australia. The island is a World Heritage area managed as a Nature Reserve by the Tasmanian Parks and Wildlife Service (Copson & Whinam, 2001). Discovered in 1810, the island's early human history involved seal harvesting (elephant seals, *Mirounga leonina;* fur seals *Arctocephalus pusillus, A. forsteri, A. tropicalis*) and penguin harvesting (king penguins, *Aptenodytes patagonicus* and royal penguins, *Eudyptes schlegeli*). Many non-native species of flora and fauna were introduced during this time, both intentionally and inadvertently. Ongoing control of cats and rabbits by various methods and at varying levels of effort led to fluctuating populations (Robinson & Copson, 2014; Terauds, et al. 2014). Consequently, native fauna and vegetation were impacted by varying levels of predation and grazing (Scott & Kirkpatrick, 2008; Scott & Kirkpatrick, 2013; Bergstrom, et al., 2009; Whinam, et al., 2014). Over time, island managers have removed almost all invasive vertebrate species from Macquarie Island (Copson & Whinam, 2001), the most recent being cats in 2000 (Robinson & Copson, 2014) and rabbits and rodents in 2014 (Springer, 2016). The latter were the target of the Macquarie Island Pest Eradication programme, which was the largest multi-species project of its kind at the time, costing AU$24.5 million. The project's overall objective was to '…restore Macquarie Island biodiversity and geodiversity to a natural balance – free of the impacts of introduced pest species… [with] …vegetation, seabird and invertebrate populations recovered to levels naturally supported by the environment' (Parks and Wildlife, 2009). We developed a study to assess the success of this project for invertebrates; specifically, to better understand if they have 'recovered' following removal of mammalian herbivores and predators, using both historic data and contemporary surveys.

Invertebrates play a key role in ecosystem function (Kremen, et al., 1993; Hutcheson, et al., 1999; Gerlach, et al. 2013). They drive nutrient-cycling and decomposition processes on SOI (Smith & Steenkamp, 1990; 1992; Smith, 2007; 2008). Thus, establishing a baseline and measuring their response to ecosystem change informs the state of the island ecosystem. Many types of invertebrates are useful proxies for assessing ecosystem change, reflected in their species richness, species turnover and community composition (Kremen, et al., 1993; Hutcheson, et al., 1999; Towns, et al., 2009). Indicator taxa are particularly useful in monitoring the effects of habitat management at the ground layer (e.g. ants, millipedes, snails, ground beetles, some spiders), in foliage (e.g. ants, leaf beetles, some spiders and moths), and in open habitats (e.g. ants, crickets, grasshoppers, and butterflies) (Gerlach, et al., 2013). Moreover, their high density, short life span, ubiquity and rapid response to changing environmental conditions, make invertebrates ideal for long-term monitoring (Samways, et al., 2010; McGeoch, et al., 2011).

Despite their suitability as indicators monitoring of invertebrates post-eradication is rarely undertaken and their response to eradication is infrequently determined.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 381–388. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Developing appropriate survey methods and sampling strategies is crucial for a monitoring programme. Here we test a variety of invertebrate survey techniques and report on the merits of using specific invertebrate trapping methodologies to establish baselines for future invertebrate monitoring and to facilitate comparisons with previous surveys. Our recent surveys included most of the invertebrate trapping techniques previously employed on the island by historical surveys. Our survey design aimed to measure invertebrate response to vertebrate eradication and vegetation rehabilitation, track change in invertebrate community composition and numbers, and establish baselines for future monitoring. Specifically, our objectives in this paper, are to 1) compare the efficacy of using different invertebrate trap types in achieving monitoring objectives, 2) assess the effectiveness of historical trapping methods in informing contemporary survey design, and 3) investigate the benefits and limitations of using historical data for tracking changes over time. We also discuss how choosing appropriate methods is a key process for effective and efficient post-eradication monitoring of invertebrates.

METHODS

Survey design

Determining invertebrate community changes over time requires definitive and repeatable methods and detailed site information. Our experimental design (i.e. our choice of survey/trapping techniques and site selection) was informed by analysing invertebrate trapping experimental designs, methods and results from historical surveys on Macquarie Island. Following a thorough review of the scientific literature five key resources were selected to inform our experimental trapping design and methods: Watson (1967), Greenslade (1987), Anonymous (1993–94, reported in Stevens, et al., 2010), Davies & Melbourne (1999), and Stevens, et al., (2010). Each of these historical surveys utilised different combinations of methods (Table 1). Based on this information, the following survey methods were tested in our study: pitfall traps, sweep netting, litter extraction, and timed hand collecting (referred to as '20-minute counts').

Site selection

For this study, sampling was carried out at ten historic and ten new sites (Fig. 1). This provided 20 sites in total for the 2015/16 post-eradication survey. The ten new sites were selected to ensure broader island coverage and survey additional vegetation communities across the five dominant vegetation structures on Macquarie Island (based on Selkirk, et al., 1990) – feldmark (plateau), lower coastal slopes dominated by *Stilbocarpa polaris* (Macquarie Island cabbage), tall grassland (tussock) dominated by *Poa foliosa*, short grasslands (including *Deschampsia* spp., *Festuca contracta, Agrostis magellanica, Luzula crinita, Uncinia* spp.), and herbfield dominated by *Pleurophyllum hookerii*. Most sites were heavily impacted by rabbits in the past (Bergstrom, et al., 2009; Whinam, et al., 2014). In total, four *Stilbocarpa polaris* sites were surveyed in 2015/16, three short grassland sites, five tall grass sites, four herbfield sites, and four feldmark sites.

Sampling techniques

Five pitfall traps were established at each of the 20 sites, in a line transect along a recorded bearing, five metres apart. Expert advice from the Tasmanian Department of Primary Industries, Parks, Water and the Environment (M. Driessen, pers. comm.), informed the pitfall trap preparation, spacing, pattern of positioning, and preservative used. Pitfall traps were constructed of straight sided, plastic jars 7 cm in diameter, approximately 7 cm deep, with ca. 1 cm of 100% propylene glycol preservative added. Pitfall diameter was selected based on other studies

Table 1 Trapping methodology employed during invertebrate sampling studies on Macquarie Island – Watson in 1961 (reported in Watson, 1967), Greenslade in 1986–87 (reported in Greenslade, 1987), Anonymous in 1993–94 (reported in Stevens, et al., 2010), Davies and Melbourne in 1996 (reported in Davies & Melbourne, 1999), Stevens, et al., in 2009–10 (reported in Stevens, et al., 2010).

that have proven the effectiveness of larger trap sizes (Brennan, et al., 1999; Ward, et al., 2001; Work, et al., 2002; Woodcock, 2005). Propylene glycol was chosen a preservative due to it being environmentally benign, highly viscous and slow to evaporate. Pitfall trap holes were dug with a soil corer to ensure a snug fit and the pitfall rim was flush with the ground surface. Where necessary, a small amount of vegetation was cleared from the trap rim. At the 20 sites, pitfall traps were collected approximately every 10 days between October and December and reset upon collection for a total period of up to ca. 42 days. Further pitfall sampling was repeated monthly in January, February and March for approximately 5–10 days at eight sites.

For litter sampling, at each site, a 1m² quadrat was used to define the collection area, and three collections were made of one litre of litter at each site. Litter was transported back to the station laboratory for sorting and invertebrate extraction within a maximum of three days from collection. In feldmark sites where litter was scarce, litter collection was over 4 m² and up to 1 litre of material – the exact area and volume was recorded.

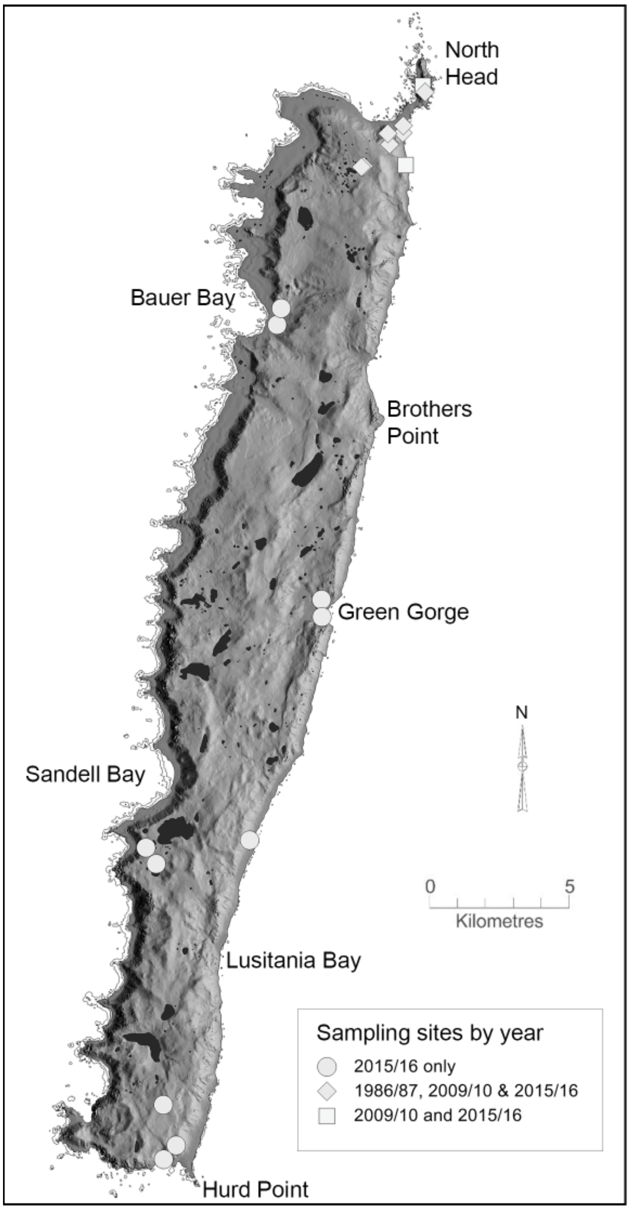

Fig. 1 Map of 20 invertebrate trapping sites surveyed at Macquarie Island in 2015/16. All historic sites sampled in 1986/87 (indicated by grey diamonds) were resampled in 2015/16.

Timed counts of 20 minutes were conducted at least twice over the study period at each site, involving focussed searching with an aspirator tube and tweezers, collecting all invertebrates encountered, particularly at the base of vegetation and under stones.

Sweeping of vegetation tops with nets required dry conditions with light winds. Hence, sweeping was conducted opportunistically, at a minimum of twice at each site over the study period, in all vegetation types regardless of the canopy (i.e. also in feldmark), by walking slowly and dragging the net across the vegetation tops 30 times, on three different trajectories in the site area per sampling event.

One temperature logger i-button was installed at each of the 20 sites to monitor microclimate, at the first pitfall trap of each transect. They were attached approximately 10 cm above the ground surface on a stake with a protective housing. At each site, site-specific features such as aspect, altitude, landscape features, vertebrate fauna presence and vegetation were noted.

Processing and identification

All samples were transferred promptly to 100% ethanol and transported back to the Australian Antarctic Division for identification and storage. Using a dissecting microscope, specimens were counted and identified to species where possible, except for Acarina, Annelida, and Nematoda, which were identified to Class or Phylum level.

Data analysis

We undertook preliminary comparisons of the 2015/16 survey data on Order richness and diversity with data from historical sites established in 1986/87 (Greenslade, 1987). We calculated taxonomic richness and diversity of invertebrates in different trap types, vegetation groups and in historical data. For these purposes we pooled data from different sites to obtain the total number of taxa trapped in different trap types and vegetation groups. Invertebrate richness was calculated by summing the total number of invertebrate Orders recorded in the trap type or vegetation group of interest. Simpson's Index of Diversity (SID) was selected to compare diversity, as it takes into account both abundance and richness in each habitat. We compared the Order richness and diversity of our pitfall traps to seven historical sites and also quantified changes in abundance for three target groups (beetles, spiders and moths), using a subset of the historic and contemporary pitfall data.

We analysed data at the level of Order/Class/Phylum (hereafter referred to as 'Order') to facilitate preliminary comparison with historic data sorted to Order resolution. For analysis, larval stages and adults were grouped together for Lepidoptera, Thysanoptera, Coleoptera and Diptera.

RESULTS

Contemporary survey

Our preliminary results from the 2015/16 survey demonstrated that pitfall traps collect the largest number of individuals – in particular, Collembola (Table 2). Even when Collembola were removed from the analysis, pitfalls still collected more individuals than other trapping methods. Despite the abundance of invertebrates in pitfalls, there was considerable variance in the nature and abundance of taxa caught by the different trapping methods, with some methods proving more effective for specific taxa than others (Table 2).

Richness (number of different orders caught) and diversity (SID – richness combined with the relative

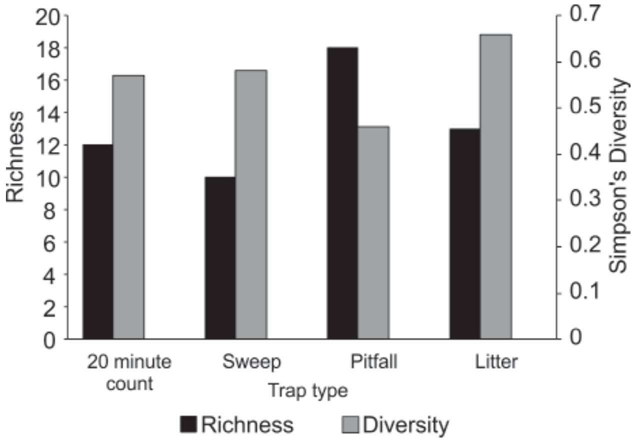

Fig. 2 Order richness (summed across 20 sites) and Simpson's diversity of four different trapping methods on Macquarie Island in 2015/16 following mammal eradication.

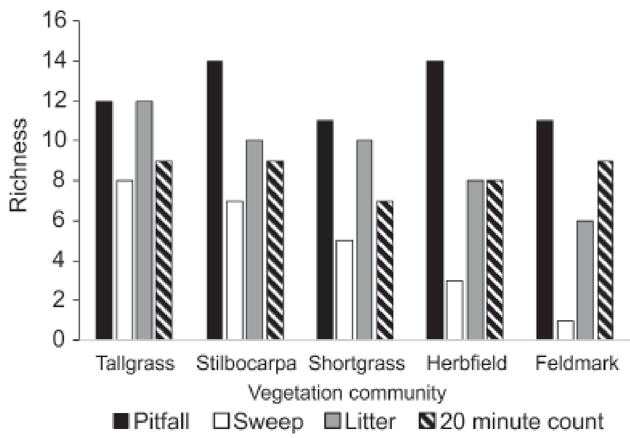

Fig. 3 Order richness (summed across 20 sites) of four trapping types in five vegetation communities on Macquarie Island in 2015/16 following mammal eradication.

abundance of the different orders caught) varied between trapping methods (Fig. 2). The SID demonstrated that although pitfalls traps yielded the greatest richness, they also had the lowest diversity, attributable largely to the dominance of Collembola. Conversely, sweeping had relatively low species richness but high SID, an indication of the greater relative abundance of different taxa trapped.

Pitfalls collected the most species regardless of habitat type (Table 2, Fig. 3). Effectiveness of the other trap types varied by vegetation community (Fig. 3). Sweeping vegetation was far more effective in tall grassland and *S. polaris*, which are often characterised by dense protective foliage, than for herbfield and feldmark vegetation, which typically have more prostrate, sparsely distributed plants. Litter collection also yielded high relative Order richness, particularly in tall grassland and short grassland vegetation communities. Twenty-minute counts were effective in feldmark, where richness was proportional to effort. The low number of taxa in this habitat were found more readily through this method of focused searching (disturbing stones and turf), than via passive pitfall trapping or surface litter collection.

The SID of pitfall trap samples across vegetation types was almost the inverse of their richness (Fig. 4). Across all vegetation types (except for feldmark), pitfall trapping diversity was much lower than for other trap types; a likely reflection of the dominance of the Collembola in pitfall traps except in feldmark. For short grassland, litter sampling proved to be exceptionally diverse. Interestingly, although taxonomic richness of sweeping in herbfield was relatively low, SID was high. Across all vegetation types, 20-minute counts were almost equal in diversity.

Table 2 The number of individuals from each Order of invertebrates collected via four different trapping methods on Macquarie Island following mammal eradication: pitfall traps, sweeping, 20-minute counts, and litter collection in the 2015/16 season following mammal eradication.

Order	Common Name	Pitfalls	Sweep	20 minute count	Litter
Gastropoda	Snails/slugs	935	2	1,294	1,019
Psocoptera	Booklouse	44	2	0	129
Hemiptera	Aphids/Bugs	3	0	0	0
Thysanoptera	Thrips	144	21	4	4
Coleoptera	Beetles	2,512	2	12	240
Diptera	Flies	945	61	51	61
Lepidoptera	Moths	3	0	4	8
Hymenoptera	Wasps	1	0	0	0
Isopoda	Crustacea	209	1	207	636
Araneae	Spiders	2,467	40	169	380
Platyhelminthes	Flatworms	20	0	1	1
Annelida	Worms	284	3	493	1,489
Copepoda	Copepods	3,615	0	2	8
Tardigrada	Tardigrades	69	0	0	0
Acarina	Mites	5,219	40	108	340
Siphonaptera	Fleas	1	0	0	1
Nematoda	Nematodes	19	0	0	0
Collembola	Springtails	43,641	277	3,609	5,040
	TOTAL	60,131	449	5,954	9,356

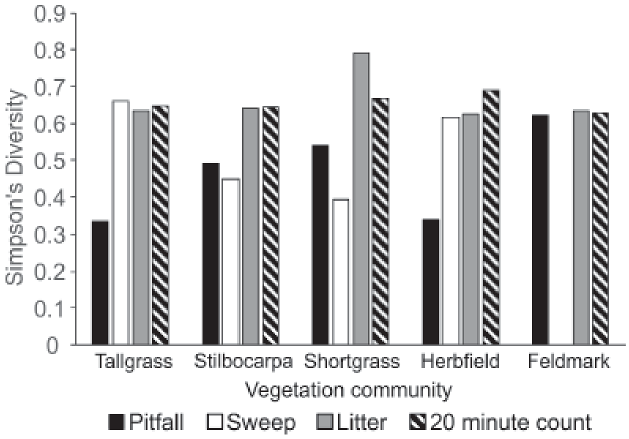

Fig. 4 Simpson's Index of Diversity (Order) of four trap types in five vegetation communities on Macquarie Island in 2015/16 following mammal eradication.

Comparisons with historical surveys

Preliminary comparisons of our data on Order richness and diversity data from the 1986/87 sites (Fig. 5) indicate considerable changes in invertebrate communities since the earlier surveys. Both Order richness and SID were generally lower during the earlier sampling period compared to 2015/16, with the exception of the feldmark F2 site, where 1986/87 samples were more speciose and more diverse. Diversity in the tall grassland site P2 and herbfield H1 were also lower in 2015/16 sampling, though richness was much higher.

Mouse prey species that were predicted to respond favourably to mouse removal, such as Coleoptera (beetles), Lepidoptera (moths) and spiders (Araneae), were trapped via pitfalls in 1986/87 and again in 2015/16 at seven sites across five vegetation types (Table 3). Coleoptera abundance was inconsistently higher in 1986/87, whereas Araneae were trapped in much higher numbers during the 2015/16 sampling. Lepidoptera were rarely trapped in both sampling events, present only in the feldmark F2 site.

DISCUSSION

When monitoring ecosystem responses following an eradication, it is critical to first identify the objectives of the management intervention. In this case, the facilitation of the "recovery" of macro-invertebrates on Macquarie Island was explicit. However, no mechanisms were put in place to assess the success (or otherwise) of this objective. Here, our preliminary study tackles the issue of how to effectively survey a suite of invertebrate species on a Southern Ocean island to detect recovery and response of invertebrates after an eradication event, and informs the selection of appropriate survey methods for specific species.

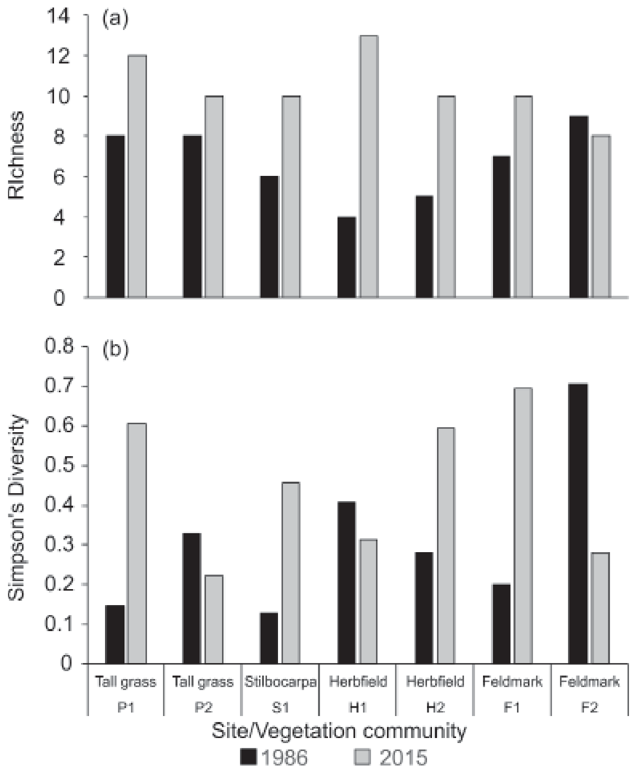

Fig. 5 (a) Order richness (summed across 20 sites) and, (b) Simpson's Index of Diversity of pitfall trapping (Order level) at seven invertebrate monitoring sites at Macquarie Island that were first sampled in 1986/87 (prior to mammal eradication) and repeat sampled in 2015/16 (post mammal eradication).

One of the clearest findings of our study was that pitfall traps collect the greatest abundance and richness of invertebrates, particularly Collembola, although they were the least diverse. Despite the difficulties in comparing abundance and sampling effort across different techniques (for example, the longer deployment time of pitfall traps compared to other trapping techniques), it is apparent that different trapping methods are more effective at capturing certain taxonomic groups. This is based on the functional traits, behaviours and preferred habitats of different taxa. For example, Psocoptera were primarily collected from litter samples, as they are detritivores with a preference for damp conditions under vegetation (Greenslade, 2006). However, some were also collected during vegetation sweeping, where they occur in smaller numbers under leaves (Greenslade, 2006). Tardigrades and Copepods

Table 3 Abundance of Coleoptera, Lepidoptera and Araneae in pitfall traps sampled at seven sites at Macquarie Island in 1986/87 (prior to mammal eradication) and 2015/16 (post- mammal eradication).

		Coleoptera		Lepidoptera		Araneae	
		1986/87	2015/16	1986/87	2015/16	1986/87	2015/16
P1	Tall grass	25	1,909	0	0	151	124
P2	Tall grass	19	7	0	0	105	280
S1	*Stilbocarpa*	2,426	277	0	0	84	175
H1	Herbfield	8	6	0	0	27	123
H2	Herbfield	2	1	0	0	42	191
F1	Feldmark	4	3	0	0	8	120
F2	Feldmark	4	0	1	4	28	127

were collected principally via pitfall traps, most likely due their existence in soil or at the soil surface, particularly in moist sites. Their small size makes them unlikely to be detected through other trapping means. Cosmopolitan groups like Coleoptera, Collembola and Acarina were detected by all trapping methods. For the Collembola, their ubiquity in many samples exemplified their abundance and diversity on the island, with 35 species recorded (Phillips, et al., 2017). They also occur in a variety of habitats, from soil-dwellers to canopy species (Greenslade, 2006; Terauds, et al., 2011). Similarly, the collection of predatory Staphylinidae coleopterans across all trapping methods suggests this group are wide-ranging across vegetation, possibly to maximise opportunities to encounter prey. Isopoda, Annelidae and Platyhelminthes were collected by all means except sweeping (with a few exceptions), in line with their cryptic habits under vegetation, close to the soil surface and in litter (Greenslade, 2006).

Knowledge of the target group is critical to inform the experimental design of trapping. For example, and perhaps counter-intuitively, sweeping did not yield high numbers of moths or flies. One reason may be that many resident flies on Macquarie Island are flightless and largely stay close to the ground (Greenslade 2006). Furthermore, the endemic moth *Eudonia mawsoni*, which is not nocturnal, is known to drop to the ground when dislodged from vegetation (i.e. by sweep nets) (Jackson, 1995), and often stays close to the ground, taking shelter in winds over 10 km/hr (Greenslade, 2006). Sweeping can only occur during low wind conditions, however winds are typically high on the island (Pendlebury & Barnes-Keoghan, 2007), dispersing many taxa (both flightless and flying) (Hawes & Greenslade, 2013). The moth's flight is stimulated by rain, however sweeping is not possible during rains as wet vegetation renders the sweep net ineffective. Such background understanding of target taxa and the environment informs the design and interpretation of trapping surveys.

If the monitoring or management objectives focus on a particular group or species it is important to consider the varying effectiveness of trapping methods (Zou, et al., 2012). For example, mice on SOI prey mainly on invertebrates, especially spiders, moths, beetles, aphids, Orthoptera (e.g. crickets), snails and earthworms (Copson, 1986; Crafford & Sholtz, 1987; Rowe-Rowe, et al., 1989; Le Roux, et al., 2002; Jones, et al., 2003; Angel, et al., 2009; St Clair 2011; Russell, 2012). Copson (1986) identified that mice on Macquarie Island had a particular preference for spiders (67% of 108 mouse stomach contents), caterpillars of the endemic moth *E. mawsoni* and, to a lesser extent, other invertebrates such as beetles and dipteran larvae. Therefore, increases in these taxa following mouse eradication and the removal of predation pressure could be anticipated. Our preliminary comparisons provided some support for this hypothesis (see below). To measure the response of invertebrates preyed upon by mice on Macquarie Island, our results indicate that pitfall trapping is effective for spiders and beetles and is therefore the most efficient mechanism for assessing their recovery. Monitoring of moths will require greater consideration and ongoing effort, as they were not detected in high numbers by any trapping method during the 2015/16 season.

Comparisons to historic datasets are vital to detect responses to eradication. It is important to consider there may be different responses and recovery times in different species. Again, although our comparative analyses are only preliminary, they do show a higher abundance of spiders in pitfalls in 2015/16 compared with 1986/87 pitfalls, across all sites. There is a high likelihood that this is related to the eradication of mice, given spiders were a major prey item (Copson, 1986). However, beetle abundance did not change consistently between the two trapping events, with numbers trapped varying across sites and between years (Table 3). One possible reason is that Staphylinidae beetles (which comprised all of the beetles caught) can occur in dense numbers where rich detritus or rotting material is present on coastal terraces in vegetation (Greenslade 2006). As a result, they can be very abundant in an individual sample from one event, and then absent in others at the same site. Vegetation recovery is slow, and therefore, if beetle abundance is driven by vegetation, there will be a delay in beetle response to rabbit eradication.

For the moth *E. mawsoni*, despite anecdotal reports of increased abundance across the island, our preliminary data do not show this. The moth pitfall counts were similar in 1986/87 and 2015/16, with adults rarely trapped, which is consistent with other studies on Macquarie Island (Jackson, 1995; Potts, 1997; Stevens, et al., 2010; Hawes & Greenslade, 2013). The low number of adults in our data could be due to the timing of our sampling regime, i.e. our trapping effort was low in late December and early January – the time when adults are most abundant and active (Watson, 1967). Davies & Melbourne (1999) captured many adults using yellow pan traps. With this knowledge, we have added this method to our trapping regime for future seasons of the invertebrate monitoring project to identify change. We also extended our future sampling to occur later in the summer, between January–March, to identify seasonal changes in species, improve likelihood of encountering different species, and improve chances of detecting different life stages in species (such as the moths and moth larvae). Species life history must be considered when designing trapping to inform responses to management.

Terrestrial invertebrate communities that are dependent on or restricted to specific vegetation or habitat types are hypothesised to be most likely to be impacted by rabbit grazing on Macquarie Island (Parks and Wildlife, 2009). Vegetation has undergone considerable changes between 1986/87 and 2015/16 (Copson & Whinam, 1998; Bergstrom, et al., 2009; Shaw, et al., 2011). Our preliminary results highlight the potential utility of historical data, when combined with targeted and appropriate sampling techniques, to explore the relationship between vegetation and invertebrates. Overall, there appears to be an increase in richness and diversity from 1986/87 to 2015/16. During the period of the initial sampling in 1986/87, rabbit numbers and the commensurate vegetation damage were relatively high (Terauds, et al., 2014), which may explain the low numbers of vegetation-dependant invertebrates. Herbfields were favoured by rabbits and heavily impacted by grazing (Scott, 1988; Selkirk, et al., 1990; Copson & Whinam, 1998). Herbfield invertebrate communities were particularly low in richness and diversity in 1986/87. Feldmark communities vary little between 1986/87 and 2015/16, most likely as rabbit impacts were low in this high-altitude vegetation group (Copson & Whinam, 1998).

Another important consideration of these comparisons is that the historical survey data we accessed were generally based on higher taxonomic groupings, which may impact our ability to detect subtle changes in invertebrate communities over time (e.g. Grimbacher, et al., 2008). Higher taxonomic groupings, unsurprisingly, do not necessarily reflect the finer details of invertebrate community assemblages, nor nuanced changes in their structure and responses (Grimbacher, et al., 2008; Driessen & Kirkpatrick, 2017) and may aggregate species that have different ecological or functional traits and responses to disturbance (Lenat & Resh, 2001; Heino & Soininen, 2007; Schipper, et al., 2010). A limitation of using historical datasets is that often clarification and further detail is simply not available.

Identification of specimens to fine taxonomic resolution, such as to species level, takes considerable time. Although we focussed on higher-level taxa here, our forthcoming analyses at finer taxonomic resolution, (such as to family, genus and for some groups, species) will provide further insights on trapping efficacy, survey design and most importantly, invertebrate community changes over time. However, there is also good evidence to suggest that higher-level identification can be appropriate surrogates for species and effective for detecting major disturbance events on invertebrate community structure, particularly where there are significant environmental perturbations or gradients (Driessen & Włodarska-Kowalczuk & Kędra, 2007; Bevilacqua, et al., 2012; Kirkpatrick, 2017). Sorting samples to higher taxonomic resolution is often more practical and cost-effective as it requires less training and maximises the potential for swift sample processing (Driessen & Kirkpatrick, 2017). The selected taxonomic resolution must be balanced between available resources and the value of results – the decision ultimately depending on the study objectives (Driessen & Kirkpatrick, 2017). It is fundamentally important to decide at the outset which invertebrate taxa, (if not all of them), are the focus of the monitoring, and what taxonomic resolution will best meet the objectives of the monitoring. For example, the varying ranges and habitat associations of the five Staphylinidae beetle species on Macquarie Island are not represented when grouped to the Coleoptera order in our data. A second example is the ubiquitous and numerous Collembola (springtails), that when aggregated to Order, fail to highlight the very different species trapped by each medium, such as those that were trapped via sweeping which inhabit the canopy, foliage and flowers in vegetation, and those edaphic groups trapped via pitfalls that either inhabit the soil or live close to the surface. Such details are important to our Macquarie Island monitoring objectives as we assess invertebrate communities in recovering vegetation.

The availability of historical data greatly enhances the power of long-term effective monitoring. In this instance, considerable time was invested in tracking down historical datasets and their metadata. Our future work will include in-depth analysis of contemporary survey results in relation to a broader suite of historical data. Whether historical data are available at the outset or not, establishing a baseline from which to measure changes into the future is critical for long-term monitoring, for making informed management decisions, and assessing management success. Our preliminary results demonstrate that invertebrate monitoring in a post-vertebrate eradication ecosystem can yield important and promising results. Effective monitoring for invertebrates also leads to improved surveillance for non-native species arrivals and potential non-native species impacts. Our future work includes the collection of two additional years of invertebrate surveys (2016/17 and 2018) across Macquarie Island and the establishment of four additional invertebrate monitoring sites to improve island and vegetation community coverage. We will also employ additional trapping methods (vegetation beating and yellow-pan trapping), and use Berlese funnels in the 2016/17 and 2018 surveys for more efficient litter processing. These improvements combined, will further develop baseline knowledge of invertebrate communities on Macquarie Island and inform future monitoring. This work will provide a comprehensive snapshot of ecosystem function and recovery following vertebrate eradication. We will use these results to develop and propose an efficient means of invertebrate monitoring using specific taxa or groups as biological indicators of broader ecosystem changes, to enable robust and efficient monitoring into the future.

ACKNOWLEDGEMENTS

We thank Michael Driessen for input to research design and analyses. We thank Jasmine Lee for helpful comments on the draft manuscript. We are grateful for the helpful advice and comments given by two anonymous reviewers. We thank Kimberley Mitchell, Marcus Salton, George Brettingham-Moore, Rowena Hannaford, Jacqueline Comery and Penelope Pascoe for their assistance in the field with invertebrate trapping. We thank the Australian Antarctic Division for logistic support and the Tasmanian Parks and Wildlife Service for granting access to the island and permits to collect invertebrates (this work under Scientific Permit FA15234). This study was supported by funding from the Australian Government's National Environmental Science Programme through the Threatened Species Recovery Hub and the Australian Antarctic Science program (AAS 4305).

Introduction of biological control agents against the European earwig (*Forficula auricularia*) on the Falkland Islands

N. Maczey[1], D. Moore[1], P. González-Moreno[1] and N. Rendell[2]

[1]CABI, Bakeham Lane, Egham, Surrey, TW20 9TY, UK. <n.maczey@cabi.org>. [2]Falkland Islands Government, Environmental Planning Department, P.O. Box 611, Stanley, Falkland Islands.

Abstract The Falkland Islands (FI), as with many island ecosystems, is vulnerable to invasive species, which can cause wide ranging social and environmental consequences. Control of invasive species is widely recognised as a priority, but there have never been attempts to use classical biological control (CBC) for this purpose in FI. The European earwig was recently introduced to the FI and has since become abundant in the Stanley area and some other settlements on the islands. Earwigs now cause considerable damage to garden crops and also pose a number of health hazards. There are also concerns that earwigs have started to spread into grasslands and irreversibly alter this important native ecosystem. After extensive stakeholder consultations it was decided to use the invasive earwigs as a case study for the introduction of CBC to the FI. Based on previous work on earwig control, supplemented by additional host range testing, two tachinid flies, *Triarthria setipennis* and *Ocytata pallipes*, were selected as the most suitable control agents for the Falkland Islands. Extensive awareness raising activities, focusing on the threat of invasive species, benefits and risks of CBC, secured the support of the wider public to go ahead with the release of both control agents during 2015 and 2016. Major challenges encountered during the release process were the need to install makeshift quarantine facilities and the switchover of the life-cycle of both control agents to southern hemisphere seasons.

Keywords: awareness raising, invasive species, *Ocytata pallipes*, tachinid flies, *Triarthria setipennis,* UK Overseas Territories

INTRODUCTION

The European earwig, (*Forficula auricularia*, Order Dermaptera) is widely regarded as a beneficial predator of insect pests in fruit orchards within its native range of Europe and West Asia (Nicholas, et al., 2005; Dib, et al., 2010), however outside this range there are reports that this species can cause significant agricultural problems (Kuhlmann, et al., 2001). In 1997/1998 the European earwig was reliably recorded for the first time in the Falkland Islands (FI), an archipelago in the South Atlantic Ocean, around 500 km off the southern Patagonian coast of South America. Since then the earwig has become a significant pest on the islands causing damage to garden and greenhouse plants and leading to a halt in the production of a number of commercial crops (Maczey, et al., 2012). The earwigs are also posing a number of health hazards, particularly in autumn (March/April) when they invade buildings in large numbers. They have been found in asthma inhalers and beneath the seals of oxygen masks causing the local hospital to introduce additional safety procedures checking equipment for the presence of earwigs prior to use. Many households currently spend substantial amounts of money to control earwigs primarily by having the foundations of their houses sprayed with pesticides once or twice a year. Since its introduction the earwig has become common in the Stanley area and a number of settlements in the wider countryside. There is also concern they may spread into native grasslands, with a risk of irreversibly altering the indigenous ecosystem posing a particular threat to a high number of endemic arthropods (Maczey, et al., 2012).

Classical biological control (CBC) has the potential to offer effective, economic and sustainable control of this invasive species. This method involves the deliberate release of specialist natural enemies – mainly insects and fungi – from the invasive's native range. The aim is to reduce the abundance of problem species in its introduced range below an ecological or economic threshold. The European earwig is a promising target species for CBC on the FI, particularly as chemical sprays are ineffective, and because of its great mobility (Santini & Caroli, 1992). Off the shelf solutions using parasitoid tachinid flies from Europe, including Great Britain, are feasible. One such species *Triarthria setipennis* has established successfully in British Columbia and Newfoundland where studies have indicated a considerable reduction in earwig numbers, most probably due to high levels of parasitism in the mid-1970s (Morris, 1984). However, since 1978, no further evaluation of parasitoid impact has been undertaken. A second species of parasitoid, *Ocytata pallipes*, was introduced into Canada to control the European earwig during the 1990s but no monitoring took place and establishment is unknown (Kuhlman, et al., 2001). *Ocytata pallipes* and *T. setipennis* have also been introduced into the USA as early as the 1920s (Oregon) and also into New Zealand (Kuhlman, et al., 2001). Again, little is known about the success of these releases.

During a workshop in Stanley in March 2012 there was consensus on the feasibility of biological control of invasive non-native species on the South Atlantic UK Overseas Territories and that the European earwig would be a target well suited for CBC in the FI. Experts working on invasive species on the FI and also members of the general public saw an urgent need for sustainable control of this species. Equally, the Government of South Georgia saw this as an opportunity to reduce the risk of future introductions of earwigs to South Georgia. The Falkland Island Government (FIG) therefore decided to commission a host range testing programme to assess the safety and suitability of two parasitoid flies, believed to be host specific to the European earwig, for introduction into the FI (Maczey, et al., 2016).

No native earwig species inhabit the FI, therefore host range tests were conducted on insect species (crickets and cockroaches) representing insect orders which are closely related to earwigs. The Falklands have one native species of cricket, the camel cricket (*Parudenus falklandicus*). The results showed that there was no indication that either of the two assessed fly species (*O. pallipes* and *T. setipennis*) can develop or otherwise impact on the viability of any of the test species, even when artificially forced to ingest parasitoid eggs or inoculated with fly larvae, which would rarely happen under natural conditions (Maczey, et al., 2016). The tests confirmed our opinion that there would be

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 389–393. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

no risks to non-target species if one or both of these highly earwig-specific tachinid fly species were released on the FI (Maczey, et al., 2016).

Based on the results from the host range testing, the Environmental Committee and Executive Council of the FIG decided to go ahead with the release of both agents, provided there was sufficient support from the wider public. Up until this point stakeholder acceptance for the introduction of a new species into the FI had not been assessed and the Environmental Committee decided to conduct a range of awareness raising activities to encourage residents to voice their concerns and engage in open discussion on the safety and scope of CBC of earwigs. This paper covers both the outcomes of the awareness raising activities and the results of the subsequent release of the control agents conducted between 2015 and 2017.

MATERIALS AND METHODS

Stakeholder consultation

We wanted to engage with the residents of the FI to understand whether biological control, in general, and the release of two parasitoid fly species, in particular, was of any concern or would be largely welcomed by the general public and/or experts and scientists working in conservation or agriculture on the FI.

At the core of all consultations with stakeholders we communicated four major premises:

- The release of the control agents is safe and does not pose any risks for native species, human health or food production, in contrast to the current use of large quantities of a highly toxic pesticide (Demand® CS).
- Costs for release would largely be covered through secured funding from Defra (Darwin Initiative).
- Although we saw no major hurdles for a successful establishment of both fly species, establishment can never be guaranteed, and this could be a reason for failure.
- Equally, if successful establishment has taken place, the amount of control exerted by the released agents is difficult to predict. Although in the absence of hyperparasitoids (in this case parasitic wasps known to develop inside the pupal stage of the tachinid flies) the likelihood for a good control is high, this is something which cannot be predicted with absolute certainty.

Stakeholder consultation regarding the biological control of earwigs focused on three main steps:

Providing initial background information

Information explaining the principles of biological control and the safety testing of the proposed control agents, including a 'frequently answered questions' (FAQ) section, was made available on the FIG website. In addition, a two-page flyer providing information on our work was distributed throughout Stanley prior to any public events.

Advertising opportunities to get more detailed information and voice any concerns

Website and flyer announcements were made of the dates for presentations and opportunities for open discussions. The documents also gave contact e-mails to arrange meetings or discussions outside these dates or to voice any concerns via e-mail. Times and locations for all events were also broadcasted by radio and announced in the local newspaper. An invitation to add to the FAQ was also given on the website. Presentations given – one broadcasted by local TV – also included invitations to forward any questions or concerns to the project team.

To present CABI's work on earwig control and engage with the public

Aside from the widely advertised events, discussions with residents took place on many other occasions. These included meetings with pest controllers, members of the legislative assembly (MLAs), scientists from government departments and NGOs, teachers, commercial growers and farmers. Discussions continued after FIG was confident enough that it would have the backing of the public for the release of the control agents throughout the length of the project and also included direct demonstrations of the activities at the release facilities.

Release programme

In the native range, rates of parasitism by *T. setipennis* and *O. pallipes* vary considerably between meta-populations of earwigs, and large numbers of the host need to be collected to obtain sufficient parasitoids for release and establishment. There are no estimates of how many individuals need to be released to achieve the formation of a parasitoid population in a new environment, but as a general rule the more individuals are released the better the chances are for establishment.

Trapping of earwigs took place in orchards in England during 2015 and 2016. Sites selected for collecting focused on locations combining ease of access with high numbers of specimens, both of earwigs and parasitoids likely to be obtained. Trapping involved installing flowerpots, 10 x 10 x 17 cm, filled with egg cartons, into trees 1 to 2 m above ground. Distribution of traps and the collecting regime are given in Table 1. Earwigs were collected at roughly monthly intervals three times per year.

Collected earwigs were kept in 40l plastic containers, housing no more than an estimated 2,500 earwigs per container. Egg cartons were used to provide hiding places and lids were fitted with netted openings to give sufficient aeration. The edges of containers were covered with

Fluon® to prevent earwigs escaping. Food consisted of a mixture of vegetables (lettuce and carrots) and dry dog food applied three times a week. The earwigs were kept for a period of six to eight weeks and, afterwards, when the majority of parasitoid larvae had left their hosts, were released back at the trapping sites.

Earwig cultures in the lab were checked for parasitoid pupae three times a week. Pupae were separated to species and stored in glass tubes sealed with a mesh cover to allow aeration whilst preventing any potential hyperparasitoids from escaping (Fig. 1). The tubes were then placed inside a larger plastic container with a meshed opening to allow for aeration. Inside this plastic container moistened tissue facilitated high humidity to prevent desiccation of the pupae.

In 2015 all pupae were stored at 16˚C until mid-September, afterwards *O. pallipes* at 12˚C and *T. setipennis* at 8–10˚C until their shipment to Stanley in November 2015. In 2016, pupae of *O. pallipes* were stored at 10–12˚C. At this temperature hatching was delayed long enough to allow two separate shipments to Stanley in August and September. Pupae of *T. setipennis*, which hibernates in this stage, were stored at room temperature (18–20˚C) to mimic natural conditions. From October onwards, the pupae of *T. setipennis* were kept at 10˚C to simulate more natural overwintering conditions.

On arrival at Stanley, sealed storage boxes containing vials with pupae were stored in a specifically developed quarantine shed (details provided at: <http://www.darwininitiative.org.uk/project/DPLUS033/>) and kept at 20˚C to trigger hatching. Quarantine facilities were used as a safety precaution in case hyperparasitoids had contaminated the fly cultures. Hatched flies were transferred into rearing tents located in a polytunnel on a daily basis. *O. pallipes* were kept there for mating and depositing of micro-eggs on carrot pieces previously exposed to earwigs, so that they had obtained the scent of the host species. The carrot pieces contaminated with fly eggs were then fed to locally collected earwigs. After inspection confirmed that most fly eggs had been ingested by earwigs, these were released at sheltered locations in Stanley with high densities of earwigs. Adult flies of *T. setipennis* were kept only 4–5 days in rearing tents, to allow mating, after which they were released at sheltered locations with high host densities.

Fig. 1 Pupae of *T. setipennis* inside their storage containers.

RESULTS

Stakeholder consultation

Attendance of public events varied from only three visitors on one occasion to up to 30 visitors during the demonstration of the release facilities. Feedback after presentations centred on the safety of CBC. Most frequent questions were: whether the release control agents could replace one nuisance species with a second one; or what the flies would feed on once earwigs went down in numbers. Our impression was that within the attending audience it was relatively straightforward to dispel such concerns by explaining in more detail the host specificity and dependence of the control agents on host density levels and that CBC will not lead to complete eradication of the target species.

People were relieved when seeing the small size of pinned specimens of the agents passed around, having expected something much larger. Worries about flies invading buildings could be dispelled by pointing out that these species, in contrast to house flies and other species, will not actively be attracted to houses. Some gardeners worried that eggs or larvae of the biological control flies would end up on vegetables; although not being a health hazard in any way this was seen as unpleasant. The answer to this was that the flies will deposit eggs and larvae only on items already smelling strongly of earwigs and in the case of food items these would be already heavily damaged crops beyond consideration for human consumption.

Repeatedly, residents raised general concerns about the continued use of pesticides. Worries about the build-up of resistance, has already led to changed usage of different products. There were also concerns that spraying may temporarily reduce earwig densities to a satisfactory level which in turn could result in diminished support for CBC. However, most residents seemed to be aware of natural fluctuations and also that earwig numbers would be likely to increase when the use of pesticides is reduced. Several times the decline in native ‘black beetles’ (a species of rove beetle, Staphylinidae) was pointed out, which was also attributed to the use of pesticides. The loss of native ‘black beetles’ was mostly regretted but on occasion the intrusion of insects of any kind into buildings was seen as undesirable. On occasion it was suspected that the decline of native species was caused by the earwigs themselves and related to a scarceness of such species in areas with high earwig densities.

Frequently, people had questions about possible obstacles to the establishment of the control agents. Comments were made on the possible impact the current use of pesticides may have on the establishment and efficacy of the control agents. Pesticides are mostly applied in autumn when the *T. setipennis* will only be present as dormant pupae. However, spraying may still have some impact on the *O. pallipes*, which overwinters as larvae inside living earwigs. Given the climatic conditions on the FI the majority of earwigs will still overwinter outside and therefore escape pesticides. We expect that as the flies begin to establish and gradually start to control the population of earwigs in Stanley the need for spraying will reduce so impacting less on both earwigs and flies. There was also concern about the availability of flowers providing pollen and nectar for adult flies, something we believe is not a problem during the time period when adult flies occur during late spring and summer. Generally, the audience was also keen to reconstruct the history of earwig introduction with various speculations on time and entry points being discussed. There was general agreement that the biological control will support a reduction in demand for chemical treatment both reducing costs and risks for human health and the environment.

Release programme

During 2015, an estimated 50,000 earwigs were collected in the UK. In 2016 numbers dropped to 18,500 earwigs despite an increase of traps from 573 to 716. Earwig densities peaked in mid-August with the majority collected up to this time still being larvae. In each year, numbers dropped considerably until the end of the collecting period at the end of September.

A total of 147 pupae of *T. setipennis* and 237 of *O. pallipes* were obtained from the earwigs up to 28 October 2015. Discounting prematurely hatched flies, altogether 145 pupae of *T. setipennis* and 212 of *O. pallipes* were shipped to Stanley for a first release trial on the Falkland Islands in November 2015. In 2016, 358 pupae of *T. setipennis* and 284 of *O. pallipes* were collected until 21 December. Discounting prematurely hatched flies, a total of 256 pupae of *T. setipennis* were shipped to Stanley in January 2017, and 225 of *O. pallipes* in August and September 2016. A breakdown of collected parasitoids per site and estimated parasitism rates is given in Table 2.

In November 2015, hatching rates of *O. pallipes* at quarantine facilities in the FI were poor, with all flies dying shortly after emergence. The most likely cause for this was the prolonged storage of fly pupae under cold conditions prior to the release, which aimed to synchronise hatching with the onset of summer in the southern hemisphere. At the same time *T. setipennis* did not hatch at all and emergence only started in January/February 2016. Only a few flies hatched over several weeks, which were kept in the mating tents (Fig. 2) and, after six days, altogether only 15 flies were released into an open polytunnel containing high densities of earwigs.

Shortened storage periods for *O. pallipes* and prolonged hibernation of *T. setipennis* allowed a significantly improved hatching rate in 2016. More than 200 *O. pallipes* hatched in August and September 2016. They mated and subsequently deposited a large number of micro-eggs on carrot pieces which had previously been exposed to earwigs. 1,800 earwigs collected locally were then fed with pieces of carrots contaminated with fly eggs and released in Stanley in October. From 256 pupae of *T. setipennis* transported to Stanley in January 2017, 185 flies hatched during February. Some flies died within a short period after hatching, but a large proportion were released into sheltered places in Stanley.

DISCUSSION

Stakeholder consultation

This was the first introduction of a non-native species for the control of an invasive species on the FI, and a certain level of concern from expert stakeholders and the general public was anticipated. Therefore, we tried to encourage residents to voice their concerns and engage in open discussion on the safety and scope of CBC. At the core of all consultations were these premises:

The release of the control agents is safe and does not pose any risks for native species, human health or food production

Both successful establishment of CBC agents and the amount of control they can exert can never be guaranteed and these can be a reason for failure.

The general feedback most people gave was that of cautious optimism and being in favour for biological control provided it is safe. It was important for most people to have the assurance that biological control does not lead to the introduction of a species which could become problematic. We believed that through in-depth discussions worries and concerns could largely be dispelled. People became willing to trial a release hoping that it would provide the anticipated long-term solution to the earwig problem, whilst being fully aware that there remains a certain risk of failure. However, this was only partly driven by direct support of CBC versus an equal measure of concern about risks and side-effects associated with the current use of toxic pesticides.

Compared to the amount of advertising preceding public events, the overall turnout was ~1% of the population of

Table 2 Earwigs, parasitoids and % parasitism recorded in 2015 and 2016.

Site/orchard	Year	Earwigs collected	*T. setipennis*	*O. pallipes*	% parasitism *T. setipennis*	% parasitism *O. pallipes*
Darenth	2015	3,000	16	3	0.5	0.1
Darenth	2016	2,800	49	6	1.8	0.2
Silwood	2015	1,000	6	0	0.6	0.0
Silwood	2016	950	52	8	5.5	0.8
EMR total	2015	46,000	125	234	0.3	0.5
EMR total	2016	10,300	149	234	1.4	2.3
Target farm	2016	4,250	108	36	2.5	0.8

the Falklands and thus relatively low (although one might consider drawing in 1,000 attendees in four events in a large town of 100,000 a very good turnout). Attendance during the first open day at the release facilities was (~30 visitors) comparably high and attracted the attention of local radio and television. However, this dropped significantly in the second release year, going down to just a handful of visitors. The same was true for other types of engagement towards the end of the project. Once initial concerns were dispelled there was increasingly less new information between individual events, both from the side of release activities and any residual concerns to be shared. This may have resulted in a declining interest or possible increasing acceptance by the public over time compared to the start of the project.

Release programme

Despite intensified efforts, earwig trapping in England during 2016 yielded less than half the numbers of earwigs obtained in the previous year, which was mainly due to a drastic population crash in a single cherry orchard at East Malling Research. In addition, earwig densities at Target farm varied strongly throughout the year with few earwigs being collected in September. Low earwig numbers in 2016 were offset by a recovery of parasitoid populations, which had been very low in 2015. In both years the quantity of *T. setipennis* pupae collected was substantially lower compared to 1,000+ pupae collected from 20,000 earwigs in 2013 when the host range testing took place (Maczey, et al., 2016). It remains unclear whether *T. setipennis* suffered a population crash in 2015 or if the collecting sites chosen in 2015/2016 were more generally characterised by low rates of parasitism. Studies in continental Europe recorded, on average, higher rates of parasitism for this species (Kuhlmann, 1995). In both years, although a few individuals emerged very early in the season, most *T. setipennis* pupae were found from the beginning of September onwards. This coincides with field observations of some pupae very early in the season in England indicating a more pronounced second generation compared to its phenology on the continent, where occurrence of pupae peaks in August (Kuhlmann, 1991). Collecting earlier would not have yielded more pupae for release though, as these mostly emerged early without a hibernation period, far too early for a release in the FI.

The low number of collected parasitoids and a low hatching rate in Stanley in 2015 was not sufficient to enable establishment of either of the two species. One major problem was switching the lifecycle from a northern hemisphere rhythm to the seasons in the FI. The lack of synchronisation of life cycles between the northern and southern hemisphere is a well-documented problem in biological control (Waterhouse & Sands, 2001; De Clerck-Floate et al., 2008). *Ocytata pallipes* normally remains in the pupal stage only for a short period and initially we tried to delay hatching until the Falkland summer through storage at lower temperatures, hoping to slow down development. However, the species does not tolerate being stored for long periods at low temperatures resulting in poor survival rates. In 2016, this was addressed by shipping pupae of *O. pallipes* to Stanley several times between August and October. Release in Stanley during late winter relied on creating a suitable local environment to allow it to parasitise earwigs soon after arrival. Therefore, flies were kept in an artificially heated polytunnel warm enough to allow both earwigs and flies to be active during the winter months.

The first release trial for *T. setipennis* also failed but for a different reason. November was too early to break the dormancy of this species, which hibernates in the pupal stage, and early exposure to elevated temperatures (20°C) only led to unsynchronised emergence in January/February. For the second release, pupae were kept at low temperatures until mid-January. This resulted in a much better synchronised hatching whilst still allowing a sufficiently long period during the summer in the FI for the completion of a full life-cycle.

The adapted methodology led to much improved results and both fly species were successfully released, albeit with lower numbers than initially hoped for. For *O. pallipes*, this was mitigated in 2016 by keeping hatched flies initially in cages up to the point of eggs being deposited and releasing larger numbers of earwigs fed with contaminated pieces of carrots. The ecology of *T. setipennis* does not allow a similar approach, but for this species hatching rates had strongly improved compared to the previous year and the chances for mating were increased by keeping this species caged for six days before the release.

At this stage of the release programme we do not know whether either or both fly species have established. If establishment has been successful, it is still far too early to observe an impact on earwig numbers and this will only become apparent during future years.

ACKNOWLEDGEMENTS

We would like to thank Jeremy Poncet for his immense contributions to the project. A big thank you goes also to the residents of FI for their support. Funding for this project was provided by FIG and the Darwin Initiative (Darwin+).

Abstract Eradication of invasive rodents has become a powerful tool to protect native island biota. Use of brodifacoum, an anticoagulant rodenticide, has contributed to hundreds of successful invasive rodent eradication efforts on islands. Application of bait containing brodifacoum for this purpose requires appropriate consideration of adverse effects on non-target wildlife. Thus, a priori identification of non-target risks and, where needed, approaches to mitigate these to acceptable levels, is now an essential component of eradication planning and implementation. As part of the plan for eradicating invasive rats and mice from Floreana Island in the Galapagos, we experimentally tested the effect of brodifacoum on the Galapagos endemic land snail species *Naesiotus unifasciatus*. Importantly, the trials were designed to evaluate effects of particular components of the bait pellets, namely the active brodifacoum, the pyranine biomarker, and a blue dye. We found no evidence for increased snail mortality following exposure to any of these bait components. We review results of past toxicity studies on terrestrial molluscs and find that, as for our own study, there is likely to be little impact of anticoagulant rodenticide on terrestrial mollusc survival as the result of application of brodifacoum bait. However, given the limited taxonomic representation in the toxicity tests performed on terrestrial molluscs so far, we recommend the continued used of captive toxicity trials to assess potential effect of any rodenticide applications on native malacological fauna on a case-by-case basis where large-scale eradication programmes are planned and undertaken.

Keywords: anticoagulant, brodifacoum, Bulimulidae, islands, restoration, rodent eradication

INTRODUCTION

Invasive mammal eradications are powerful conservation tools to protect biodiversity and prevent extinctions on islands (Lorvelec & Pascal, 2005; Bellingham, et al., 2010; Nogales, et al., 2013). Three rat species (*Rattus rattus*, *R. norvegicus*, *R. exulans*) and house mice (*Mus musculus*) are the most common rodents introduced to islands worldwide (Atkinson, 1985). These species are responsible for population declines and extinctions of insular flora and fauna, and they are known to interrupt ecosystem processes with negative cascading effects (Fukami, et al., 2006; Steadman, 2006; Towns, et al., 2006; Jones, et al., 2008; Kurle, et al., 2008; Varnham, 2010; Dunlevy, et al., 2011; St Clair, 2011). To recover endangered species and restore ecosystem processes, invasive rodents on islands are increasingly targeted for eradication, with at least 637 successful rodent eradications to date (based on DIISE island data ranked as good or satisfactory; DIISE, 2015). Ninety-seven percent of successful rodent eradications have involved the use of rodenticide, with brodifacoum having been used in 76% of them.

The common mode of toxicity of anticoagulant rodenticides in mammals and birds is to inhibit Vitamin K metabolism in liver, which in turns prevents the formation of chemical factors essential to blood coagulation (e.g., Rattner, et al., 2014). In mammals and birds a lethal exposure will cause these clotting factors to deplete to a level so that blood can no longer coagulate, resulting in death through internal haemorrhage (MacNicoll, 1993). ‘First-generation’ anticoagulants, such as warfarin, are most effective against rodents in multiple feeds but their intensive use as rodenticides resulted in the development of heritable resistance in some rodent populations (Rattner, et al., 2014). This prompted the development of the more potent ‘second generation’ anticoagulants, such as brodifacoum, which are effective against target rodents in a single feed (Rattner, et al., 2014). Sublethal or chronic effects of anticoagulants are not well described in wildlife (Rattner, et al., 2014), but sublethal exposure may result in the retention of residual anticoagulant concentrations in liver tissue. In this regard the ‘second generation’ anticoagulant rodenticides are more persistent in animal tissues, especially liver, than ‘first-generation’ anticoagulants (Fisher, et al., 2003). The second generation anticoagulant brodifacoum has been the most commonly used rodenticide for eradicating invasive rodents from islands, with a high success rate (Howald, et al., 2007; Parkes, et al., 2011; DIISE, 2015). Brodifacoum, incorporated at 20–50 ppm (0.002–0.005%) into cereal or wax baits, is applied to every rodent territory via bait stations, or broadcasted by hand or from a modified agricultural spreader bucket suspended from a helicopter. Large-scale broadcast of bait has facilitated increasingly large and complex island restoration projects involving the eradication of invasive rodents (e.g., Towns & Broome, 2003), but it also raises concerns about environmental contamination and adverse effects on non-target wildlife (Pain, et al., 2000; Eason, et al., 2002). Thus, *a priori* identification of non-target risks and the potential mitigation of these to acceptable levels is now an essential step to inform feasibility of large-scale eradication projects.

Invasive rats are known to prey upon terrestrial invertebrates (e.g., St Clair, 2011). On Galapagos, endemic land snails are particularly vulnerable (Clark, 1981), and recent field collections of land snail shells suggest that rats are particularly voracious snail predators on Floreana (Parent, unpublished data). Although the eradication of invasive rodents would likely benefit terrestrial molluscs, the potential impact of bait on non-target species should be evaluated. Indeed, a range of terrestrial invertebrate species, including snails and slugs, have been found to feed on cereal-based baits used for rodent control (e.g., Spurr & Drew, 1999; Johnston, et al., 2005). Reports that bait containing brodifacoum caused mortality in captive introduced and endemic snails (*Achatina fulica* and *Pachnodus silhouettanus*) from the Seychelles Islands that fed on the baits, and suspected field mortality of *Pachystyla bicolor* snails following operational baiting

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 394–399. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

(anecdotally reported in Gerlach & Florens (2000a; 2000b) and Gerlach (2005)) raised concerns for other native and endemic snail species on islands where rodent eradication using anticoagulants was proposed. Limited information suggests that invertebrates are generally less susceptible to brodifacoum toxicity than mammals and birds (Booth, et al., 2001; Eason & Spurr, 1995), but current knowledge of snail physiology is insufficient to predict with confidence its effect on snails. To assess the feasibility of using brodifacoum to eradicate rats and mice from Floreana Island in the Galapagos (Island Conservation, 2013), a need to investigate risk to endemic land snails was therefore identified.

Land snails are known for their remarkable diversity in island systems (Cameron, et al., 2013). On Galapagos Islands, the land snail fauna comprises 103 endemic species distributed in 13 genera. Approximately 80 species and subspecies belong to the genus *Naesiotus* (Family Bulimulidae) and form the most species-rich adaptive radiation of these islands (Parent, et al., 2008). Recent field and genetic work suggests that most (if not all) Galapagos bulimulid species are single-island endemics (Parent & Crespi, 2006; Parent, unpublished data). Twenty species (and eight subspecies) of endemic land snails are known from Floreana Island. Eight of these species are critically endangered, and three are endangered (IUCN, 2015), whereas others remain to be evaluated. Thus, given the conservation status of Floreana endemic snails, we identified the need to evaluate whether exposure of these endemic snails to the brodifacoum bait type proposed for rodent eradication was likely to cause mortality.

Four previous experimental studies, together assessing twelve species of terrestrial molluscs, have failed to find significant effect of brodifacoum exposure on individual short-term mortality. The only exception to this trend is the study reported by Gerlach & Florens (2000a; 2000b) mentioned above. Therefore, a precautionary approach demands that the effects of exposure to brodifacoum bait should be tested on island endemic snails prior to large-scale rodent eradication measures on islands. Importantly, the rodenticide baits are composed of more than 99% inert ingredients, most of which is compacted cereal grains but may include other inert ingredients such as dye or biomarkers. Past studies failed to explicitly test the effect of inert ingredients on land snails. Thus, the main objectives of the study are to: (1) test various bait formulations to identify which component(s) of the baits are responsible for any mortality that might be observed in land snails, and (2) review and synthesize the literature on experimental toxicity tests of bait-based rodenticides on terrestrial molluscs.

MATERIALS AND METHODS

Site description

Floreana Island is part of the Galapagos archipelago, which straddles the equator approximately 1,000 km off the western coast of Ecuador. The islands are oceanic and have never been connected to any continent. Floreana is volcanic in origin, and at 17,253 ha is the sixth largest island in the archipelago. The maximum elevation of the island is 640 m, and its generally conical shape results in two distinct habitat types: dry lowlands and lush central highlands, which meet and overlap to some extent into what is referred to as a transition zone (McMullen, 1999). Over 98% of the island land area is Galapagos National Park, with the remaining 2% divided between a small town in the lowlands and agricultural and pastoral areas in the highlands (DPNG, 2014). The island is home to an estimated 140 residents as of 2014.

Snail population

Snails were collected at Cerro Pajas on Floreana (Latitude: 01.2968°S, Longitude: 90.4559° W) in November 2012. The Cerro Pajas site was selected based on the relatively high density of snails found there (Parent, unpublished data). We collected snails opportunistically from leaf litter on the ground and from low (< 0.5 m) vegetation. We chose to collect snails near the ground because those snails would be more likely to encounter bait pellets on or near the ground. There are at least three Galapagos endemic species of land snails occurring at that particular site (*Naesiotus nux*, *N. unifasciatus*, and *Succinea brevior*; endangered, critically endangered, and unknown status, respectively), and these species are expected to be either detritivores or to consume algae and lichens scraped from the substrate. For the present study, we used adult individuals of *N. unifasciatus* since the population density of this species was the highest and we felt confident that our sampling would not impact the survival of the population at that particular location (100 adult individuals were collected, less than 5% of the individuals encountered over a period of approximately one hour). We did not collect specimens from any other snail species because their population density was such that we would have had to collect more than 5% of the adult individuals encountered for our experiments. It is important to note that the information gathered from our toxicity experiments will by far outweigh the potential detrimental effects of our population sampling of *N. unifasciatus*. Bulimulid snails are hermaphrodites and therefore sexing them was not applicable.

Experimental design

We housed snails in small cylindrical plastic containers (11 cm high, 17 cm and 14 cm in diameter at the top and base of the container, respectively) replacing lids with tightly covering mesh secured with rubber bands to prevent snail escapes. Two sheets of task wipe (Kimwipe ®) paper were placed on the bottom of each container and kept moist for the duration of the experiment. A small amount of litter from which the snails were collected was sifted and visually inspected to remove any other small invertebrates. Approximately 10 grams of sifted litter was added to each container as a source of natural food and shelter. Each container held five snails at the beginning of the experiment.

We used three types of pelleted bait as experimental treatments: (1) non-toxic baits containing a blue dye (well less than 1% of pellet content) that is a standard proprietary component of the bait formulation, (2) non-toxic baits containing pyranine (a fluorescent marker dye allowing easy detection of metabolized bait in snails' bodies, faeces and slime trails when exposed to ultraviolet (UV) light, also representing well less than 1% of pellet content); and (3) bait containing blue dye and 50 ppm brodifacoum. For treatment groups, one moistened bait pellet was placed in each container at the start of the trial. Control group containers had no pellets, but were otherwise the same as treatment containers. We prepared five containers per treatment and for the control group (total n = 100 snails). All containers were kept on Floreana, at sea level in the shade at ambient temperature (25-28°C). In parallel, we kept five pellets in a container under the same conditions but without snails to evaluate the effect of the containers on the pellets themselves. All containers were opened twice daily to increase circulation of fresh air and to remoisten the tissue paper and bait pellet by spraying water, as necessary.

The experiment was conducted in two parts; the first over 10 days during which all containers with snails were monitored daily for mortality. A 10-day period was selected as slightly longer than the four to eight days that bait pellets are likely to be available to snail populations in the Floreana highlands (Island Conservation, unpubl. data) and substantially longer than the maximum of 72 hours over which snail mortality occurred in the study reported by Gerlach & Florens (2000a and 2000b).

Snail activity was noted twice a day by recording whether the snails were immobile and firmly attached to substrate (i.e., estivating) or moving in the containers. Snails found estivating were moved onto the vegetation and sprayed with water; this reliably caused the snails to become active once again. Snails found dead were frozen immediately in individual vials to preserve tissue and be dissected later if any statistically significant mortality effects were to be detected in our study. In addition, containers were visually inspected daily by illumination with a UV light to detect any fluorescent traces of pyranine in the slime trails and faeces of the snails in containers of treatment 2 which would have indicated ingestion of this bait by the snails. Control containers were inspected in the same manner. Finally, we also monitored bait consumption by noting any changes to the surfaces of the bait pellets. At the end of the 10-day period, living snails from the two treatment groups using non-toxic bait types were returned to the location where they were collected.

In the second part of the experiment, the remaining snails in the control group and the treatment group with brodifacoum baits were monitored for an additional 11 days (for a total of 21 days, well in excess of the period over which signs of poisoning and mortality would have occurred in mammals) and any snails alive were euthanized by freezing at the end of this second part of the experiment to use in subsequent residue content analysis if any significant mortality was observed.

Statistical analyses

We used a logistic regression approach with a Bernoulli (binomial) distribution to evaluate the effect of each bait component on the survival of the snails. We used post-hoc tests to determine whether any of the bait components had a significant effect on snail survival. We implemented all statistical analyses in R version 3.1.0 (R Core Team, 2014).

RESULTS

Snails remained active (i.e., not estivating) throughout the experiment. Individuals were confirmed to consume baits, either by direct observation (snails on bait pellet) or evidence of blue dye or pyranine fluorescence in the snails' bodies, faeces or slime trails. We did not track each individual snail's consumption of bait, but the observed evidence suggested that most snails consumed or were in direct physical contact with bait when available.

The survival of snails over the course of the bait treatments did not differ significantly from the survival of snails in the control groups without baits (Fig. 1). Because our treatment groups did not represent all possible combinations of bait type (with/without brodifacoum, presence/absence of blue dye, and presence/absence of pyranine), we could not directly compare the individual effect of each of these bait components on the snails. However, we found that when all treatments were analysed simultaneously, none of the components had a significant effect on snail survival (Fig. 1). In contrast, in a post-hoc test for individual effects of each component, we found that the survival of snails exposed to bait containing pyranine was greater than the survival of snails exposed to bait without pyranine (Fig. 2; Welch two-tailed t-test for unequal sample size, $t = 3.056$, d.f. = 14, $P < 0.01$). The survival of the snails over 21 days in the containers with bait containing brodifacoum did not significantly differ from the control (Welch two-sample two-tailed *t*-test, $t = 1.497$, d.f. = 5.611, $P > 0.05$).

DISCUSSION

The goal of our study is to quantify the short-term impacts of anticoagulant rodenticide bait on Galapagos endemic land snails. Importantly, any potential short-term impact the bait might have has to be considered against the long-term benefits that rodenticide bait application can bring to terrestrial malacofauna. These potential benefits include, for example, release from invasive rodent predation and general habitat improvement.

Our results suggest that none of the baits tested were toxic to the snails over the 10-day exposure period (i.e.

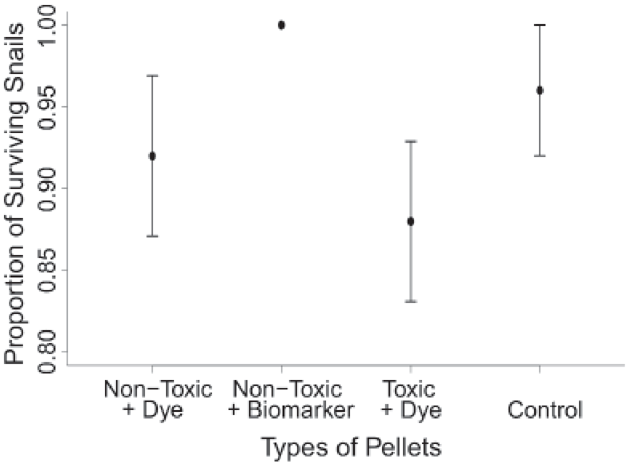

Fig. 1 Survival of snails exposed to different types of pellets: non-toxic pellets with blue dye, non-toxic pellets with biomarker, pellets with 50 ppm brodifacoum and blue dye, and control populations without pellets. Survival for all treatments was not significantly different than the survival of the snails in the control populations ($P > 0.05$). Error bars represent standard errors.

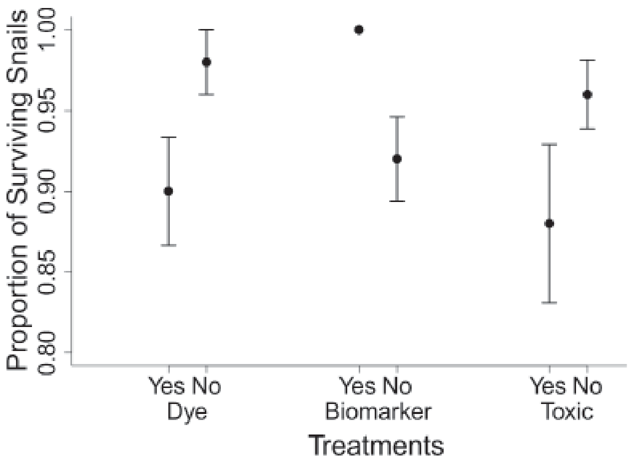

Fig. 2 Survival of snails as a function of presence/absence of pellet components: blue dye, biomarker, and brodifacoum. A logistic regression approach with a Bernoulli (binomial) distribution including all samples at once reveals no significant effect for any of the components ($P > 0.05$). However, a post-hoc t-test indicates that snails exposed to pellets with biomarkers have significantly higher survival than snails exposed to pellets without biomarker ($P < 0.01$). Error bars represent standard errors.

Table 1 Terrestrial mollusc species experimentally tested for the effects of anticoagulant rodenticides.

Species	Family	Locality	Use of control(s)?	Number of individuals tested	Anticoagulant rodenticide	Brodifacoum exposure time (max no of days)	Effect on organism survival	Reference

survival of snails exposed to any bait treatment was not significantly different than 1.0). For the purposes of a conservative risk assessment, our experiment simulated a 'worst case' exposure to snails through use of 50 ppm brodifacoum in bait, compared to the lower concentrations proposed for the rodent eradication on Floreana (25 ppm) and used in previous similar experiments with snails (e.g., Booth, et al., 2003; Brooke, et al., 2011; Table 1). In confining snails under conditions favourable for foraging and in close proximity to bait, we also simulated a worst-case exposure potential, in comparison to the expected availability of bait to snails following an operational aerial application. Application rates for rodent eradication on Floreana Island remain to be determined, nonetheless relatively few snails are expected to encounter and consume bait before it is removed by other animals or breaks down naturally. Additionally, the operation will occur during the driest time of the year, corresponding to the time when snails are more likely to be estivating (Parent, unpublished data).

An apparent absence of toxic effects of brodifacoum bait on snails was further supported by survival being significantly higher in a post-hoc test in snails exposed to non-toxic baits that contained pyranine compared to snails exposed to baits without the biomarker during the first 10 days of the experiment. It is possible that one or some of inert components of the bait types used in our experiment provided a nutritional supplement benefiting the snails. Any such benefits from a boost in diet would become more evident over time. However, this pattern of increased survival did not carry over in snails that were kept for the full-length (21 days) of the experiment.

Our results add to a growing body of research suggesting that exposure to rodenticide bait formulations containing brodifacoum does not cause significant mortality in snails (Table 1). Reports by Gerlach & Florens (2000a; 2000b) and Gerlach (2005) appear to be exceptions, but are also brief and lacking in detail that would allow statistical evaluation. While the absolute toxicity of brodifacoum and its mechanism in snails remain to be established, in the context of potential exposure to rodenticide baits it is important to also consider the possible effects of other, nominally inert, ingredients of specific bait formulations (e.g., binders, preservatives, emulsifiers, pH regulating, flavouring or colouring agents). In designing our study we sought to account for some of these factors and recommend that future studies of the effects of rodenticides on invertebrates contain a mechanism to ensure any observed mortality is in fact due to the active anticoagulant agent and not other bait components or experimental conditions.

We caution that our tests were performed on a single species of land snail, and are therefore not extensive enough to confirm that exposure to brodifacoum bait would not have adverse effects in other terrestrial malacofauna on Galapagos or elsewhere. However, given that most Galapagos endemic snail species are of the same genus as the species tested here, we feel confident that at least this important group will not be affected by exposure to brodifacoum bait if it was applied for eradication of invasive rodents on Floreana and other Galapagos Islands. Most importantly, these snails are known to be consumed by introduced rats (Clark, 1981; Parent, unpublished data), and therefore eradication of invasive rodents is more likely to result in positive effects on Galapagos endemic snail populations.

Secondary exposure pathways must be considered when assessing non-target risk and when developing measures to prevent non-target mortality (Eason, et al., 1999). We did not test for residual brodifacoum concentrations in the bodies of exposed snails in our study, but Booth et al. (2003) measured brodifacoum residues in the bodies of some snails that had consumed bait. We expect that any snails that consume bait on Floreana Island could constitute a secondary exposure pathway for their predators such as some of the larger land birds. The only Galapagos birds that have been verified to be preying on endemic snails are the Galapagos mocking birds which have been extirpated from Floreana Island. There are no other known potential secondary exposure pathways for non-target species on Floreana Island involving the endemic snails as intermediate.

Evidence to date and our results indicate that rodent bait containing brodifacoum does not present a high risk of non-target mortality to terrestrial snails. However, our study is limited to the detection of mortality (i.e. we did not monitor for other potentially negative effects) and was over a short period of time. Given the general trend across terrestrial molluscs of the effect of brodifacoum on snail mortality, we recommend a re-evaluation of this effect for the species included in the study reported by Gerlach & Florens (2000a; 2000b) that would incorporate a more complete set of treatments and controls. More specifically, we recommend more toxicity tests on the invasive giant African snails (*Achatina fulica*) given its broad distribution (tests could be conducted in a range of localities on continents and islands) and the negligible impact these tests would have on this highly invasive species (Lowe, et al., 2004). We conclude that it is prudent to continue to assess toxicity risk on a species by species basis, where rodent eradication using brodifacoum or other rodenticides is planned. Trials to determine whether captive snails would eat baits and whether exposure to baits results in measurable mortality are a relatively straightforward and low-cost means to test theoretical assessments of non-target risk.

ACKNOWLEDGEMENTS

The authors thank Walter Gilberto Mora Mora, Jimy Andres Mora Mora, and Francisco Morena Naula for their help in the field. We are grateful to the Galapagos National Park Directorate for sampling permission and the Charles Darwin Foundation for logistical support, especially Luis Ortiz-Catedral. We also thank Claudio Cruz Bedon and María de Lourdes Soria Rivera for logistic support while on Floreana Island. This work was supported by funding from The David and Lucile Packard Foundation and The Leona M. and Harry B. Helmsley Charitable Trust. During this work CE Parent was supported by an NSERC PDF, and the authorship contribution of P Fisher was supported by the New Zealand Ministry of Business, Innovation and Employment (Project C09X0910). Lynn Booth provided improvements to earlier drafts of this manuscript.

Criteria to help evaluate and guide attempts to eradicate terrestrial arthropod pests

Abstract Attempts to eradicate invasive terrestrial arthropods are often regarded as gambles. They offer the possibility of long term freedom from a pest but are usually confronted with substantial uncertainty and come with a range of technical, economic, environmental, social and political risks. Few guidelines are available for evaluating eradication attempts against terrestrial arthropods. Here, we build on scientific literature, including six criteria previously developed to evaluate the feasibility of vertebrate eradications, and our own experiences to define nine criteria that are intended to both assist experts to evaluate proposed arthropod eradication attempts and guide attempts that are underway. The criteria are straight forward and easily interpreted, though evaluating them for a particular programme relies on expert group assessment that will often benefit from rigorous supporting statistical and/or modelling analyses.

Keywords: area wide management, decision support, eradication attempt, eradication campaign, eradication feasibility, invasive species, pest control

INTRODUCTION

Invasive species eradications make substantial contributions to conservation (Keitt, et al., 2015; Hoffmann, et al., 2016), agriculture (Vreysen, et al., 2007b; Suckling, et al., 2014a) and human health (Kay & Russell, 2013; Monteiro, et al., 2014). They offer perpetual benefits over long-term pest damage and associated control costs, but are usually expensive, can be disruptive both socially and ecologically, require whole-hearted long-term commitment from those involved, and success is far from guaranteed (Myers, et al., 2000; Myers, 2003; Tobin, et al., 2014; Liebhold, et al., 2016). Thus, eradication attempts invoke a range of technical, economic, environmental, social and political risks. Weighing up information about the potential benefits, costs, risks and probabilities of success of eradication attempts can be fraught with uncertainty (Brown, et al., 2019; Cannon, et al., 1999) and demands that diverse technical issues and societal perspectives be considered (Simberloff, et al., 2013).

Bomford & O'Brien (1995) defined six criteria to help evaluate the feasibility of eradicating vertebrate pests. They drew from lessons learnt in eradicating feral goats from islands, coypus in England, and infectious human diseases in various countries. These criteria have become widely adopted (Brown & Sherley, 2002; Burbidge & Morris, 2002; Clout & Veitch, 2002; Simberloff, 2003a), and have been used in New Zealand by the Department of Conservation (DOC) and Ministry for Primary Industries to help assess the feasibility of eradicating various vertebrate and arthropod pests (Cromarty, et al., 2002; Ashcroft, et al., 2010). We were members of a Technical Advisory Group convened by DOC to assist it with its eventually successful attempt to eradicate a non-native butterfly, *Pieris brassicae* (Lepidoptera: Pieridae), from New Zealand (Phillips, et al., 2016; Brown, et al., 2019). This Palearctic butterfly was regarded as a major risk to New Zealand's 79 native (mostly endemic) Brassicaceae species, many of which were already at risk (Hasenbank, et al., 2011; de Lange, et al., 2013), and also to cultivated exotic brassicas. We began using Bomford & O'Brien's (1995) criteria while evaluating the *P. brassicae* eradication programme and found them useful, though not entirely appropriate for arthropods. Moreover, we were cognisant of valuable insights about arthropod eradications that had been described in the literature since Bomford & O'Brien (1995). Thus, we refined and added to their criteria near the outset of the *P. brassicae* eradication attempt, then used these modified criteria throughout the programme to help both evaluate if the campaign should continue and identify the improvements required to maximise its chance of succeeding.

We present our refined set of criteria here with the aim of assisting others with expertise in pest eradication and arthropod ecology to evaluate and guide further arthropod eradication attempts. Other authors have summarised the elements and processes needed to mount an effective eradication campaign (Cromarty, et al., 2002; Hosking, 2002a; Hosking, 2002b; Vreysen, et al., 2007b; Pacific Invasives Initiative, 2013). However, to our knowledge, criteria developed specifically to help evaluate attempts to eradicate terrestrial arthropods have not previously been documented. Information about previous eradication programmes has recently been compiled in an on-line database (Kean, et al., 2018), yet much valuable information about eradication attempts remains either as grey literature or unrecorded, which impedes improvements in eradication methods (Myers, 2003; Hoffmann, et al., 2011). Thus, we endeavour to document some of our own lessons here.

We do not: review any eradication programmes (Vreysen, et al., 2007b; Hoffmann, et al., 2011; Suckling, et al., 2014a); discuss the growing ecological knowledge and developing technologies that are steadily increasing the potential for eradication attempts to succeed (Vreysen, et al., 2007b; Liebhold, et al., 2016; Alphey & Bonsall, 2017; Scott, et al., 2017); or discuss the enormous benefit of protecting countries or regions from invasions by new pests and diseases (Leung, et al., 2002; Hoffmann, et al., 2011; Lovett, et al., 2016). Nor do we attempt to provide a list of criteria that must be irrefutably met before choosing to initiate – or persevere with – an eradication attempt. Rather, we aim to list some readily interpretable, easily used criteria to assist constructive discussion, decision making and planning within the broader context of what is at stake if the pest is allowed to persist and spread, the pest's priority relative to other problems, and the availability of the resources, expertise and personnel required to mount an effective campaign. Evaluating the criteria will often benefit from expert group assessment and rigorous supporting statistical and/or modelling analyses. Eradication attempts usually involve many uncertainties,

and the criteria should help to identify those that are most important to resolve as programmes proceed. Certainly, we will have missed our goal if the criteria impede prompt, effective action (Simberloff, 2003a; Simberloff, 2003b; Martin, et al., 2012; Sims & Finnoff, 2013).

METHODS

We adapted the six criteria of Bomford & O'Brien (1995) to make them clearer and more directly applicable to arthropod eradications. We reviewed science literature about factors that influence the success of eradication attempts, and used the insights gained from the science publications to further refine the six criteria. Based both on the literature and our own experiences of eradication attempts, we also developed three additional criteria.

RESULTS

The nine criteria are listed below, each with clarifying comments and, where available, supporting evidence from the literature. The list begins with criteria that deal mainly with details of the species being considered, the tools available to suppress it, and the physical environment in which it occurs, and ends with those that relate more to the societal and organisational context of the eradication attempt. Criteria 1–3, 5, 7 and 8 are based on the six criteria of Bomford & O'Brien (1995), though we modified them to make them clearer and more directly applicable to terrestrial arthropod eradications. Criterion 6 is from Pacific Invasives Initiative (2013), and we added criteria 4 and 9 based both on recent research (Pluess, et al., 2012a; Pluess, et al., 2012b; Tobin, et al., 2014; Buddenhagen & Tye, 2015) and our own experiences (Cromarty, et al., 2002; Brown & Brown, 2015; Keitt, et al., 2015; Phillips, et al., 2016; Brown, et al., 2019).

1. The pest population can be forced to decline from one generation to the next, irrespective of its density.

This is a re-wording of criterion 1 of Bomford & O'Brien (1995): *Rate of removal exceeds rate of increase at all population densities.* Myers, et al. (2000), in a review that covered eradications of species from several phyla including arthropods, also emphasised that the pest must be susceptible to control. Our changes recognise that terrestrial arthropods typically have several life stages per generation, which will likely have differing susceptibilities to control. Thus, it may be acceptable for particular life stages to numerically increase (e.g., egg-stage offspring may outnumber their adult parents) provided the overall effect of control measures is to cause inter-generational declines. Moreover, the availability of tools to suppress the pest population both at very high and at very low population densities should be considered. The eradication attempt must be capable of driving the population to extinction once it has been suppressed to very low densities and becomes more difficult to detect. Some commonly used pest control methods, such as host plant removal, biological control, and insecticide applications, do not require direct detection of pest individuals, and have potential to be effective across a range of population densities. Some species suffer Allee effects at low population densities, which can drive them to extinction once they have been suppressed to below critical density thresholds (Blackwood, et al., 2012; Liebhold, et al., 2016).

2. Every pest individual must be at risk of control at some stage of its development.

This is a re-wording of criterion 3 of Bomford & O'Brien (1995): *All reproductive animals must be at risk.* Our changes recognise that terrestrial arthropods typically have several life stages per generation, and these will likely have differing susceptibilities to control. A combination of control techniques targetting different life stages could increase the likelihood the pest will be successfully eradicated (Blackwood, et al., 2012; Suckling, et al., 2014b; Hoffmann, et al., 2016). Control methods might include augmenting natural enemies that already occur in or near the treated area to increase predation or parasitism of the pest (Montoya, et al., 2007; Hogg, et al., 2013; Richards, et al., 2016).

3. Pest individuals can be detected at low population densities.

This is a minor re-wording of criterion 4 of Bomford & O'Brien (1995): *Animals can be detected at low densities.* It is supported by many studies (Myers, et al., 2000; Simberloff, 2003a; Tobin, et al., 2014). The latter study analysed factors that influenced the outcomes of 672 arthropod eradication programs and found that high detectability contributed to success rates. Population declines must be measurable and, assuming the pest population is eventually suppressed, management tools should be adequate to confirm it has been eradicated. Are effective lures, attractants or traps available, or can they be developed in a timely fashion? When such tools are unavailable and eradication attempts depend on visual searches, they are more successful when targeting easily-observed foliage-feeding species, rather than species that occupy more cryptic niches such as roots, fruit or stems (Tobin et al., 2014). Moreover, programmes without sensitive detection tools that capitalise on citizen reports of sightings have higher probabilities of success than those that do not (Tobin et al., 2014). Thus, detection will be more likely when: effective attractants are available; the pest and its feeding damage are conspicuous and easily recognised; the pest's host plants are low growing, easily searched and of interest to gardeners, commercial growers and/or citizen ecologists; and citizen surveillance is supported by effective outreach programmes. Some control methods may impede detection. For example, using pheromones to disrupt mating will reduce their efficacy as lures for detection (Suckling, et al., 2014b).

4. Success is favoured by small spatial extent of the population.

Bomford & O'Brien (1995) acknowledged pest population spatial extent as important under 'Other factors'. The meta-analysis of Tobin, et al. (2014) considered 672 arthropod eradication programs that involved pest infestations ranging in area from about 0.1 km^2 to about 100,000 km^2. Overall, there was a base rate of 59% success, and the spatial extent of the targeted population was the most important factor explaining variation around this rate (Tobin, et al., 2014). Population spatial extent was also recognised as a critically important factor in the outcomes of 136 eradication programs against invertebrates, plants and plant pathogens (Pluess, et al., 2012a). When infested areas are small, eradication attempts are less expensive and more likely to be successful (Myers, et al., 2000; Simberloff, 2003a; Brockerhoff, et al., 2010; Pluess, et al., 2012a; Tobin, et al., 2014). This is why "wait and see" responses to detections of new pests are seldom justifiable even when uncertainty is high (Sims & Finnoff, 2013).

5. Immigration and emigration can be prevented.

Here, we added 'and emigration' to criterion 2 of Bomford & O'Brien (1995) (*Immigration prevented*) because an attempt to eradicate a localised arthropod population will fail if individuals disperse from the eradication zone and establish new undetected populations nearby. Myers, et al. (2000) and Hoffmann, et al. (2016) emphasised that immigration (reinvasion) must be prevented, and Bomford & O'Brien (1995) acknowledged pest dispersal rates as important under 'Other factors'. Attempts to eradicate isolated localised populations (e.g. on islands or other geographically isolated areas) might benefit from low likelihoods of natural pest dispersal in or out of the eradication zone (Myers, et al., 2000), though an analysis of 173 eradication programmes found no evidence that eradication attempts were more successful on islands (Pluess, et al., 2012b). The likelihood the pest will be transported in or out of the infested area in association with humans must also be considered, as should the extent to which this risk can be mitigated (e.g. by implementing regulatory controls on host plant movements). Pluess, et al. (2012b) found that implementing sanitary measures to restrict pest emigration made an important contribution to eradication success rates. A further consideration is the capability of the programme to identify when immigration or emigration is occurring, and to respond effectively to such processes. Recognising that immigration is occurring may be challenging, though genetically characterising the population within the eradication zone could help to identify new immigrants if they differ genetically from the initially targeted population (Barr, et al., 2014; Hiszczynska-Sawicka & Phillips, 2014; Piertney, et al., 2016). Detecting emigrants will depend on the extent, intensity and efficacy of active and passive surveillance outside the known infested area.

6. Environmental impacts of the programme are acceptable.

Most methods used to manage pests will have non-target impacts (Bomford & O'Brien, 1995; Pacific Invasives Initiative, 2013). These include host plant removal, biological control, synthetic pesticides, biopesticides and traps (e.g. due to by-catch). Eradicating a pest from an ecosystem could release other non-native species from competition, predation or parasitism, thus solving one problem while exacerbating another (Myers, et al., 2000). Decision makers must consider if such impacts will be reversible and/or socially and environmentally acceptable, and if they will be substantially less than those likely to be sustained if the pest became permanently established and more widely distributed. If the infested area being treated is small and the expected term of the programme is short, then environmental impacts might be ephemeral because those non-target species negatively impacted by the eradication programme may be able to recover once the programme ends.

7. Benefit-cost analysis favours eradication over control.

This is a minor re-wording of criterion 5 of Bomford & O'Brien (1995): *Discounted benefit-cost analysis favours eradication over control*. It was also listed by Pacific Invasives Initiative (2013). We omitted the word 'discounted' from Bomford & O'Brien's (1995) criterion because discounting in benefit-cost analysis remains controversial (Gollier & Hammitt, 2014; Hockley, 2014). Myers, et al. (2000) acknowledged that evaluating the benefits and costs of eradication is difficult, and contended that the benefits of eradication are often over estimated and the costs of eradication under estimated. Nevertheless, many successful eradication programmes have been regarded as highly cost-effective (Brockerhoff, et al., 2010; Buddenhagen & Tye, 2015; Scott, et al., 2017). Benefit-cost analyses provide useful frameworks for aggregating information about an eradication attempt to support decision making. However, they must often include educated guesses about parameter values, struggle to quantify the value of biodiversity and ecosystem services, and seldom address uncertainty (Born, et al., 2005; Epanchin-Niell & Hastings, 2010; Simberloff, et al., 2013; Hockley, 2014; Brown, et al., 2019).

8. Suitable social, political, legal and institutional environment.

This is a minor re-wording of criterion 6 of Bomford & O'Brien (1995): *Suitable socio-political environment*. It was emphasised by Buddenhagen & Tye (2015) and similar criteria were listed by Pacific Invasives Initiative (2013) and Simberloff (2003a). Myers, et al. (2000) also stressed that funding must be sufficient and lines of authority clear. Our changes more clearly specify the need for eradication programmes to be supported by every facet of society that has an important role or stake in the programme. Those evaluating eradication attempts must ask questions like: Will property owners allow or support eradication activities on their land? Would those implementing the eradication programme have legal authority to implement control actions on private and public land? Will the programme be supported by stakeholders such as local and regional authorities, farmer organisations and environmental advocacy groups? Will all management levels of the institution(s) attempting the eradication remain fully committed – especially financially – to the programme for the long haul?

9. Programme is effectively managed, and its status is reliably monitored and accurately recorded.

Efficient, meticulous and effective planning and management are critical to eradication success (Cromarty, et al., 2002), as are clear lines of authority (Myers, et al., 2000; Simberloff, 2003a). These programme attributes must be supported by efficient and robust data collection and analysis to enable progress to be monitored, assumptions tested, weaknesses identified, and improvements devised and implemented (Vreysen, et al., 2007a). Brown & Brown (2015) suggested that systematic and persistent effort by individuals with a "completer-finisher" personality type (Belbin, 2010) or an "eradication attitude" can increase the likelihood of success. For arthropod eradications, it is clearly important to involve people with expertise in arthropod ecology and management.

DISCUSSION

We propose that the nine criteria can help to focus discussion and evaluate and guide attempts to eradicate terrestrial arthropods. We repeatedly scored the criteria throughout the *P. brassicae* eradication programme (Phillips, et al., 2016) and, although our individual assessments often differed, they always provided a valuable basis for discussion and planning. Moreover, our individual assessments all became progressively more optimistic as the programme proceeded and uncertainty declined (Phillips, et al., 2015). In fact, optimism grew even as the pest's known geographical distribution increased because we also gained confidence that the pest was detectable and controllable.

We found it useful to classify each criterion as being either 'not met', 'marginally met' or 'substantially met'. These qualitative terms recognised that criteria can be met to varying degrees and using just three classes simplified the assessment process and eased interpretation. Criteria were classified as 'not met' if the eradication attempt was likely to fail unless improvements to that aspect of the programme were urgently made. Criteria were considered 'marginally met' if there was some evidence the criterion could be (or was being) met, but knowledge gaps caused uncertainty to be high and made assessing the criterion difficult. This classification also signalled a need for action because important knowledge gaps had to be addressed to ensure eradication feasibility. Criteria were scored as 'substantially met' when these elements of the eradication attempt appeared (likely to be) effective. Improvements to aspects of the eradication classified as 'not met' or 'marginally met' were regarded as critical and urgent, and improvements to those classified as 'substantially met' were regarded as desirable.

In the context of vertebrate eradications, Bomford & O'Brien (1995) considered criteria 1, 2 and 5 (numbers as used in the main text of the Results in this paper) as essential to success, and criteria 3, 7 and 8 as desirable, though they emphasised that negatives in the latter three criteria "will greatly reduce the feasibility and desirability of eradication". With our criteria for terrestrial arthropod eradications, we suggest that all of the criteria except numbers 4 (small spatial extent) and 7 (benefit-cost analysis) will need to be substantially met before eradication is eventually achieved. However, it may be reasonable to initiate an eradication attempt before many of the critical criteria are substantially met. This is because, with thoughtful management, new knowledge and tools will often be developed during the course of a programme (Vreysen, et al., 2007b; Scott, et al., 2017) that will rectify some or all of its deficiencies and/or enable the criteria to be scored with more confidence. Indeed, the criteria aim to highlight those aspects of programmes that most need improvement. In cases where few critical criteria are substantially met, it will be particularly important to specify conditions under which the attempt will cease (e.g. when a key programme deficiency is not rectified by a specified date) in order to minimise expenditure on programmes that are doomed to failure.

The capability to robustly evaluate programme progress and confidently reclassify criteria is especially dependent on criterion 9 (excellent management). It is also highly desirable that a (proposed) programme substantially meets criteria 4 (small spatial extent) and 7 (benefit-cost analysis). Yet, with criterion 4, there are examples of arthropod populations with very large spatial extents that have been successfully eradicated (Vreysen, et al., 2007b; Monteiro, et al., 2014; Scott, et al., 2017), thus scores of 'not met' or 'marginally met' may be acceptable in cases where the other criteria for achieving eradication can be substantially met and resources are available to work effectively across large geographical areas. For criterion 7, perceptions of the potential economic and/or environmental benefits of an eradication attempt will strongly influence the level of risk that is deemed acceptable when deciding whether to initiate or persist with the attempt. However, the previously mentioned limitations of benefit-cost analyses (Born, et al., 2005; Epanchin-Niell & Hastings, 2010; Simberloff, et al., 2013; Hockley, 2014; Brown, et al., 2019) combined with overwhelming evidence of negative impacts of many invaders suggests that the precautionary principle (Simberloff, et al., 2013) should be applied particularly to criterion 7, and scores of 'marginally met' may be adequate to justify action.

We intend the criteria to be used by people with expertise in pest eradication and arthropod ecology and management. During the *P. brassicae* eradication attempt, we found it productive to discuss programme performance against each criterion as a group because our individual perspectives often initially differed. Our evaluations of one or more criteria were frequently supported by statistical and/or modelling analyses of data being collected by the programme. Eventually we would reach a consensus that enabled us to provide better advice to the programme than any one of us could have alone. Thus, we advocate using the criteria in fora similar to the 'Technical Advisory Groups' that are often applied in New Zealand to support management decision making. We believe that using the criteria to help evaluate the feasibility of an eradication attempt and its progress towards success will help to improve decision making and increase programme success rates. However, the quality of decision making will of course also depend on the values and motivations of decision makers, the experience and problem-solving abilities of the expert group, the quality of data analysis, and the preparedness of all involved to fill knowledge gaps and take timely action.

Eradication of invasive alien crayfish: past experiences and further possibilities

R. Sandodden

Norwegian Veterinary Institute, Environmental and Biosecurity Measures, Pb. 5695 Sluppen, NO-7485 Trondheim, Norway. <roar.sandodden@vetinst.no>.

Abstract The EU regulation 1143/2014 "On the prevention and management of the introduction and spread of invasive alien species" entered into force on 1 January 2015. On 13 July 2016, the EU list of invasive alien species that require action was adopted. The list includes five different crayfish species. Member states will be required to take measures for early detection and rapid eradication of these species. Except for some eradications performed in the United Kingdom and Norway, there has not been much effort put into eradication of invasive crayfish species throughout Europe. The reasons for this are probably complex and differ between member states. Are the main reasons legislative constraints, ability to eradicate or lack of knowledge and experience? Is eradication of alien crayfish possible and desirable, and what is left to save in Europe? Focus could be put into identifying or creating island populations of special concern and preserve them for the future survival of European native crayfish populations. Eradication measures should be considered as an option in this work. What are the experiences from completed eradication efforts in Europe? Two crayfish eradications have been performed in Norway, and both have been successful. The eradications were performed in locations with several ponds and small streams and performed using the synthetic pyrethroid-based pharmaceutical BETAMAX VET®. Both legislative and funding constraints seem less prominent as successful eradications have been confirmed. Time will show if this trend will spread throughout Europe.

Keywords: crayfish management, invasive alien species, IAS, pyrethroids, signal crayfish

INTRODUCTION

The EU regulation 1143/2014 "On the prevention and management of the introduction and spread of invasive alien species" (<http://data.europa.eu/eli/reg/2014/1143/oj>) entered into force on 1 January 2015. On 13 July 2016 the EU list of invasive alien species, IAS that requires action was adopted. The list includes five different crayfish species, spinycheek crayfish (*Orconectes limosus*), virile crayfish (*Orconectes virilis*), signal crayfish (*Pacifastacus leniusculus*), red swamp crayfish (*Procambarus clarkii*), and marbled crayfish (*Procambarus fallax*) (<http://data.europa.eu/eli/reg_impl/2016/1141/oj>). Crayfish are one of the most successful and widely distributed invasive species in the world (Holdich, et al., 2014). Twenty eight different crayfish species have been translocated from their native range, and seven of them have been identified with invasive potential (Gherardi, 2010). At least ten non-native species of crayfish have been introduced to Europe (Souty-Grosset, et al., 2006). The five indigenous European freshwater crayfish species are all threatened by different factors, but the most detrimental is probably the North American signal crayfish *Pacifastacus leniusculus* and the crayfish plague caused by the oomycete parasite *Aphanomyces astaci* (Holdich & Sibley, 2009). Signal crayfish are natural hosts for the crayfish plague (Unestam, 1972), the causal agent of crayfish plague, and a disease lethal to European freshwater crayfish (Alderman, et al., 1990; Souty-Grosset, et al., 2006), causing dramatic population reduction and in many cases extinction (Holdich, et al., 1999). The signal crayfish exhibits a number of biological adaptions which allow it to tolerate extreme environmental conditions (McMahon, 2002). This flexibility may facilitate the further spread of both he crayfish and the crayfish plague.

The EU regulation on invasive alien species includes restrictions on keeping, importing, selling, breeding and growing listed species. Taking action as early as possible and preventing introduction will ensure that unnecessary suffering of animals is avoided and is more cost effective than eradication. On the other hand, member states will be required to take measures for early detection and rapid eradication of listed species. If a new population is detected there is an eradication obligation, whereas for widely spread species management measures must take place. The list mainly contains species already present in the EU, but future updates are expected to introduce more species not yet present in the EU. Member states select the measures appropriate to the local conditions and do not have an obligation to eradicate IAS of Union concern that are already widely spread in their territory.

Throughout Europe there have been several attempts to eradicate different crayfish species. Reviews of possible methods for controlling nuisance populations of alien crayfish are available (Holdich, et al., 1999; Hiley, 2003; Ribbens & Graham, 2004; Peay & Hiley, 2006; Freeman, et al., 2010; Stebbing, et al., 2014). These methods include different legislative, mechanical, biological and physical measures, including the use of biocides and pheromones. Mechanical methods, such as trapping, seining, and electrofishing can control, but not eradicate crayfish populations (Holdich, et al., 1999; Hiley, 2003; Peay & Hiley, 2006). It seems that only chemical based treatments offer any hope for effective eradication of invasive crayfish species (Peay, 2001).

Except for some eradications performed in the United Kingdom (Peay, et al., 2006) and Norway (Sandodden & Bardal, 2010; Sandodden & Johnsen, 2010), there has not been much effort put into eradication of invasive crayfish species throughout Europe using chemicals. The reasons for this are probably complex and differ between countries. Are the main reasons legislative constraints, unwillingness or lack of knowledge and experience? Is eradication of alien crayfish possible and desirable, and what is left to save in Europe?

Chemical methods of eradication include the use of biocides, surfactants and pheromones. Ribbens & Graham (2004) review the use of biocides for control of crayfish populations. Organophosphates and organochlorines are reported to be effective, but these chemicals are known to bioaccumulate through the food chain (Holdich, et al. 1999). Crayfish can bioaccumulate organochlorines and, as crayfish are eaten by many predators, this is obviously important in terms of biomagnification through the food

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 405–409. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

chain (Ludke, et al., 1971) In contrast, both natural pyrethrum (Pyblast) and synthetic pyrethroids, which have been shown to be effective at very low doses, break down rapidly and do not bioaccumulate (Holdich, et al., 1999; Hiley, 2003; Peay & Hiley, 2006). Synthetic pyrethrum is based on the chemical structure and biological activity of natural pyrethrum, an extract of plants of the genus *Chrysanthemum* (Holdich, et al., 1999).

Eversole & Seller (1997) concluded, in a comprehensive study based on 35 different chemical groups, that synthetic pyrethroids were the most poisonous to crayfish. Both natural pyrethrum and synthetic pyrethroids have low toxicity to birds, mammals, plants and many invertebrates (Van Wijngaarden, et al., 2005). They are, however, in varying degrees toxic to non-target fauna, including crustaceans, insects, arthropods, fish and amphibians (Mayer & Ellersieck, 1986; Burridge & Haya, 1997). The environmental fate and degradation of pyrethroid insecticides were reviewed by Leahey (1979). He concluded that pyrethroids do not persist in the environment for long periods, do not accumulate in the biosphere and do not biomagnify in the food chain. Ecosystem recovery is fairly rapid, with the toxic effect of pyrethroids lasting from days to months, and all major animal groups recovering within a year (Gydemo, 1995). Holdich, et al. (1999) states that ecosystems can recover fairly rapidly from the toxic effects of pyrethroids. Compared to natural pyrethrum the synthetic forms are more toxic, less degradable by light, more readily available and less expensive (Morolli, et al., 2006). To date, no crayfish-specific biocide has been developed.

O`Reilly (2015) suggested that lower concentrations of the natural pyrethrum may be suitable to eradicate or control signal crayfish in small standing waterbodies. Where the risk of damage to non-target species is not an issue and the water is not being used for another purpose, cheaper alternative biocides such as synthetic pyrethroids could be used.

Two successful signal crayfish eradications have been performed in Norway. On the basis of these results and EU regulation 1143/2014, more focus should be put into identifying or creating island populations of special concern and preserve them for the future survival of European native crayfish populations. Eradication measures should and must be considered as an option in this work. The number of eradication attempts probably will increase in Europe as both the knowledge base and environmental impacts increase.

MATERIALS AND METHODS

Both successful eradications were performed in southern Norway close to the capital Oslo (Fig. 1). The locations consisted of several ponds and small streams and involved the application of the synthetic pyrethroid-based pharmaceutical BETAMAX VET®, which is a cypermethrin-based pharmaceutical originally developed for treatment of salmon louse (*Lepeophtheirus salmonis*) infestation of farmed Atlantic salmon (*Salmo salar*). Cypermethrin is a synthetic pyrethroid and a common agent in many insecticides licensed throughout Europe.

Both eradications involved two separate consecutive treatments separated by two weeks and a partial drainage of some of the ponds. The first eradication was performed in the Dammane watershed in Telemark County, during May 2008. The watercourse consists of a creek with five small ponds, the largest measuring approximately 2,000 m^2 (Table 1). The treatment is described in detail in Sandodden & Johnsen (2010). The second eradication was undertaken using the same pharmaceutical, methods and equipment in the Oslo & Akershus County at Ostøya, an island in Oslo-fjord, during October 2009. The treatment involved six ponds on a golf course. The two largest ponds were close to 2,200 m^2 (Table 1). The treatment is described in Sandodden & Bardal (2010, in Norwegian). All ponds were treated with the help of pumps placed in a boat or on the shore (Fig. 2). The chemical was dispersed both on the water surface, along the pond bottom and on a 10 m onshore belt around each pond. Continuous drip stations were placed at the most upstream location of each creek or seep to ensure treatment of the whole drainage basin. This ensured a continuous, constant dosage of BETAMAX VET® during treatment. In the smallest of seeps, enclosed water bodies and small upstream creeks, watering cans were used to dispense a dilution of the chemical. For more details regarding methods, see Sandodden & Johnsen (2010).

The requirements set by the Norwegian Food and Safety Authority for issuing an eradication confirmation after eradication of signal crayfish are described in Johnsen, et al., (2010) and state: 1. No crayfish caught during trapping five to five and a half years after eradication is performed. 2. Noble crayfish (*Astacus astacus*) placed in cages in the treated area have shown no signs of crayfish plague during the last three years of monitoring. 3. Analyses of water and sediments show no sign of crayfish plague spores five to five and a half years after eradication. The methodology is described in Vrålstad, et al., (2009). Based

Table 1 Area, mean depth, volume and BETAMAX VET® used during treatment of the ponds at Dammane and Ostøya locations.

		Area m^2	Mean depth metres	Volume m^3	BETAMAX litres
Dammane	Dam 1	371	0.82	303	0.14
	Dam 2	697	0.92	639	0.17
	Dam 3	1,146	2.27	2,602	1.41
	Dam 4	3,154	1.92	6,054	2.78
	Dam 5	1,346	1.73	1,996	0.57
Ostøya	Dam 14	2,242	3.00	6,726	3.56
	Dam 18	1,400	1.80	2,520	1.33
	Dam 13	990	1.80	1,782	0.94
	Dam 2	2,200	1.80	3,960	2.09
	Dam 1	1,054	1.80	1,897	1.00
	Dam 8	370	2.00	370	0.20

on the investigations involved in eradication confirmation, the Norwegian Food and Safety Authority can issue a self-declaration of freedom of disease (OIE, 2009).

RESULTS

Dammane

No surviving crayfish was observed or found during the second treatment or during drainage of the ponds. On the basis of the Norwegian Food and Safety Authority self-declaration of freedom for disease procedure, the County Governor carried out trials with caged live noble crayfish in 2010 and 2011. In 2010, a total of 31 male crayfish were placed in three cages in three of the treated ponds. The caged crayfish suffered a high mortality during the trials that lasted for 136 days. Analyses performed at the Norwegian Veterinary Institute showed that the cause of death was not crayfish plague. In 2011, a total of 30 male crayfish were placed in three cages in two of the treated ponds. The caged crayfish suffered a high mortality during the trials that lasted for 129 days. Analyses performed at the Norwegian Veterinary Institute showed that the cause of death was not caused by crayfish plague. In 2011 a trapping trial for crayfish was carried out in two of the treated ponds. No crayfish were caught.

Regarding eradication confirmation, the Norwegian Food and Safety Authority concluded on the basis of these results in December 2011 that they could either issue an eradication confirmation based on the results alone or carry out trials with caged crayfish for another year. The relatively new method using molecular investigations based on water samples in search of crayfish plague spores might be carried out as an addition, but the more realistic approach would be caged crayfish trials. The Norwegian Food and Safety Authority's final advice was to issue an eradication confirmation based on the results given in Dammane. They have not yet issued a formal letter or report declaring eradication confirmation (Jan Egil Aronsen, Norwegian Food and Safety Authority pers. comm., 2017).

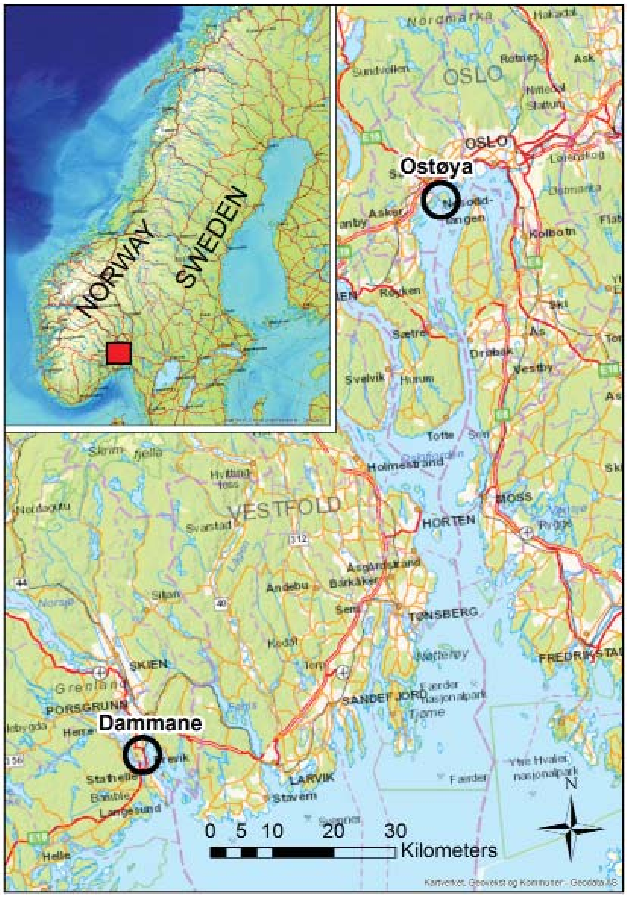

Fig. 1 Dammane and Ostøya locations in southern Norway.

Ostøya

No surviving crayfish was observed or found during the second treatment or during drainage of the ponds. The County Governor carried out trials with caged live noble crayfish in 2013 and 2014. Cages were placed in five of the treated ponds. No signs of disease or crayfish plague were detected. In 2014 a trapping trial for crayfish was carried out. No crayfish were caught. In June 2014 the Norwegian Veterinary Institute collected water samples for analyses of crayfish plague spores in two of the treated ponds (unpublished data). No spores were detected. On the basis of these results the County Governor concluded that the signal crayfish and the crayfish plague is eradicated form the infected ponds. These are unpublished results but summarized in a letter from the County Governor dated 17 March 2017 (ref. 2017/1978-1 M-NA).

DISCUSSION

What is left to save in Europe?

There are still significant native crayfish populations in Europe, which are being decimated through the spread of introduced invasive non-native crayfish (Gherardi, et al., 2011). Action to control invasive non-native crayfish would protect these rare and valuable species. Equally, the impacts from invasive non-native crayfish are wider, ranging from damage to river and flood defence banks (Guan, 1994), through to impact on recreational fisheries. So, there is a case for action based on both ecological and socio-economic factors.

Is eradication of alien crayfish possible and desirable?

As this paper shows, there are possibilities for crayfish eradication. We have the scientific evidence base regarding the species, their risks and impacts; we have the processes to make a robust case, tools, techniques and expertise to take action and now the powers under EU IAS regulations to make that a reality. It is possible to make robust cases to government and only by doing this can we tackle the final funding barrier. Reporting successful eradications should both inspire and motivate future eradication projects. To justify the use of chemicals, it is important to conduct and report the environmental impacts following the eradication attempts and evaluate these in comparison to not taking action.

Fig. 2 Boat mounted pump used to apply BETAMAX VET® during the Dammane and Ostøya treatments.

Lack of eradication projects

The answer to why there have been no eradication projects until now is probably mostly a combination of legislative constraints and lack of experience. Not all European countries are EU- members and most European countries have national legislation regulating the use of chemicals in freshwater. Both local and national regulatory agencies seem not to know where to start and which legislation to apply when trying to implement an eradication strategy involving chemicals. The answer to why not in future is, while complex, now only down to making a strong case to secure political backing and funding to take eradications forward.

Legislation is now a reason for crayfish control

To date, legislation has probably been one of the greatest constraints. Many countries lack effective legislation to carry out pro-active management/control of invasive non-native crayfish species. Legislation controlling import and trade of crayfish species, as well as introduction to the wild has, on the other hand, existed in several European countries (Edsman, 2008; Holdich & Sibley, 2009; Stentiford, et al., 2010), although there is no international regulatory framework for the trade of live animals (Chucholl, 2013). At least in principle, legislation has prevented introduction, and controlled exploitation to reduce risk of spread. Legislation to allow action to control spread or attempt to eradicate once invasive crayfish have been illegally introduced has been missing in many countries. That has all changed with the introduction of the EU invasive alien species regulations, which provide member states with mechanisms to issue Species Control Orders, and the powers behind them to take direct action to eradicate high risk invasive species. We have yet to see how this regulation will be enforced.

Ability to eradicate

Where the threats have been recognised, there seems to have been willingness to take action within the regulatory agencies and conservation bodies on the ground. However, that has been hampered by the lack of legislative powers, scientific evidence base and funding. This has been combined with a lack of public will (and therefore pressure on government) to take action. In most cases, the impacts from invasive crayfish species were not seen or understood by the general public.

Lack of knowledge?

This has probably been an important reason for not performing eradications. Lack of knowledge has been in three main areas: 1. a clear understanding of the species biology, impacts and risks; 2. leading on from this, an understanding of recognised processes such as risk assessments, risk management assessments, invasive species action plans etc. to build a robust case for action; and 3. a lack of knowledge regarding effective tools and techniques to translate that into action. Most of these areas we have now largely addressed or are working to do so. When a bigger experience base has been built more countries probably will try to address the legislative and funding issues necessary to reduce the detrimental effects of invasive non-native crayfish.

Lack of experience?

Historically this has been a factor. Biocide based programmes have only fairly recently become an alternative. Conventional means to manage aquatic invasive fish and crustaceans have been netting, trapping, electrofishing, draining waterways and liming etc. All of the above methods have been trialled to attempt eradication of invasive alien crayfish, but none have achieved more than population reduction (Peay, 2001). Eradication has not been feasible using conventional methods and long-term control is not financially or operationally sustainable, because of the costs associated and work load necessary. As in Norway, that is now changing, and the expertise, tools and techniques we have developed for application of rotenone-based pesticides are directly transferable to application of biocides (synthetic or natural pyrethrins) for crayfish management. These methods have been trialled and found to be very effective if applied correctly (Sandodden & Bardal, 2010; Sandodden & Johnsen, 2010). Total eradication of invasive alien crayfish in Europe is no longer feasible, but emphasis should be placed on sustaining viable island populations of native crayfish and creating new ones. Eradication programmes should be made an option throughout Europe during identification and establishment of suitable island populations and areas. Knowledge and experience to carry out successful crayfish eradications exists. The new EU regulation 1143/2014 is a new tool for securing necessary local legislation and funding.

CONCLUSION

There seems to be an increase in governmental willingness in Norway to conduct chemical eradications when projects are feasible and have acceptable short term environmental impacts. The opportunities for successful eradications should be weighed against not only the environmental impact but also the size and complexity of the waters holding the introduced species. Both legislative and funding constraints seem less prominent as successful eradications have been confirmed. Time will show if this trend will spread throughout Europe.

ACKNOWLEDGEMENTS

I would like to thank the Norwegian Environment Agency for funding the eradications and the Norwegian Food and Safety Authority, the County Governors in Telemark and Oslo & Akershus for cooperation before, during and after the eradications.

Abstract Biological invasions are one of the major threats to biodiversity, especially on islands where the number of endemic species is the highest despite their small area. In the Canary Islands, the relationships among invasive alien species (hereafter IAS) and their environmental and anthropogenic determinants have been thoroughly described but robust provisional models integrating species spatial autocorrelation and patterns of IAS communities are still lacking. In this study, we developed a Generalised Linear Spatial Model for Invasive Alien Species Richness (IASR) under a Bayesian framework, using a methodological approach that encompass GIS and geostatistical analysis. In this study, we hypothesised that the inclusion of spatial autocorrelation can improve model performance thus obtaining more IASR-reliable predictions. In addition, this method provides uncertainty maps that prioritize areas where further sampling efforts are needed. Our model showed that IASR in Tenerife is mainly driven by a combination of anthropogenic and natural processes, highlighting favourable conditions for IAS from the coastline to about 800 m a.s.l., especially on the windward humid aspect. Among anthropogenic factors, a clear positive relationship between road kernel density estimation and IASR was found. Indeed, road density has recently increased especially in low to mid altitudinal zones on the Canary Islands, strictly associated with urban expansion and it has been widely demonstrated to be one of the main IAS pathways. Hence, higher road density can be related to increased 'propagule pressure' which is, together with source of disturbance, one of the most important factors explaining richness in alien species invasion success. Our main conclusions highlight the importance of considering spatial autocorrelation and researchers' prior knowledge to increase the predictive power of statistical models. From a practical perspective, these models and their related uncertainty, will serve as important management tools highlighting those portions of territories that will be more prone to biological invasions and where monitoring efforts should be directed.

INTRODUCTION

Islands display unique ecological and evolutionary processes, hosting more than 20% of the terrestrial plant and vertebrate species in the world, within less than 5% of the global terrestrial area (Courchamp, et al., 2014). Endemics on islands are present with a magnitude higher than on continents (Kier, et al., 2009). In fact, more than one third of biodiversity hotspots in the world are entirely, or largely, within islands (Bellard, et al., 2014).

Besides their high diversity, islands host extremely fragile environments: 50 out of 80 of the documented plant extinctions in the last 400 years occurred on islands and more than 2000 endemic island taxa are currently thought to be on the verge of extinction (Ricketts, et al., 2005; Whittaker & Fernández-Palacios, 2007; Fernández-Palacios, et al., 2015). Nowhere in Europe is this pattern more conspicuous than in Macaronesia, the biogeographic region that encompasses the oceanic islands of the Azores, Madeira, the Canaries and the Cape Verde archipelago (Whittaker & Fernández-Palacios, 2007; Fernández-Palacios, et al., 2015). Macaronesia is widely recognised as an outstanding biodiversity hotspot worldwide due to its high rates of endemism in angiosperms and in bryophytes (40% and 6.5%, respectively, Whittaker & Fernández-Palacios, 2007).

Invasive Alien Species (IAS) pose a serious threat to the conservation of biodiversity and ecosystem integrity worldwide (DAISIE, 2009; Scalera, et al., 2012). Island systems, in fact, are extremely susceptible to biological invasions due to low habitat diversity, their simplified trophic webs and higher rate of endemic species (Courchamp, et al., 2003; Millennium Ecosystem Assessment, 2005; Vilà & Lopez-Darias, 2006; Barni, et al., 2012; Bacaro, et al., 2015).

Oceanic islands perform as an *open-air laboratory* in the field of invasion biology, because of their long history of large-scale anthropogenic disturbances and the recent introduction of non-native species (Whittaker & Fernández-Palacios, 2007; Denslow, et al., 2009), allowing us to generalise about the outcome of biotic invasions and to test the consistency of invasive organisms' behaviours (Kueffer, et al., 2010).

Several factors may determine the composition and the abundance of alien floras, including climate, geology, land use, landscape context, human impact, competition with natives and natural or anthropogenic disturbance and residence time (Crawley, 1987; Pyšek, et al., 2002; Arévalo, et al., 2005). Anthropogenic factors, such as inhabitants and trade networks, were imputed as main drivers of plant IAS introduction and spread: most populated islands should have more opportunities to import (and export) novel species due to the high rate of trade and transport with mainland areas (Pyšek, et al., 2010). Roads are anthropogenic features that can have greater influence on the distribution of IAS, particularly increasing the IAS propagule pressure (Lockwood, et al., 2005) or promoting the spread of generalist species with short life cycles and high reproductive rates (Parendes & Jones, 2000; Pauchard & Alaback, 2004; Arèvalo, et al., 2005; Dietz & Edwards, 2006; Arteaga, et al., 2009). In the Canary archipelago, as well as worldwide (Pauchard, et

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 410–416. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

al., 2009), elevation and topography are factors driving the structure and distribution patterns of alien species spread (Arévalo, et al., 2005; Rejmánek, et al., 2005; Arteaga, et al., 2009)

Ecologists agree on the need for preventive tools such as early alert systems, given that control or eradication of already-established populations is more difficult and costly (Hobbs & Humphries, 1995; Bax, et al., 2001). Predictive invasion models, in fact, allow for evaluating the present and future extent of plant invasions. Furthermore, their outcomes are useful tools supporting the development of eradication/control programmes (Wace, 1977; Alpert, et al., 2000; Rejmánek & Pitcairn, 2002).

Spatial autocorrelation (SAC) is rarely included in ecological models thus potentially leading to biased parameter estimates. Furthermore, classic geostatistical models assume that data are Gaussian distributed, which may be an unrealistic assumption for count data, such as species richness. Generalised linear spatial models (GLSMs) provide a more robust model definition able to cope with response variables belonging to the exponential family distribution (Diggle, et al., 1998, 2003; Zhang, 2002; Christensen & Waagepetersen, 2002; Diggle & Ribeiro, 2007). By definition, the GLSM is a generalised linear mixed model in which the random effects are derived from a spatial process. The Bayesian approach allows parameter estimation by combining information coming from the observed data (via the likelihood function) as well as information coming from other prior sources (i.e. previous studies, subjective judgments) which is formalised through prior distributions. Therefore, Bayesian GLSMs (BGLSM) offer a flexible and robust approach for incorporating spatial correlation and prior knowledge into the modelling approach. In addition, the possibility of obtaining uncertainty maps may provide useful information where data are missing and further sampling efforts should be addressed. In this study, we hypothesised that the inclusion of SAC can improve model performance and therefore more reliable predictions, assuming that a variable selection process has been adopted. Specifically, we investigated alien species richness distribution on Tenerife (Canary Islands) using a multidisciplinary approach encompassing Geographic Information Systems (GIS), geostatistical calculation and statistical modelling. The main goals of this study are: i) to compute an ecologically and spatially reliable model of ASR spatial pattern in the island ii) to test if the inclusion of SAC into the modelling framework improves model performance.

MATERIALS AND METHODS

Study area

The study was carried out on Tenerife, the largest (2,033 km^2) island of the volcanic Canary archipelago situated in the subtropics ca. 70 km off the northwest coast of Africa (27–29° N, 13–18° W; Fig. 1). It is characterised by steep altitudinal gradient and it has a triangle-based pyramid shape with a truncated apex at 2,000 m a.s.l. at Las Cañadas, from which the volcano Teide rises (3,718 m a.s.l.)

The climate on Tenerife is semiarid to humid Mediterranean type (Arteaga, et al., 2009), with mean annual temperature reaching 19° C on the windward aspect and 21 °C on the leeward one. Mesoclimate is affected by trade winds that create a contrast between the northern and windward aspect (more humid and cloudy) and the southern and leeward aspect (more arid and cloudless).

Strong variation in elevation and aspect, which define local mesoclimatic zones and land use, are primary factors in structuring both native and alien plant communities on the Canary Islands (Whittaker & Fernández-Palacios, 2007). On Tenerife, vegetation can be simplified into five ecosystems based mainly on elevation and orientation gradients: succulent coastal scrub (0–700 m a.s.l.), thermophilous forest (200–600 m), laurel forest or *laurisilva* (500–1,000 m), Canarian pine forest (800–2,000 m), and summit or high-mountain scrub (> 2,000 m) (Fernández-Palacios, 1992; del Arco Aguilar, et al. 2006).

Statistical methods

Response variable

The distribution of Invasive Alien Species on the Canary Islands is available at ATLANTIS (Gobierno de Canarias, 2016). This database contains the occurrences of alien species within a grid of 500 m × 500 m square cells covering the entire archipelago. Species records span from 1970 to 2013. Invasive Alien Species Richness (IASR) on Tenerife was obtained by aggregating species occurrences in those ATLANTIS grid cells covering Tenerife Island land (5,514 cells out of 8,519 selected). Seventy-two species are present in the dataset (out of 701 alien species reported for the entire archipelago; Arechavaleta, et al., 2010).

Predictor variables

Three sets of abiotic variables, namely landscape, anthropogenic and climatic predictors, were derived in order to take into account all the the potential factors

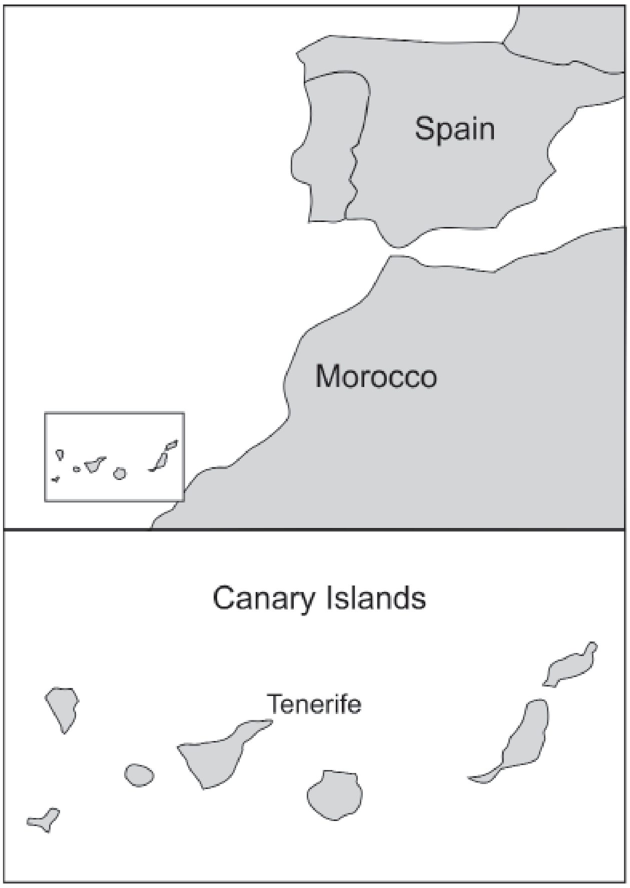

Fig. 1 Canary Islands and position of Tenerife Island within the Canary archipelago.

influencing alien species richness. Specifications of the variables chosen are addressed below.

Landscape predictors

The Digital Elevation Model (DEM) was downloaded from Cartográfica de Canarias S.A. (GRAFCAN, <https://www.grafcan.es/>). Aspect and slope were derived from the DEM for each 10 ×10 m pixel using QGIS 2.16.0 with GRASS 7.0.4 (Quantum GIS Development Team, 2016). The standard deviation of slope was calculated as an index of roughness (Grohmann, et al., 2010).

All the predictors were resampled to 500 m of spatial resolution using the nearest neighbour algorithm, accordingly to the spatial resolution of the species abundance grid. The relative abundance of vegetation classes (del Arco Aguilar, et al., 2010) within each cell was used to classify each grid cell, while the percentage of protected area per cell was used as a proxy of landscape nature conservation.

Anthropogenic predictors

As a proxy of anthropogenic impacts (e.g. fragmentation, Bacaro, et al., 2011) the Shannon index based on the relative abundance of land use classes within each cell was computed using the R package "*vegan"* (Oksanen, et al., 2017). We calculated a density proxy for roads using a Kernel density estimation (Rosenblatt, 1956; Parzen, 1962) using four regularly distributed classes of sample points on the road network distant from each other 5, 10, 20 and 50 km. As above, data were downloaded from Cartográfica de Canarias S.A.

Climate predictors

Climatic data were obtained from Agencia Estatal de Metereologia (AEMET) spanning from 2005 to 2014. Since recorded data showed many gaps throughout the entire time series of every single weather station, we used only those weather stations having records covering at least 80% of the full-time series for Precipitation (P) and 60% for Temperatures (T).

For each dataset mean annual (ma), mean seasonal (Winter: December, January, February (DJF); Spring: March, April, May (MAM); Summer: June, July, August (JJA)) were calculated. In order to obtain continuous representation of the phenomena, the co-kriging spatial interpolation technique (Myers, 1984) was applied using elevation, slope and aspect as covariates using "*geoR*" R package (Ribeiro & Diggle, 2001).

Data analysis and modelling

Spatial autocorrelation in explanatory variables was checked by computing Moran's I, using R package "*spdep*" (Bivand & Piras, 2015). In order to avoid multicollinearity, a forward variable selection with a double-stopping criterion approach (Blanchet, et al., 2008) was adopted in order to select the reduced set of predictors using "*adespatial*" (Dray, et al., 2017).

This procedure consists of computing the global model explained by all explanatory variables via a constrained ordination such as Redundancy Analysis and, if the resulting model is significant, calculating the adjusted coefficient of multiple determination (R^2_{adj}). Then variables were added to a null model (including only the intercept) using a forward procedure: the procedure stops when no more significant variables were founded (for a given alpha level) or when the R^2_{adj} of the model is greater than the global model R^2_{adj}. This double-stopping criterion should prevent the selection method from being too liberal and consequently inflating type I error rates. Once the reduced set of predictors was obtained, this was further evaluated via AIC comparisons using an iterative automatic routine (package "*glmulti*", Calcagno & de Mazancourt, 2010). The set of predictors thus obtained was then used for computing the BGLSM. The resulting model was used as a starting point for the BGLSM.

Unfortunately, probably as an effect of the high number of predictors retained in model selection, we came across issues in algorithm convergence. For this reason, we decided to further reduce the number of predictors chosen, among the reduced list previously obtained, to three which are known to be important drivers of the alien species community along the elevation gradient (Arévalo, et al., 2005, 2010; Barni, et al., 2012, Bacaro, et al., 2015). Thus, only the roads 10 km kernel density, P_{MAM} and elevation were included in the final model (Table 1).

To take into account the spatial correlation of count data, a BGLSM using the Langevin-Hastings Markov Chain Monte Carlo (MCMC) algorithm was computed using the "*geoRglm"* R package (Christensen & Ribeiro, 2002). To complete the Bayesian model formulation of the geostatistical models, a strong-informative uniform prior distribution (Rocchini, et al., 2017a) based on the result of the geostatistical model was specified. Simulations were run with the following specifications: four chains, 20,000 iterations, burn-in period of 6,000 iterations and a thinning rate of 100. To ensure a good mixing of the chains, convergences were assessed both visually and with Geweke's diagnostic (Geweke, 1992), along with the autocorrelation within the chains through "*coda*" package (Plummer, et al., 2006). The Bayesian framework also allows uncertainty of the model to be taken into account, that is the uncertainty of the prediction in the sampling units (Gelman & Hill, 2006). This statistic is crucial for correctly interpreting results and avoiding inappropriate decision-making.

Finally, the linear relationship between Predicted vs Observed IASR values was evaluated and the R^2 was calculated as a measure of goodness of fit.

All analyses were performed using the R 3.4 environment (R Core Team, 2017).

RESULTS

A total of 72 IAS were present in the dataset, with a mean of 4.18 species per cell (range: 1–27). The most common species on the island are *Opuntia maxima* (3,161

Table 1 Summary statistics of predictors used in the MAM. The variables units are shown in the last column.

	Mean	1st quantile	3rd quantile	Min	Max	Units
Roads 10 km kernel density	0.06523	0.02160	0.08953	0.00010	0.41928	-
$P_{MAM2005\text{-}2014}$	25.808	14.878	36.546	1.647	63.103	mm
Elevation	578.9934	240.0000	794.0460	0.5685	2421.3621	m

occurrences), *Ageratina adenophora* (2,239 occurrences) and *Ricinus communis* (1,615 occurrences). On average, the northern (and windward) part of the island has higher values than the southern (Fig. 2), where the biggest cities are (Santa Cruz de Tenerife and San Cristóbal de La Laguna on the NNE coast, Puerto de La Cruz on the NW coast). Furthermore, a decreasing altitudinal trend in IASR was also observed, with higher values of IASR near the coast and lower values above 1,500 m a.s.l. SAC in IASR values were confirmed by the Moran's Index value (I = 0.873, $p < 0.001$).

The inclusion of SAC in the minimum adequate model resulted in a consistent improvement in general model performance (ΔAIC 7,366). In the BGLMS, Markov chains show good mixing and convergence as highlighted by Geweke's diagnostics. Positive linear relationships of IASR were observed with road kernel density estimation (10 km) and $P_{MAM2005\text{-}2014}$, while elevation showed a negative trend (Table 2). Suitable areas for IAS appear to be located in urban areas, especially on the humid leeward aspect of the island (Fig. 3). Model output summarised in Table 3 and Fig. 4 shows the uncertainty in the predicted IASR

Table 2 Model output derived from the maximum likelihood analysis: τ^2 is the nugget, σ^2 is the sill, Φ is the range and gives information about the spatial autocorrelation of the sampling units.

Variables	Coefficients
Intercept	3.4966
Roads 10 km kernel density	18.7518
$P_{MAM2005\text{-}2014}$	0.0126
Elevation	-0.0017
τ^2	5.7100
σ^2	10.7700
Φ	2.8950

Table 3 Descriptive statistics of model outputs.

	Mean	1st quantile	3rd quantile	Min	Max
Predicted	3.47	1.29	4.44	0.33	27.39
Uncertainty	0.75	0.40	0.90	0.14	4.48

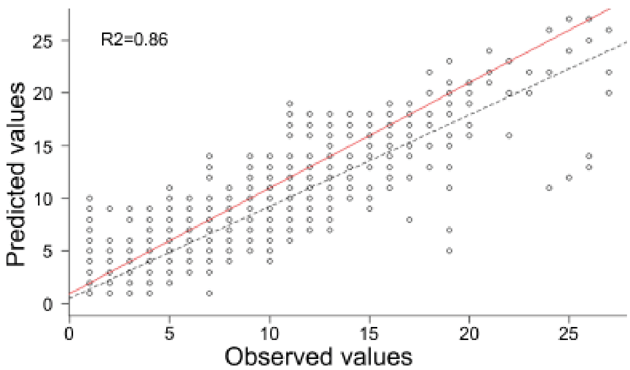

Fig. 5 Predicted vs. observed alien species richness. The solid line represents best prediction line, dashed line the fitted linear model.

values. Figure 5 shows the predicted *versus* observed values scatterplot suggesting a good performance of model fit.

DISCUSSION

The approach used in the selection of covariates and the incorporation of the spatial autocorrelation leads us to build a reliable ecological model to understand the IASR behaviour on Tenerife Island (Fig. 5). The outcomes of the model largely agree with most of the results previously published in the literature, taking into consideration both natural and anthropogenic processes. However, the ΔAIC suggests that incorporating SAC into GLM allows a consistent improvement in general model performance. Moreover, it allows us to obtain maps of the predictions that can be easily consulted by local governments. The map of uncertainty of the prediction provided in the Bayesian framework represents a powerful tool to highlight those areas where sampling efforts should be directed, providing valuable guidance in the decision-making process. On average, uncertainty in the model was quite low and evenly dispersed across the island. The areas where the uncertainty was higher are where human-related land uses occur, mainly in the arid coastal belt at low elevations (Fernández-Palacios & Nicolás, 1995; Rocchini, et al., 2017b).

The Canary Islands, particularly Tenerife Island, are chiefly characterised by a steep altitudinal gradient causing potential variations in several abiotic conditions such as water availability, temperature, precipitation, and solar radiation even over relatively short distances (Alexander, et al. 2009). IASR is inversely proportional with elevation as already observed in Arévalo, et al. (2005), Arteaga, et al. (2009) and Bacaro, et al. (2015), among others. The positive relationship between elevation and limiting factors such as drought, low temperatures and solar radiation were thoroughly investigated. Accordingly, it has been observed that at higher elevations, thermic and hydric stresses reduce the number of successful colonisations of alien species in different regions of the world (Fernandez-Palacios, 1992; Alpert, et al., 2000; Godfree, et al., 2004; Pauchard & Alaback, 2004; Becker, et al., 2005).

In general, mild environmental conditions associated with reduced drought stress enhance alien establishment and spread (Whittaker & Heegaard, 2003). These conditions were found at ca. 800–1,000 m a.s.l. (Arévalo, et al., 2005; Arteaga, et al., 2009). It has been observed that invasion success is mainly linked to the biogeographical affinities and environmental tolerances of the species (Wilson, et al., 1992; Arévalo, et al., 2005; Daehler, 2005). Accordingly, we found a positive relationship between P_{MAM} and IASR, and the BGLSM highlights as suitable the humid areas below 1000 m a.s.l, especially on the windward aspect, whereas the model did not predict suitable areas above 1500 m, except where roads are present. These findings reflect well the same pattern already observed in other studies performed both in Tenerife and in other oceanic islands (e.g. Arévalo, et al., 2005, Pauchard, et al., 2009; Bacaro, et al., 2015). In addition, Daehler (2005) observed similar patterns on the islands of Hawaii, where the relative importance of temperate species on the community composition increased strongly above 1,400 m a.s.l to detriment of the tropical ones.

Other authors (e.g. Nogués-Bravo, et al., 2008; Marini, et al., 2013) pointed out that relationships between IASR and anthropogenic factors are concentrated at low elevations, consequently increasing the opportunities for the introduction and establishment of propagules. Accordingly, our results showed a peak of alien species richness at a relatively low elevation. Species might have been introduced in the lowlands from different sources and in several historical periods. The kernel road density estimation shows a clear positive relationship with IASR. Bacaro, et al. (2015) reported that alien species were absent from plots located at higher elevation in plots sampled near the main Tenerife road network, consistent with previous observations (Pauchard & Alaback, 2004). Road density has increased especially in low to mid elevation belts of the Canary Islands, strictly associated with urban expansion and, consequently, to the spread of exotic plants. Roads may facilitate the dispersal of propagules of alien species via three main mechanisms: 1) as a source of disturbance that creates new environmental conditions that are suitable to ruderal and pioneer species; 2) they may facilitate the dispersal of propagules via air movement associated with the transit of vehicles; and 3) they may boost the rate of invasion by reducing competitiveness of native species that can cause the potential disappearance of even entire stands (Trombulak & Frissel, 2000; Bacaro, et al., 2015).

In this study, we assessed the incorporation of SAC into an ecological model built using ecologically reliable predictors. The incorporation of SAC improved general model performance and allows for for uncertainty to be accounted for in the model framework, providing a way to prioritize areas where more survey is needed along with further monitoring actions in order to reduce uncertainty.

Mild environmental conditions may be responsible for quick establishment and dispersal of aliens on islands. Accordingly, compared with current literature, our results showed higher alien species richness in mild environmental conditions and at a relatively low elevation. This can be also due to the fact that human land use is concentrated at low elevations, consequently increasing the opportunities for the introduction and establishment of propagules. To cope with plant alien species invasion, local governments have tried different approaches (Foxcroft, et al., 2007) but the most effective method still remains mechanical or hand removal (Gobierno de Canarias, 2014). In a global warming scenario, a modelling approach that takes into account spatial autocorrelation of data may play an even more crucial role in alien species monitoring, highlighting those portions of territories that are more prone to biological invasions, especially in fragile ecosystems such as in the Canary Islands.

Abstract Invasive alien ornamental plants are a global problem, especially on oceanic islands, and can have severe impacts on native biodiversity. *Pinanga coronata,* is an ornamental palm tree that can form mono-dominant stands in its native habitat and is widely cultivated throughout the tropics. Here we investigate the introduction, spread, impact and management of this invasive palm in the Fiji Islands, using extensive discussions with local experts and field surveys. *Pinanga coronata* was introduced in the 1970s to the Colo-i-Suva area, eastern Viti Levu island, Fiji´s principal island, and has since become invasive in mahogany plantations and lowland rainforest. It has also been introduced and is becoming invasive on the western side of that island. However, the distribution of *P. coronata* remains geographically limited to the immediate vicinity of introduction sites but it is rapidly spreading. In each location, the species has formed mono-dominant stands in the understorey and appears to be displacing native plant species, as suggested by a negative correlation of its abundance with that of native tree ferns. This highlights the need for rapid control of *P. coronata* in Fiji. Local experts state management should involve manual removal of seedlings and saplings, killing of adult palms by injection of herbicide, and education and legislation to prevent the further spread of the species. Based on these recommendations and field data, management actions to control *P. coronata* are proposed and steps to develop these into a management plan are discussed. Given *P. coronata* threatens native biodiversity in Fiji and has the potential to invade other rainforest ecosystems in the tropics, proposed management approaches are urgent and relevant for other tropical countries.

Keywords: biodiversity loss, biological invasion, island biology, mahogany plantation, management plan, mono-dominant protected area, ornamental

INTRODUCTION

The tropical Pacific islands are highly vulnerable to the impacts of invasive alien plant species because of the region's geographic isolation and evolutionary traits that leave species vulnerable to competition (Gurevitch & Padilla, 2004; Denslow, et al., 2009; Caujapé-Castells, et al., 2010; Woinarski, 2010; Minden, et al., 2010b). The region has the greatest rate of increase in the number of invasive alien plant introductions with respect to area in the world (Van Kleunen, et al., 2015). Furthermore, invasive species are a major cause of extinction on Pacific Islands (Tye, 2009). With increasing economic development in nations of the Pacific, the diversity and impact of invasive plants in the region is likely to increase (Kueffer, et al., 2010).

Pinanga coronata, or ivory cane palm, is an ornamental palm tree that is cultivated and traded throughout the tropics (Palmpedia, 2017). The palm is native to lowland rainforests in Java and Sumatra (Kimura & Simbolon, 2002) and has been identified as a potentially invasive alien plant species on Pacific and other oceanic islands (Meyer, et al., 2008). Introduced to Fiji in the 1970s for its ornamental properties, the palm has become invasive in lowland rainforest and mahogany plantations (Keppel & Watling, 2011) but the current extent of its distribution is unknown. The Fiji Islands have a unique and highly diverse biota that is severely threatened by habitat loss, exploitation, pollution and invasive species (Myers, et al., 2000; Keppel, et al., 2014).

Pacific small island developing states (SIDS) have limited information, funding and trained professionals for invasive species management and conservation in general (Tye, 2009; Keppel, et al., 2012). However, local communities and experts often have extensive knowledge about their environment (Lefale, 2010; Keppel, 2014; Keppel, et al., 2015). In Fiji, expert knowledge plays a crucial role in conservation and protected area management (Keppel, 2014) and has provided important information about the conservation status of rare trees (Keppel, et al., 2015).

Using results from a quantitative field survey and qualitative expert knowledge, we demonstrate that *P. coronata* is threatening biodiversity and displacing native tree ferns in lowland rainforests and mahogany plantations. We then combine these two lines of evidence as the basis for a management framework to address the *P. coronata* invasion and its impact on native biodiversity in Fiji. Acknowledging the current challenges in the Pacific for invasive species management (Tye, 2009), the framework incorporates methods that are economically viable, develops capacity building and promotes awareness for all stakeholders related to the *P. coronata* invasion.

METHODS

Site description

The Fiji Islands include over 300 islands and islets in the western South Pacific (Mueller-Dombois & Fosberg, 1998). Fiji has a tropical climate with a wetter season from November to April and a drier season from May to October. Due to the south-east trade winds orographic rainfall produces higher precipitation in the south-east of topographically more complex islands (Mataki, et al.,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 417–423. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

2006). The capital of Fiji, Suva, is in the south-east of the archipelago's largest island, Viti Levu, and has an average annual rainfall of about 3,000 mm and an average surface temperature of 25.4°C (Mataki, et al., 2006).

The Colo-i-Suva area is approximately 12 km north of Suva (Fig. 1) and has four protected areas. The Colo-i-Suva Forest Park has no legal status but comprises the Colo-i-Suva Forest Reserve (FR; 370 ha) and the Maranisaqa-Wainiveiota FR (77 ha). Adjacent are the Savura FR (448 ha) and the Vago FR (24.7 ha). The area is mountainous and the vegetation communities are fragmented, lowland rainforest and mahogany plantations amongst agricultural and urban landscapes. The Savura and Vago FRs are mostly comprised of lowland native rainforest with minimal disturbance. These FRs constitute a major catchment for the Savura Creek, which secures the water supply for the capital city (Keppel, et al., 2005). Colo-i-Suva Forest Park is a mahogany plantation that has not been commercially logged since its establishment in the 1960s (Tuiwawa & Keppel, 2012). The Forest Park has conservation values because the mahogany plantations support a rich native understorey (Tuiwawa & Keppel, 2012), and is also frequented for recreational activities including local and international tourism (Malani, 2002).

Study species

Pinanga coronata, is native to western Indonesia, on Java and Sumatra where it is abundant in the rainforest understorey and occurs from sea-level to about 1800 m (Kimura & Simbolon, 2002). The species can be found on steep hillsides, lowland flats and exposed ridges, and juvenile palms are found at higher densities on lower slopes and moist areas (Kimura & Simbolon, 2002). Tolerating low light conditions, *P. coronata* forms mono-dominant clusters in the rainforest understorey, where it can reproduce sexually and asexually from vegetative shoots (Kimura & Simbolon, 2002; Kimura & Simbolon, 2003; Witono & Kondo, 2007). *Pinanga coronata* has rapid growth rates, reaches fecundity at <1 m in height, and can then continuously reproduce (Kimura & Simbolon, 2002).

Pinanga coronata has shown signs of becoming invasive in Hawaii and Tahiti (Daehler & Baker, 2006; Meyer, et al., 2008), but is not believed to currently be threatening biodiversity (US Forest Service, 2015). In Fiji, *Pinanga coronata* was introduced to the Colo-i-Suva area on Viti Levu during the 1970s for its ornamental properties

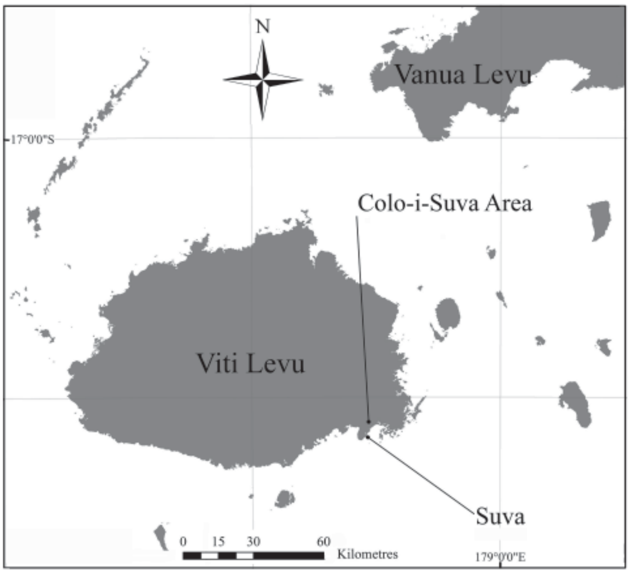

Fig. 1 Study locations on Fiji's largest island, Viti Levu.

(Keppel & Watling, 2011) and was first recognised as a potentially invasive species in 1992 (Watling & Chape, 1992). Since its introduction the palm has become dominant in the understorey of mahogany plantations (Watling, 2005) and invasive in native lowland rainforest, forming mono-dominant stands (mature palms and saplings) of several metres in diameter (Keppel & Watling, 2011).

Interviews

Experts were consulted by the lead author through informal discussions during fieldwork, and in semi-structured interviews in the office from July to September 2016, regarding the invasion history of *P. coronata*. Discussions were open ended but the key themes were the introduction history, distribution and dispersal, impact on native flora and recommended management of *P. coronata*.

Field survey

A systematic field survey was conducted in the Colo-i-Suva Forest Park and Savura FR. The aim was to identify areas of management priority and to determine if *P. coronata* is spreading. Using the Fishnet Tool in ArcMap 10.2.2, a 300 x 300 m grid with 11 columns and 15 rows was overlaid on the boundaries of Colo-i-Suva Forest Park and Savura FR. The centre point of each grid cell was imported into a Garmin Etrex 30® as waypoints. A 5 x 5 m plot was placed at each waypoint within the boundaries of the two forest reserves.

The abundance of *P. coronata* was recorded in ninety-two 5 x 5 m plots in Colo-i-Suva Forest Park (54 plots) and Savura FR (38 plots). The abundance of the palm was determined as the number of mature (stem > 1 m in height), juvenile (>0.5–<1.0 m) and seedling (< 0.5 m) palms, calculated by counting their numbers in each plot. The abundance of tree ferns was estimated by counting the number of mature (caudex > 1 m), juvenile (0.1–1 m) and tree fern saplings (< 0.1 m) (Ash, 1986; Ash, 1987). Additionally, opportunistic sightings of isolated *P. coronata* palms were recorded on a GPS Etrex 30®. Palms were only considered isolated if they were not near other *P. coronata* palms and were not a part of a mono-dominant stand.

RESULTS

Introduction history

Although there are no official records about the exact location and year *P. coronata* was introduced to Fiji, it was likely first introduced to a quarantine station north of Fiji's capital Suva (Fig. 2), for the propagation and trade of exotic palm trees. Palms were likely sold from this location to horticulturalists around Fiji. *P. coronata* is believed to have spread from the site through the surrounding, now cleared, mahogany plantation. Although the quarantine site has been abandoned and is now surrounded by an agricultural landscape, *P. coronata* is still present around the remains of the buildings.

The first official record of *P. coronata* in Fiji is a specimen in the South Pacific Regional Herbarium (number DA 18579) collected from the former Emperor Gold Mine guesthouse at Colo-i-Suva (about 2 km north of the former quarantine station) by Saula Vodonivalu on 16 February 1975. The habitat was described as a roadside and the specimen was flowering, with the tallest palm being approximately seven feet. This specimen originated from plantings around the mine's guesthouse, which were planted for ornamental purposes. This guesthouse was on the site of what is now an agricultural property that grows fresh produce for Joe's Farm supermarkets (Fig. 2). At some stage *P. coronata* was also introduced to a residential property within the interior of Colo-i-Suva Forest Park, which had a diverse collection of exotic ornamental plant species. This garden is still private property but the lease will return to the Ministry of Fisheries and Forests.

Distribution and dispersal

We believe that the distribution of *P. coronata* is currently restricted to the Colo-i-Suva area but is spreading rapidly. Our observations record that the species has now spread through the Savura and Vago FRs, occupying a total area of about 1,500 ha, and is most dense in the mahogany plantations near Joe's Farm and in the north of Colo-i-Suva Forest Park (Fig. 2).

P. coronata is cultivated ornamentally in several gardens in Suva, including the University of the South Pacific, Laucala Campus. It has escaped from cultivation in and around the Garden of the Sleeping Giant near Nadi Airport, on the western side of Viti Levu (Fig.1) and is distributed as an ornamental by landscapers and horticulturists in Suva and across Fiji, especially to hotels and tourism resorts. No estimates of the numbers of palms dispensed is available.

Within Colo-i-Suva Forest Park, we observed *P. coronata* to be most dense along streams and watercourses. We believe that one means of dispersal for the species is by seeds falling into waterways leading to establishment downstream. Once established near streams, *P. coronata* probably expands its distribution by moving up slopes bordering water courses.

Birds are believed to disperse *P. coronata* seeds. DW found a *P. coronata* seedling sprouted in his garden approximately nine kilometres from the introduction locations and main infestations. In the Colo-i-Suva area (Colo-i-Suva Forest Park and Savura FR) dense patches of *P. coronata* seedlings are commonly found below the canopy of tall native (especially *Gymnostoma vitiense*; Casuarinaceae) and exotic trees (*Maesopsis eminii*; Rhamnaceae) used as perching locations by native members of the Columbidae family, suggesting that fruits are eaten by birds that forage in the lower canopy and understorey . The island thrush, (*Turdus poliocephalus*) and the red-vented bulbul (*Pycnonotus cafer*) are likely dispersers in mature and open/edge forests, respectively.

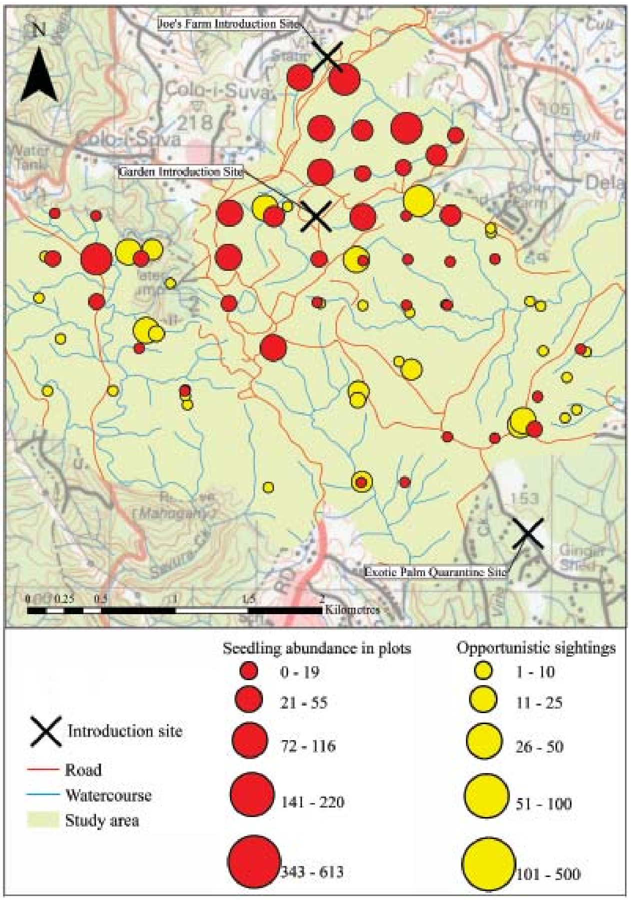

Fig. 2 The distribution of palm seedlings in plots and isolated populations in Colo-i-Suva Forest Park and Savura Forest Reserve.

Impact on native flora

We found mono-dominant stands of *P. coronata* in the understorey around all introduction sites in the Colo-i-Suva area. In the north of Colo-i-Suva Forest Park, *P. coronata* comprises up to 70% of the understorey and is outcompeting native understorey plants, especially tree ferns, and reducing their sapling regeneration (Mathieu 2015). Similarly, the palm is also abundant and outcompeting native species in the understorey of lowland rainforests. Therefore, *P. coronata* is considered to have the potential to become dominant and outcompete native plant species in Fiji's native lowland rainforests.

Pinanga coronata was present in 54 % of the plots surveyed in Colo-i-Suva Forest Park and 17 % of plots in Savura FR. It was mono-dominant in the understorey of 19 plots (21 % of all plots), 18 of which were in the north of Colo-i-Suva Forest Park (dominated by mahogany plantations) and the other was in the north of Savura FR (consisting of native lowland rainforest). Visual inspection of the distribution map (Fig. 2), shows the highest density near putative source locations and several isolated populations in both forest reserves.

Palm cover in the understorey displayed a strong negative correlation with all three tree fern classes, tree fern saplings ($\rho \geq -0.26$, $p < 1.2 \times 10^{-2}$), juvenile tree ferns ($\rho \geq -0.38$, $p < 3.7 \times 10^{-4}$) and mature tree ferns ($\rho \geq -0.33$, $p < 1.7 \times 10^{-3}$). With increasing palm cover in the understorey, the abundance of tree ferns decreased, especially when palm cover exceeded 50 % (Fig. 3). Therefore, results from the plots surveyed reinforce our field observation-based belief that *P. coronata* is displacing native species.

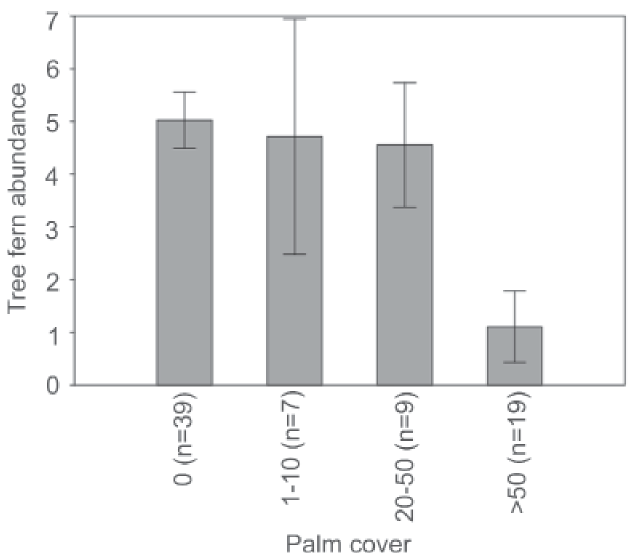

Fig. 3 The comparison of tree fern saplings and palm cover in the understorey. Tree fern abundance on the y-axis and palm cover on the x-axis. n = number of plots in the class.

Recommendation to manage *Pinanga coronata*

We believe that *P. coronata* must be listed as a pest species and be controlled as a matter of urgency. Control could be via manual removal of *P. coronata*, starting with seedlings and juvenile palms in isolated populations. Chemicals may be required to kill adult palms, because they are difficult to remove and the species can reproduce vegetatively from the base. The exotic tree *Maesopsis eminii*, which is spread throughout the Colo-i-Suva Forest Park, may need to be controlled concurrently, as this tree attracts frugivorous birds and *P. coronata* seedlings are often abundant at its base.

There also needs to be action to stop further propagation and reintroductions by horticulturalists. Furthermore, education for communities, tourism operators and the Biosecurity Authority of Fiji about the palm and its threats to native biodiversity is essential to solicit maximum support from the public and the government.

DISCUSSION

In our study, qualitative and subjective data are supported and reinforced by quantitative and objective field data. Combined, these results make a strong case that *P. coronata* is continuing to spread through mahogany plantations and native lowland rainforest in the Colo-i-Suva area. Both observations and a negative correlation between the abundance of palms and native tree ferns suggest that the introduced palm is displacing native tree ferns. Hence, both expert opinion and field data demonstrate the detrimental impact and potential threat of *P. coronata*, highlighting the need for swift and effective management actions.

However, before any management can be effectively implemented, knowledge of the exact distribution of *P. coronata* (Panetta & Lawes, 2005) and consensus among key stakeholders about the need for urgent management is needed. Knowing the palm's distribution in the Colo-i-Suva area will not only define the target area for management but also determine the stakeholders that need to be involved. Support from the most influential stakeholders will be essential for establishing and implementing a successful conservation and management plan (Keppel, et al., 2012; Moon, et al., 2015; Lenz, 2016). All major stakeholders, especially the Fiji Forestry Department and Biosecurity Authority of Fiji, need to agree that *P. coronata* is a major threat to native biodiversity and an urgent management priority. Assuming that these pre-requisites will be attained, we propose a management framework (Table 2) using a decision and risk analysis based on our knowledge and available quantitative data (Maguire, 2004; Stohlgren & Schnase, 2006; Lenz, 2016). We hope that proposing this framework will hasten the development and implementation of an effective management plan.

Management framework

Considering the high threat of *P. coronata* to native biodiversity and that its distribution is still relatively restricted, the overarching aim of a management plan should be to eradicate the species (Keppel & Watling, 2011). Eradication is defined as the total removal of all individuals, including seeds, and ensuring that reintroduction will not occur (Myers & Bazely, 2003; Meyer, 2014). However, there have been very few successful invasive plant eradications in the Pacific Islands and these were restricted to species confined to small geographic areas (Meyer, 2014). Additionally, eradication is not achievable without containment (Panetta & Lawes, 2005). Therefore, a feasibility study combining the known biological information of *P. coronata* with the total extent of the invasion (invasion syndrome) will need to be conducted to determine if eradication is achievable with the resources available (Panetta, 2015). Due to this uncertainty about the feasibility of eradication, we focus our discussion about management on control measures to reduce the abundance and spread of *P. coronata*.

Prior to control, stakeholders including the Ministry of Fisheries and Forests, NatureFiji-MareqetiViti (NFMV) and the University of the South Pacific (USP) should develop a management plan. The framework presented here could serve as a starting point. Coordinated efforts by multiple parties will be more efficient (Stohlgren & Schnase, 2006) and have a greater chance of success when decision makers for protected areas support the strategy (Foxcroft, et al., 2008). The involvement of NFMV is important because they have a strong record of effectively engaging with communities and decision-makers to achieve positive conservation outcomes (Morrison, et al., 2012). It is recommended that NFMV be the primary coordinators because invasive species management facilitated by a non-governmental organisation (NGO) that promotes education and stakeholder communication has greater chances of success (Epanchin-Niell, et al., 2010).

The second stage of management should aim to investigate the best method to control *P. coronata* through a feasibility trial. Currently there is a paucity of information on best practice for palm control (Meyer, et al., 2008) and most methods are species-specific (Langeland, et al., 2011). A pre-control feasibility study is necessary to determine which method will be the most effective (Meyer, 2014), as we have outlined in Table 1. Physical removal of palm seedlings is one of the methods to be trialled, as this has been shown to be successful at reducing seedling and juvenile abundance (Langeland, et al., 2011).

Table 1 Recommended control measures for *P. coronata* that should be trialled in a feasibility study based on literature on invasive palm management (Dovey, et al., 2004, Langeland & Stocker, 1997, Langeland, et al., 2011) and opinions from the authors. Suggestions from literature = LT and opinion from experts = AU. *Biocontrol is mentioned because it could be a successful control method if an appropriate control agent is found. However, biocontrol is not recommended at this stage and should only be considered if all other methods are ineffective and not feasible.

Management aim	Age target	Method
Control	Seedlings and juveniles	Hand pulling and removed from the area [AU]
Control	Seedlings and juveniles	Hand pulling and tied to a tree [AU]
Control	Mature individuals and clumps	Crown removal and apply herbicide to the stem [LT and AU]
	Mature individuals and clumps	Inject herbicide into the apical bud [LT]
Reduce seed load	All fruiting palms	Removal of flowers [LT]
Control		Biocontrol*[LT]

Table 2 Summary of the recommended management framework proposed to control *P. coronata* in the Colo-i-Suva area, on Viti Levu, Fiji. NFMV=NatureFiji-MareqetiViti.

Aim: Control *P. coronata* in the Colo-i-Suva area, on Viti Levu, Fiji	
Objectives	**Actions**
STAGE 1: Producing a management plan through stakeholder communication	
Create a management plan through stakeholder engagement NFMV to formalise the management plan and education programmes	Facilitate a formal discussion between stakeholders to develop a management plan. Develop an education programme for stakeholders and the community. Formalise a regular method for communication between stakeholders.
STAGE 2: Pre-control feasibility study	
Conduct a pre-control feasibility study	Trial different control methods (Table 1).
STAGE 3: Control *P. coronata* in the Colo-i-Suva area	
Control *P. coronata* in the Colo-i-Suva area	Target isolated and juvenile *P. coronata* populations. Remove the low-density populations in the centre and south-east of Colo-i-Suva Forest Park. Progressively control palms towards the dense populations in the north of the Colo-i-Suva area Simultaneously reduce the seed load and foliage area in the dense populations in the north of the reserves.
STAGE 4: Post-control monitoring and reducing the threat of reinvasion	
Post-control monitoring** Reduce the threat of reestablishment**	Periodically monitor areas where *P. coronata* has been controlled and investigate responses in native vegetation. Plant native tree ferns in areas that are vulnerable to reinvasion and monitor propagation success.
STAGE 5: Prohibiting the trade of *P. coronata* in local horticulture	
Ensure that *P. coronata* is not reintroduced into the natural environment	Ban the trade of *P. coronata* in the horticulture and tourism industries. This will require the species to be listed as a pest with involvement from the Biosecurity Authority of Fiji. Find a native non-invasive palm that can replace the trade of *P. coronata*.

**Stages three and four should be conducted simultaneously. After control efforts have removed isolated palms monitoring should take place before the dense *P. coronata* populations are managed.

There are two approaches commonly used with herbicide applications for managing clonal palms that should be trialled. The first method is cutting the palm below the crown and treating the cut stem with herbicide and the second method is injecting herbicide directly into the palm's apical bud (Langeland & Stocker, 1997). In Indonesia, densities of the invasive palm *Arenga obtusifolia* decreased and native rainforest vegetation successfully regenerated, when the palm was injected with herbicide (Konstant, 2014; Nardelli, 2016). A combined approach of applying chemical herbicides and physical removal could be implemented but has had varied success for palm species, like *P. coronata*, that can vegetatively reproduce (Langeland & Stocker, 1997; Langeland, et al., 2011).

After determining the most effective method, the third stage of management should attempt to control the spread and reduce the distribution of *P. coronata*. We consider that juvenile plants in isolated populations should be controlled first. Prioritising low-density populations will be the most efficient at containing the invasion and reducing the threat to endemic, rare and threatened plant species without significantly increasing the cost (Higgins, et al., 2000). Targeting mature and juvenile individuals in isolated populations is a recommended strategy for other invasive plants in the Pacific Islands and likely to be more successful than removing large stands (Meyer, et al., 2011).

Although not recommended as an initial control method for *P. coronata*, biocontrol may be required if physical efforts fail to control the spread. Dovey, et al., (2004) recommends the use of biocontrol in the Pacific Islands because it is resource efficient and can strengthen stakeholder partnerships. Biocontrol is typically applied when the distribution of an invasive plant is too large to be controlled by physical methods but is expensive and requires time-consuming host-specificity tests to ensure native plants from the same family will not be negatively affected (Meyer, 2014). However, reduced foliage cover of an invasive tree due to biocontrol has resulted in the regeneration of understorey species in other Pacific Island rainforests (Meyer, et al., 2012).

Monitoring (stage 4) should take place as control efforts (stage 3) of the different *P. coronata* populations progress. It is critical that management efforts are long-term and control sites are periodically monitored to ensure that the palm does not regenerate from its seed bank, the longevity of which is currently not known, and to understand changes in the vegetation community in response to efforts (Blossey, 1999; Foxcroft, et al., 2008). When invasive alien plants are removed from Pacific rainforests follow-up control efforts are often required (Minden, et al., 2010a, b).

Management should aim to stop *P. coronata* reinvading controlled areas. In healthy native forest ecosystems, the succession by native flora will naturally occur, but management may be required to reduce the likelihood of invasive plants re-establishing (Awanyo, et al., 2011). Planting native species is an expensive but effective method of reducing the risk of reinvasion (Langeland, et al., 2011). In the Colo-i-Suva region, planting tree ferns could be a novel and appropriate approach to reduce the likelihood of *P. coronata* re-establishing, because tree ferns are native and abundant in the area, especially on disturbed sites (Tuiwawa, 1999; Keppel, et al., 2005).

The final stage is to ensure that *P. coronata* is not introduced into the environment again. This would require the species to be listed as a pest plant under legislation outlined in the Biosecurity Promulgation 2008 act (Biosecurity Authority of Fiji, 2008), ideally at the beginning of the management process to provide legal support for any efforts (Lenz, 2016). Adequate enforcement of the legislation may require training and improved technical expertise within Biosecurity Authority of Fiji. Current palm stocks in local nurseries and ornamental plantings should be identified and controlled to ensure that *P. coronata* is not reintroduced (Meyer, et al., 2008; Lenz, 2016). The latter will be difficult on privately owned properties. Involving the horticultural industry is fundamental for success because they are integral in preventing continuous reintroduction through ongoing plantings (Meyer, et al., 2008).

CONCLUSION

Our opinions and field data agree on the considerable threat that *Pinanga coronata* is posing to native biodiversity. They also show that the palm is expanding its distribution and spreading into native rainforest ecosystems. There is little doubt that it will continue to do so, unless it is effectively and swiftly managed. Such management would require a thorough and effective management plan suitable to the SIDS in the Pacific and developed through participation by all key stakeholders. Given the evidence that the palm is threatening biodiversity, we propose a framework that could serve as a roadmap for developing and implementing a management plan.

ACKNOWLEDGEMENTS

We would like to thank the following people and organisations: NatureFiji-MareqetiViti and Environmental Consulting Fiji for support and design of the management framework. Robert Aebi from University of South Australia for logistics, occupational health and safety advice. Sherri Lodhar, Geon Hanson and Sunil Gopaul for support and fieldwork assistance. University of the South Pacific and staff from the Institute of Applied Science (IAS) for resources. The research was conducted with permission from and support of the Ministry of Fisheries and Forestry, Fiji. A New Colombo Plan Scholarship through the Department of Foreign Affairs and Trade of the Australia Federal Government provided financial support for Michael Dyer to live and study in Fiji. Gunnar Keppel was supported by an Alexander von Humboldt fellowship.

Abstract The South Georgia ecosystem-based habitat restoration project is a major project that began with the eradication of invasive rats (*Rattus norvegicus*) and reindeer (*Rangifer tarandus*), 2011–2017. As part of this restoration programme a non-native plant management strategy was developed and implemented. With only 8% of the whole South Georgia landmass suitable for vascular plants (ca. 283 km²) due to permanent ice and bare rock, there have been 25 indigenous vascular plants and 41 non-native plants recorded from earlier surveys. Following removal of grazing pressure from introduced mammals, surveys were conducted to quantify the current status and distribution of non-native plant populations and enable a non-native plant control strategy to be developed for the island. Due to the vast scale of the island, multiple seasons were required to carry out rapid surveys of key indicators such as species, area of plant coverage in square metres and age class (mature or juvenile). Survey and control data were entered into a spatial database to enable analysis, allow data-informed management decisions and be used for long-term control-based monitoring of outcomes. During this series of surveys, 44 naturalised, non-native plant species were identified and mapped. Of these, 34 species are now being managed at zero density with 56,851 m^2 at 184 sites controlled to date; four are managed at specific sites with 22,443 m^2 controlled to date, three require confirmation of species and the remaining three species are widely established and receive limited control. Spatially quantifying the distribution and control of non-native plants has enabled the development and implementation of an effective management strategy which contributes to the restoration of South Georgia's native biodiversity.

Keywords: Atlantic Ocean, control-based monitoring, habitat restoration, non-native plants, South Atlantic, South Georgia

INTRODUCTION

South Georgia (3,533 km², 54°21' S, 36°42' W) is located in the South Atlantic Ocean approximately 1,450 km south-east of the Falkland Islands (Fig. 1). South Georgia is a United Kingdom Overseas Territory (UKOT) managed by the Government of South Georgia and the South Sandwich Islands (GSGSSI). The island is mountainous and glaciated, and it is only the coastal fringes that are snow free in the summer months and able to support vegetation. An estimated 8% of the land mass of South Georgia (i.e. 283 km²) provides suitable habitat for vascular plants (GSGSSI GIS, 2007) and, in spite of the sub-Antarctic climate, many non-native species have naturalised or persisted for many years.

The first non-native plant species recorded on South Georgia was *Poa annua* in 1902 (Walton, et al., 1973) and this may have been introduced with early sealing expeditions. Increasing disturbance due to the activity of shore-based whaling operations after their establishment from 1904 (Burton, 2012) likely contributed to many of the later introductions. Greene (1964) classified 51 vascular species for the island with 24 as listed as native and 27 as non-native or introduced. There are now considered to be 25 native vascular species with the addition to Greene's list of the hybrid *Acaena magellanica* × *A. tenera* (Galbraith, 2011; Burton, 2012)

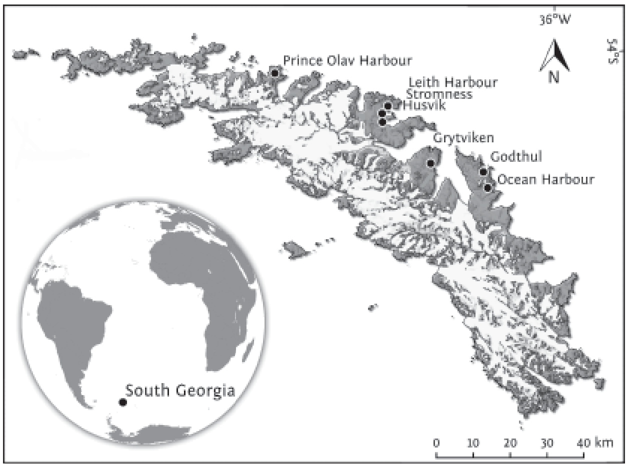

Fig. 1 Location of South Georgia Island and main whaling station locations on the island.

Osborne, et al. (2009) recorded 24 introduced vascular plant species during the survey undertaken in 2009 as part of the Royal Society for the Protection of Birds (RSPB) South Atlantic Invasive Species Project.

Local management of selected non-native plant species on South Georgia has been undertaken since 2004 when efforts to control bittercress (*Cardamine glacialis*) were initiated. In 2010 the efforts to control bittercress were increased and other non-natives were targeted at selected sites (GSGSSI, 2016).

In 2014, GSGSSI obtained funding from the UK Government-funded Darwin Plus initiative (www.darwininitiative.org.uk) for the project 'Strategic Management of Invasive Alien Plants on South Georgia'. This project enabled a more strategic approach to island-wide non-native plant control. As well as on-going control of low incidence species, comprehensive surveys were completed and the distribution and range of non-native plant species on the island were mapped. This paper outlines the processes that were undertaken to determine the extents of non-native plant species to support the development of a non-native plant management strategy for the island.

METHODS

Desktop review

The first step to determine the plant species present was a desktop review of all documents available that had location information for non-native species recorded on

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 424–429. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

South Georgia. These included published and unpublished reports, herbarium records, and personal communications with researchers, staff and visitors. Many of these records had limited spatial accuracy and were recorded by general location only, which restricted the ability to map these records. Osborne, et al. (2009) had good spatial data for the sites they visited although they had not been able to access the restricted areas in some of the historic whaling stations. All the records found in the desktop review were compiled into a filterable dataset which generated a species list by locality which was then checked for presence/absence during any visits to that area. This dataset provided the initial non-native plant species list and search targets, with more recent records given a higher search priority. While not many of these records were very accurate spatially they gave a good starting point for surveying.

Field surveys

Using the compiled historical records, surveys were undertaken to obtain accurate information on the current abundance and distribution of non-native plant species in each search area. Priority survey locations were given to those with recent records, areas of human disturbance particularly whaling stations, and where reindeer had been present. All the surveys were conducted on foot with access to some areas, where required, provided by ship or small boat.

A rapid GPS survey technique was used to cover the large areas involved. The resolution for survey points was based on plant population size whereby the larger the population, the further apart points were recorded to reduce the time required for recording. GPS waypoints were taken at the centre of each non-native plant infestation with separate waypoints for each species present. Key indicators for each waypoint were recorded i.e. the plant species, the area of plant coverage in square metres, and age class (mature or juvenile not capable of reproduction). Coverage was estimated from the ground cover of the infestation, and is the ground area covered by the plant if forming a monoculture. In the case of scattered plants the percentage cover is used to estimate the total square meters of the infestation.

From the spatial information collected non-native species were classified into 5 classes depending on population size and distribution (Table 1). Rather than determine whether a non-native species was likely to be invasive, the precautionary principle (Williams, 1997) was adopted and all non-native vascular plants have been classified as part of the strategy.

The main surveys were conducted in February–March 2015 and in February–March 2016, when most non-native plants were in flower; this made it easier to assess distribution, and the flower structures provided the diagnostic characteristics to differentiate non-native species from closely related native plants.

Accurate geographical coordinates were essential for relocating infestations; coordinates were recorded using hand-held global positioning system receivers (Garmin GPS62 & 64). To manage these data a GPS Exchange Format file (gpx) import and export capability was developed in the recording database to facilitate data storage and display. Data were collected continuously during different control and survey visits as weather and logistics allowed more time to check areas more thoroughly. Additional data were collected where necessary during these visits to improve spatial knowledge of the infested areas and outlier plants.

Control based monitoring

Along with surveys, control was undertaken on selected known sites and all control activities were recorded using the same key indicators that had been used during survey data collection (GPS coordinates, coverage in square metres and age class), with the addition of the type of herbicide, the application rate used, and the volume of water used.

Management units

In order to manage the site-led control of Class Two species, South Georgia was divided into 117 management units. The management units were determined by a two-step process; firstly the island was divided into eight eco-geographic zones, defined primarily by climate, vegetation and the historic presence of introduced mammals (Martin, et al., 2009). For the purpose of non-native plant management, these zones were further divided into smaller units based on the level of historic human disturbance, presence of non-native plants, geographical features and ease of logistical access.

RESULTS

South Georgia's vegetation is mostly short grassland or low-growing rush and sedge communities, apart from the tall stands of coastal tussac (*Parodiochloa flabellata*). Many of the non-native plants are also low-growing which makes detection very difficult; persistent surveying is required to locate all individuals. Sometimes a number of visits are needed as many species are not very visible until flowering, and timing is critical to finding and controlling these species before seed becomes viable. New infestations and new non-native species have also continued to be found which highlights the need for persistent surveys. Due to the size of the island, multiple seasons were required to survey the priority areas. Following repeated surveys between

Table 1 Classification of non-native plants on South Georgia and number of non-native plants in each weed strategy class.

Class	Description	Number of species
One	Priority species; require species-led control at the island-wide level, to control all plants before they reach maturity. All sites with these species have a 'Site Tag' in the Weeds Database, for management of follow-up visits.	34
Class Two – Site-Led	Species of moderate distribution, requiring site-led control. Priority populations are those at high-use visitor sites, and sites with small infestations where control will reduce further dispersal.	4
Class Three – Site-Led	Species which are widespread and abundant, and require management at high-use visitor sites and at some remote outlier sites where appropriate.	3
Research	More information required before classification, to confirm status.	3
Historic	Historic species, not seen for at least 10 years. A re-sighting promotes the species to Species-Led – Class One.	35

2014 and 2017, we consider there to be 44 non-native species present on the island or that have recent records from the last 10 years, with a further 35 species recorded historically but no longer present (Appendix 1).

There have now been 4,245 non-native survey locations recorded to date. Following the survey these non-native species have been classified depending on population size and distribution (Table 1).

From the survey results a non-native plant management strategy (GSGSSI, 2016) and an associated environmental impact assessment were developed. In line with GSGSSI requirements, these documents were peer-reviewed to ensure they met best practice standards. After their finalisation, more widespread control of non-native plant species was undertaken across the island.

There are 34 Class One species occurring at 184 control sites; these are managed on a species-led basis by targeting them across their entire known range on South Georgia. Each of the Class One species is managed at zero density whereby all plants are controlled where found.

Fig. 2 shows the small increase in new Class One sites found and treated each season, along with the proportion that were active (some plants found) and not active (no plants seen at that site that season).

Control-based monitoring data show that 49,202 m^2 of Class One species have now been controlled on South Georgia with 850 m^2 of follow-up required in 2016/17 (Fig. 3). The majority of the treated species controlled in 2015/16 were *Rumex acetosella* since this was the most widespread Class One species and control was undertaken only once the full extent of the infested area of this species was known after surveys that season.

There are currently four Class Two species with 221 control locations, these records total 44,903 m^2 of plants treated over the seasons shown in Fig. 3.

DISCUSSION

Spatially quantifying the distribution and control of non-native plants has enabled the development and implementation of the 'South Georgia Non-Native Plant Management Strategy 2016-2020' (GSGSSI, 2016) which contributes to the restoration of South Georgia's native biodiversity.

Control of Class Two species is prioritised according to the potential dispersal risk posed by small populations and the threat they present to surrounding areas. Spatial data from the surveys overlaid with the units was essential in presenting this information to enable decision-making for the strategic management of the surveyed species.

There were 44 non-native plant species detected during the surveys and of these, 34 are currently being controlled using a range of methods with the aim being to eradicate them from South Georgia. Many remote areas have not been able to be visited yet, and although the risk of non–native infestations at these sites is considered to be low, based on historic records, all the vegetated areas of the island will eventually need to be surveyed. This may take many years due to the logistical difficulties of accessing the island's remote areas.

To ensure success of the non-native plant strategy, persistence is required in treating all target plants until their seed bank is fully diminished. Control-based monitoring will assist in determining success by utilising the data recorded on plant coverage, age class, herbicide rates and volumes in order to measure progress season by season.

We are confident that most of the non-native species and infestations have now been located. However, due to the large size of the areas to be searched, new records are not unexpected and the weed strategy has been designed to be adaptive based on the data available.

While all high priority areas for non-native species have now been surveyed, continued checks will be required to ensure all infestations are located around the island. Also, as vegetation communities are likely to recover from grazing following the reindeer eradication, further searches for non-native plants will be required across the estimated 4,500 ha of vegetated landscape on the Barff Peninsula and in the Stromness Bay area (3,250 ha) where the reindeer were present.

Monitoring new incursions and unknown infestations will be ongoing and this persistence can be achieved only if there is a long-term commitment to providing necessary resources, as is currently the case with the present control programme funded by the Government of South Georgia and the South Sandwich Islands.

Timeliness is also vital for ensuring that populations are successfully controlled. All control operations and surveys must take place during the optimum time for locating and treating non-native targets. For South Georgia, this is between December and February.

Accuracy is also essential, all target species need to be spatially documented using GPS waypoint data to aid in re-locating plants. While there are some small differences in estimating plant coverage by observers, regular comparisons between people improve accuracy and consistency of

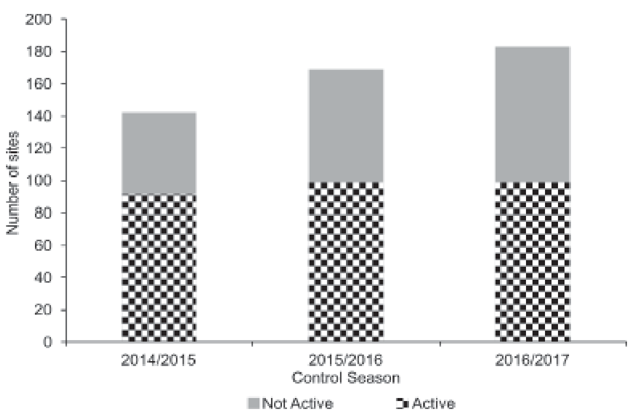

Fig. 2 Number of Class One non-native plant sites on South Georgia 2014–2017.

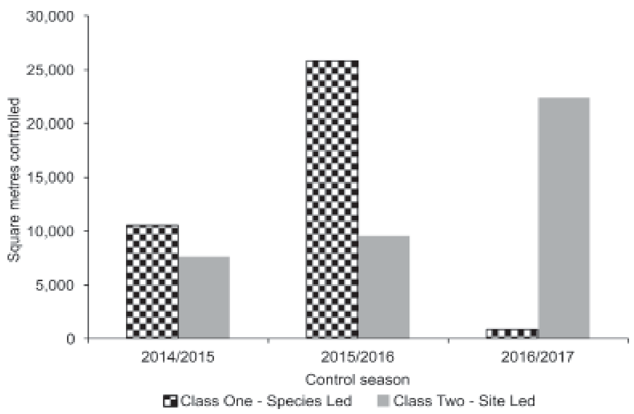

Fig. 3 Area of Class One and Class Two non-native plant sites controlled on South Georgia over the last three seasons (2014/15–2016/17).

measuring. Having data in quantifiable measures allows changes in the size and number of infested areas to be monitored as control efforts are undertaken. Control-based monitoring provides quantitative information for managing the target species and enables the comparison of control and survey data. This information will assist with further refinement of the management strategy and enable data driven decision making.

Finally, as with all eradication projects, strong biosecurity to prevent new introductions to South Georgia and the movement of already established non-native plant species between areas is essential. In South Georgia, there is a wide range of biosecurity measures in place from cargo packing facilities in the UK and mandated equipment cleaning before every landing to a bespoke biosecurity facility on the island itself. Ongoing education and awareness raising is key to ensure that all visitors to the island are aware of their biosecurity obligations and the vital role it plays in protecting native biodiversity.

ACKNOWLEDGEMENTS

We would like to thank South Georgia based Government Officers, particularly Keiron Fraser and Pat Lurcock, for their support and Stanley based GSGSSI staff, in particular Richard McKee. Thanks also to Sarah Browning for assistance in the field, to FPV *Pharos SG* for ship support and Sanfords New Zealand for transporting equipment. The contributions of British Antarctic Survey staff at South Georgia and Cambridge, in particular Helen Peat, and those of Rebecca Upson and Colin Clubbe of Royal Botanic Gardens, Kew and Eilidh Young of the Darwin Initiative Fund are gratefully acknowledged, as is the logistical support provided by HMS Clyde and IAATO member vessels who kindly assisted in getting project members to and from South Georgia.

Abstract The invasive tree *Miconia calvescens* (Melastomataceae) is a priority for control on the Hawaiian Island of Oʻahu due to its potential to replace native ʻōhiʻa (*Metrosideros polymorpha*, Myrtaceae) forests and degrade watershed function if allowed to establish. The Oʻahu Invasive Species Committee (OISC) is attempting to eradicate this species from the island of Oʻahu. OISC uses a buffer strategy based on estimated seed dispersal distance to determine the area under surveillance. This strategy has worked well enough to suppress the number of trees reaching reproductive age. The number of mature trees removed annually is now less than the number initially removed when the programme started in 2001. In 2016, just 12 mature trees were removed from 54.71 km^2 surveyed compared to 2002, when 40 mature trees were removed from 8.26 km^2 surveyed, a 96% drop in mature trees per square kilometre surveyed. However, miconia has a long-lived seed bank and can germinate after 20 years of dormancy in the soil. Funding shortages and gaps in surveys due to refusal of private property owners to allow access have resulted in some long-range extensions. OISC's results suggest that seed bank longevity is an important factor when prioritising invasive species risk and that allocating more resources at the beginning of a programme to eradicate a species with long-lived seed banks may be a better strategy than starting small and expanding.

Keywords: invasive species, invasive plants, watershed, outreach, cloud water interception, *Miconia calvescens, Metrosideros polymorpha*

INTRODUCTION

The tree miconia (*Miconia calvescens* – Melastomataceae) has been recognised as a threat to forests on Pacific Islands where it has been introduced (Meyer, et al., 2011; Medeiros, et al., 1997). Native to tropical Central and South America, it is under control programmes in French Polynesia, New Caledonia and Hawaiʻi (Meyer, et al., 2011). In areas where miconia has invaded, it has formed monospecific stands, shading out all plant species beneath it (Meyer, 1996). A miconia-dominated forest would likely not perform watershed services as well as Hawaiʻi's multi-layered native forests. Runoff and water would likely increase and replenishment of the islands' freshwater aquifer through cloud water interception would likely decrease. (Nanko, et al., 2013; Takahashi, et al., 2011). Because of its potential to outcompete native forest flora and its potential deleterious effects on watershed function, miconia has been prioritised for eradication on the Hawaiian Island of Oʻahu. Miconia was introduced to Oʻahu at the Wahiawā botanical garden in 1961 (Medeiros, et al., 1997). It was not until the late 1990s that its invasive potential became known and efforts to control it began (Medeiros, et. al., 1997). Here we describe the results of the island-wide eradication programme for miconia implemented by the Oʻahu Invasive Species Committee (OISC) since 2002.

The Koʻolau Range forms the eastern spine of the island of Oʻahu and is the location of the island's primary aquifers supplying water to the urban centre of Honolulu (Board of Water Supply, 2016). Data from miconia's native and invaded ranges shows that this species occurs in tropical areas with more than 1,500 mm of rainfall (Libeau, et al., 2017). Oʻahu rainfall data indicates that most of the Koʻolau Range, including the areas encompassing the island's most important aquifers, could support miconia (Giambelluca, et al., 2013).

Miconia's potential to replace forest ecosystems with monospecific stands is evident from its invasion history in French Polynesia (Meyer, et al., 2011). There, dense stands occur over 80,000 ha from sea level to 1,400 m (Meyer, et al., 2011). To put those numbers in perspective, the forested area of the Koʻolau Mountains is approximately 40,469 ha and its highest peak is 960 m (Koʻolau Mountain Watershed Partnership, 2017). The rainfall and elevation of the Koʻolau Range are similar to those areas in Tahiti where miconia has formed monospecific stands and is therefore vulnerable to the transformative effects of a miconia invasion (Fig. 1).

Miconia leaves can reach up to one metre in length (Chimera, et al., 2000) (Fig. 2). These large leaves reduce light levels so dramatically that understorey and groundcover vegetation under a miconia canopy are severely reduced (Meyer 2004; Nanko, et al., 2013). Rainwater collects on the large leaves and funnels it to

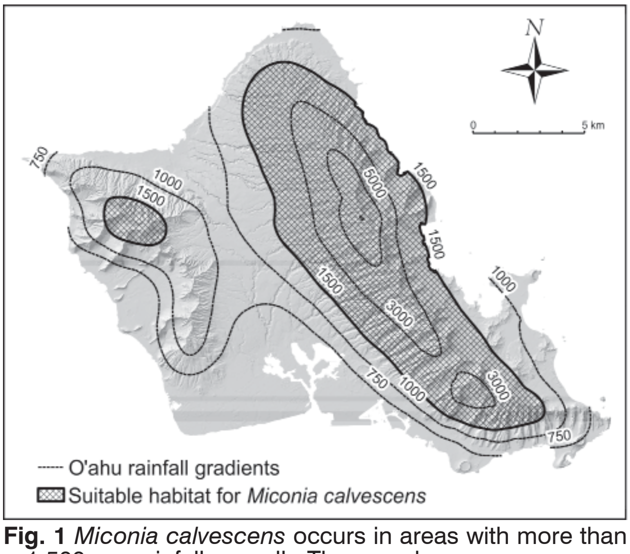

Fig. 1 *Miconia calvescens* occurs in areas with more than 1,500 mm rainfall annually. The area shown encompasses almost all of the Ko'olau mountain range on the eastern side of the island. (Rainfall data from Giambelluca, et al., 2011)

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 430–434. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

the bare ground with a velocity high enough to accelerate erosion when hitting bare ground (Nanko, et al., 2013).

Water recharge of the island's aquifers may also be at risk. A study on Hawaiʻi Island found that native-dominated ʻōhi'a forest intercepted 454 mm more cloud water than strawberry guava (*Psidium cattleyanum* – Myrtaceae) dominated forests due to the differences in bark structure and tree shape (Takahashi, et al., 2011). Miconia has smooth bark similar to strawberry guava and would likely have similar rates of cloud water interception. This is important as cloud water interception may contribute up to 32% of total precipitation in Hawaiʻi's montane wet forests (Giambelluca, et al., 2011). Based on these studies, we surmise that a structurally complex, native forest is likely better at condensing fog and cloud drip and directing rain into the islands' aquifer than a forest dominated by monospecific stands of miconia.

CONTROL OF MICONIA ON OʻAHU

Control of miconia in the Hawaiian Islands began in 1991 after scientists and conservationists saw the damage it was causing in Tahiti (Medeiros, et al., 1997). On Oʻahu, miconia was planted at three botanical gardens, at two private residences and a commercially operated park (Medeiros, et al., 1997). All voluntarily destroyed their trees when requested by the state Departments of Agriculture (HDOA) and Land and Natural Resources (DLNR). Follow-up surveillance and control were conducted by volunteers and HDOA and DLNR employees until the Oʻahu Invasive Species Committee was formed as a project of the University of Hawaiʻi in 2001.

The miconia eradication project strategy is based on delimitation, defined as conducting enough surveillance to be sure that we know how far the invasion extends; containment, defined as containing the population by removing plants before they can mature; and extirpation, defined as removing immatures until the seed bank is exhausted (Panetta & Lawes, 2005; Panetta, 2007). In order to achieve the benchmarks of delimitation, containment and extirpation, OISC designates areas within a certain radius around reproductive trees for ground or helicopter surveys and conducts outreach to property owners and outdoor enthusiasts. The search area is currently at 91.39 km^2 and encompasses 4,000 different private property lots for which we must acquire permission to access in order to survey (Fig. 3).

Ground surveys are conducted for 800 m around every mature tree and 500 m around every immature tree every three years. The 500 m or 800 m radius around trees is called the ground buffer. An analysis of OISC's miconia field data shows that 99% of immature trees fall within 350 m of a mature tree (Fujkawa, pers. comm. 2017), confirming that the size of the search area is large enough.

Fig. 2 Typical leaf size for *Miconia calvescens*.

The frequency interval of every three years is necessary since miconia can mature in as little as four years (Meyer, 1996). Areas within this 800 m ground buffer that are too steep to survey by ground are surveyed by helicopter every two years.

Ground crews locate miconia visually during both ground and air surveys. In addition to their large size, miconia's leaves have vibrant purple undersides and this makes it fairly easy to detect on both types of surveys

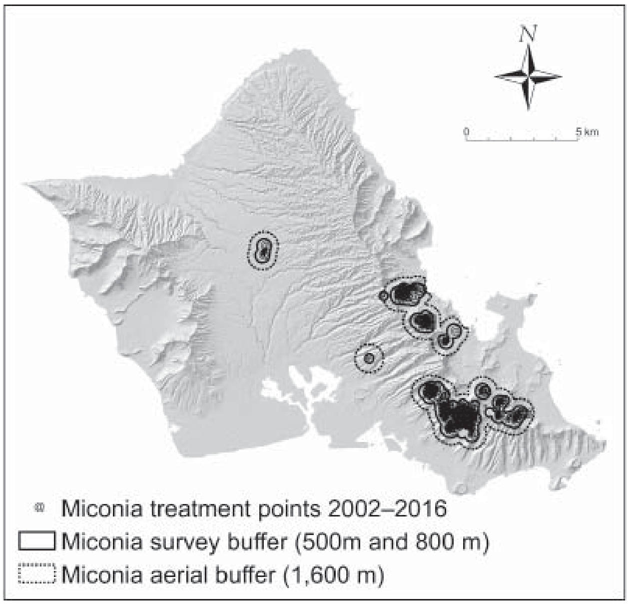

Fig. 3 The O'ahu Invasive Species Committee search area for *Miconia calvescens.*

Fig. 4 A sapling growing out of a patch of *Clidemia hirta* on O'ahu. The large leaves and striking purple undersides make miconia fairly detectable, although in heavy vegetation, trees can still be missed.

(Fig. 4). However, on ground surveys trees are sometimes missed due to dense vegetation that limits visibility. Steep terrain can also make trees difficult to detect as simply getting up a vertical slope safely may distract the surveyor from finding trees. Large trees that have already breached the canopy are also difficult to spot from the ground.

Surveyors can visually find miconia trees from a helicopter but the helicopter must fly very low and slow above the canopy. The large leaves are visible from the air and the rotor wash from the helicopter often blows the leaves around so the purple undersides are visible. Immature trees as tall as four metres have been spotted on helicopter surveys. One disadvantage of helicopter surveys is that in areas with a thick canopy, trees growing beneath may be missed. OISC's observations are that once a large tree has broken through the canopy it often matures very quickly, so areas designated as too steep for ground surveys within the ground buffer are flown every two years to compensate for the fact that trees will not be found until they are older.

Another 800 m from all mature trees is flown by helicopter to check for outliers. Despite the high cost of paying for helicopter time, the per-hectare cost is actually less than ground surveys because so much area can be covered quickly. Residential areas designated for helicopter surveys are done by ground or road in order not to disturb the residents. If a tree is found during an outlier survey, then an 800 m buffer is drawn around it and it becomes part of the area that is searched by ground.

Outreach to hikers, hunters and other outdoor recreationalists has been helpful in receiving reports of miconia. OISC engages organised groups of hikers and hunters through presentations, educational materials and social media with the aim of informing people how to identify and report miconia. We also present to schools and set up educational booths at community festivals in the areas where we are surveying. We believe that outreach also assists in gaining entry to private land. Our observation is that property owners who have heard about the invasive species problem before we call and ask their permission to survey, are more likely to let us on, although we have not specifically measured this.

RESULTS

OISC hired its first staff in November of 2001 and surveys started in 2002. The number of square kilometres surveyed per year has grown as more funding became available. Since 2002, OISC has been able to achieve a 96% reduction in mature plants from 4.8 mature trees per km^2 surveyed to 0.2 mature trees per km^2 surveyed (Table 1). There were 40 mature trees found and removed over 8.26 km^2 in 2002 and just 12 found and removed over 54.71 km^2 in 2016.

OISC also counts and takes GPS points for trees that are immature but over two metres tall. Trees over two metres that are missed will likely be mature the next time the field crew surveys. Therefore, the number of trees over two metres should also be at zero in order to achieve and ensure containment. OISC has achieved an 81% decrease in trees over two metres from 6.8 to 1.3 trees per km^2.

Three significant range extensions have recently occurred. As stated above, OISC's data shows that 99% of immature plants fall within 350 m of a mature plant. However, in 2015, one immature tree was found 6,900 m from the nearest mature tree. In 2016, another was found 1,600 m from the nearest mature tree. In 2017, a small patch of mature and immature plants was found 2,400 m from the nearest mature tree. The 6,900 m and 2,400 m extensions were found while the crew was surveying for other plant species.

DISCUSSION

Having the source trees removed from the botanical gardens and the few private properties, as well as detection of mature trees by agencies and volunteers before OISC was even formed in 2001, was a tremendous help to the eradication project. OISC was able to apply its strategy around the historical points and get a head start on delimitation. By 2010, the surveillance and delimitation phase of the project was complete. OISC did not have the resources to survey all suitable habitat, however, we took the steps described below to ensure that all known populations were mapped. We interviewed fellow natural resource agencies and hiker groups working in suitable habitats to ensure there was not a population in areas we did not have the time to look at. We conducted binocular surveys outside our survey areas in prime miconia habitat looking for large patches. We also calculated the distance of immature trees to the nearest mature tree in 2009. We found that 99% of trees fell within 400 m of a mature tree and maximum distance of an immature tree was just short of 1,600 m (Fujikawa, et al., 2009). This gave us confidence that by 2010, delimiting was complete.

After 2010, the project moved into the containment phase, but it has been difficult to achieve containment as defined by eliminating all mature plants. Although OISC has been able to achieve a significant decrease in the number of mature plants per square kilometre surveyed, we have not been able to completely suppress maturation.

Trees that are missed during one survey cycle are sometimes missed due to human error—thick vegetation and steep terrain are two factors that may decrease the efficacy of surveillance. Although our success rate with getting property owners to agree to let field crews survey their property is 95%, there are some property owners who have been reluctant to agree to surveys. In one case, it took

Table 1 Number of mature, >2m tall trees and km^2 surveyed 2002–2016.

Year	No. mature trees	No. trees >2m	Km^2 surveyed
2002	40	94	8.26
2003	4	21	9.37
2004	7	14	9.00
2005	9	54	21.00
2006	6	27	25.16
2007	6	25	29.37
2008	0	37	20.53
2009	4	89	14.07
2010	1	48	23.25
2011	3	27	27.00
2012	5	83	14.87
2013	2	94	22.20
2014	5	97	21.59
2015	12	123	39.44
2016	12	94	54.71

several years to acquire access from a property owner who owned an entire valley. By the time the crew was able to survey, trees had matured. Sometimes the 5% that say no or take a long time to say yes can be critical. In some years decreases in funding meant we did not have the resources to survey the area required by our strategy. The combination of funding fluctuations and time spent negotiating property access allowed some trees to mature. The presence of mature trees may have resulted in range extensions into new watersheds from long-distance dispersal events.

A review of the distances between immature and mature trees conducted in 2017 resulted in 99% of immature miconia falling within 350 m of a mature tree (Fujikawa pers. comm. 2017), which was similar to our 2009 results. However, the furthest immature miconia was now 6,900 m away from the nearest mature tree.

Miconia's long-lived seed bank is a complicating factor in achieving containment. Research by Meyer (2010) has estimated the seed bank at 16 years in French Polynesia, but observations on Oʻahu suggest it may be as long as 20 years. The Wahiawā botanical garden where miconia was originally introduced has found seedlings and reported them to OISC as late as 2016. They removed their mature tree in 1996 (Medeiros, et. al., 1997) and OISC has surveyed the entire area at least three times without finding any miconia whatsoever, so the likelihood that the seedlings are from the 1996 mature tree is very high.

Lessons learnt

The long-term work done on miconia in French Polynesia is key to OISC's success in preventing a full-scale miconia invasion on Oʻahu. The research was critical to raising the alarm about the species and mobilising control efforts early. Miconia is one of the few species that OISC has taken on where the seed-bank longevity is known thanks to the long-term studies done by Jean-Yves Meyer (Meyer, et al., 2011). Research from Tahiti also formed the basis of the outreach narrative. For example, one of the key talking points for outreach was the enormous area of forest that had been turned into monotypic stands of miconia and a photograph of a landslide in Tahiti was a mainstay of state-wide outreach to explain the potential erosion effects. Both Tahiti and Oʻahu offer lessons to islands where miconia might be dispersed in the future.

If possible, having adequate funds at the beginning of an eradication project to complete delimiting as soon as possible may shorten the containment phase. It took OISC eight years to be sure where the miconia population was. Private property was a complicating factor. A small percentage of larger landowners would not let the field crew survey in a timely manner and trees were allowed to mature while we negotiated access. Delimiting and containing a species before it spreads to additional private property owners will be immensely helpful in achieving eradication as quickly as possible. Taking on additional species can also be helpful in detecting long-distance dispersal events. OISC volunteered to do aerial surveys for a forest pathogen because it would require us to fly over all habitat suitable for miconia. The small patch of mature and immature trees 2,600 m away from the nearest known mature tree was discovered during this survey.

Outreach has also been helpful for the survey effort and programme managers should consider dedicating funds and employees for outreach from the beginning of the programme. OISC did not have a full-time outreach specialist until four years after the programme started. OISC has had trees reported to us but more importantly, we believe outreach has helped OISC get access to survey on private land. People seem more willing to grant access if they have heard of the invasive species problem and miconia before they receive the call asking for permission to survey.

OISC's outreach is a combination of talking directly to community groups, hiking and hunting groups and schools through presentations, participating at events and social media. We have not had the ability to scientifically test the outreach and see which methods or messages work best. Anecdotally, we believe that explaining the larger ecosystem effects and the possible effects on the island's water supply will persuade a wider group of people than those who might be motivated by preserving the native flora of Hawaiʻi. Research about which messages would be received best would be welcomed.

Although completely suppressing maturation of miconia has proved difficult due to the long-lived seed bank, OISC has been able to achieve a 96% reduction in mature trees per square kilometre since the programme began in 2002. In 2016, only 12 mature trees were found across 54.71 km^2. OISC has been able to keep the density of mature trees very low, but the long-lived seed bank means that a missed tree due to human error, an area that the field crew cannot survey due to lack of funding or the inability to get access to private property will likely result in a mature tree once the crew has access to the area. Containment for species with long-lived seed banks will be long-term projects.

For this reason, when evaluating feasibility, prioritising species for control and planning eradications, seed bank longevity should always be taken into account (Panetta and Timmins 2004). Policymakers deciding which species should be restricted for import should also consider seed bank longevity as a critical factor. While a long-lived seed bank is certainly not the only factor that makes a species invasive, if a species with a long-lived seedbank starts to become a problem, eradication will be a long-term and expensive project. Seed-bank longevity is not known for many species, and conducting longevity studies to answer that question for species under management would be very helpful to plan eradication efforts.

ACKNOWLEDGEMENTS

Weed eradication on Raoul Island, Kermadec Islands, New Zealand: progress and prognosis

C.J. West[1] and D. Havell[2]

[1]Department of Conservation, P.O. Box 10-420, Wellington 6143, New Zealand. <cwest@doc.govt.nz>.

Abstract During the 45 years that the Raoul Island weed eradication programme has been underway, eleven species have been eradicated. To complete the restoration of Raoul Island's unique ecosystems supporting significant seabird biodiversity and endemic biota, nine further transformer weeds must be eradicated. In this review of progress to date, we examine the feasibility of eradication of these transformers and identify that four species are on target for eradication: African olive (*Olea europaea* subsp. *cuspidata*), yellow guava (*Psidium guajava*), castor oil plant (*Ricinus communis*) and grape (*Vitis vinifera*). However, for four more species more staff resources are required to achieve eradication as currently infestations are establishing faster than they are being eliminated: purple guava (*Psidium cattleianum*), black passionfruit (*Passiflora edulis*), Brazilian buttercup (*Senna septemtrionalis*) and Mysore thorn (*Caesalpinia decapetala*). The ninth species, Madeira vine (*Anredera cordifolia*), is being contained but presents logistical difficulties for effective control – herbicide resistant tubers and cliff locations requiring rope access in unstable terrain. Increasing the resources for this programme now to enable eradication of these transformer weeds will reduce the total long-term cost of the programme. Eradication of rats, the 2006 eruption, recent greater cyclone frequency, increased tourism requiring biosecurity management, and staffing reductions have all impacted progress on weed eradication. Myrtle rust (*Austropuccinia psidii*), confirmed in March 2017 as the latest invasive species on Raoul Island, is establishing on Kermadec pohutukawa (*Metrosideros kermadecensis*), the dominant canopy species. The impact of this species on the weed eradication programme is unknown at this point.

Keywords: conservation, dispersal, eradication feasibility, invasive species, rats, seabirds, seedbank, transformer

INTRODUCTION

Raoul Island, the largest and northernmost of the main islands in the Kermadec Group (29° 15' S, 177° 55' W), was once home to vast seabird colonies. However, the impacts of whalers and settlers from 1800 AD through the introduction of goats (*Capra hircus*), pigs (*Sus scrofa*), cats (*Felis catus*), and Norway rats (*Rattus norvegicus*) extirpated most indigenous seabird species and a number of indigenous land birds (Veitch, et al., 2004). The goats had a major impact on the endemic vascular plants too (Parkes, 1984). Many vascular plant species were introduced for food and animal forage (Sykes et al., 2000). Twenty-five vascular plant species are endemic to Raoul Island (Sykes, et al., 2000), and most of these make up the forest that clothes the island, dominated by Kermadec pohutukawa (*Metrosideros kermadecensis*). The latest invasive species to arrive on Raoul Island is myrtle rust (*Austropuccinia psidii*). This species was first detected in March 2017 and noticed because of canopy die-off of a small area of mature Kermadec pohutukawa in Denham Bay. Myrtle rust has the potential to alter the dynamics of many native and introduced biota on the island by releasing plants from suppression by the pohutukawa canopy and reduced flowering and nectar production which will impact some land birds. Raoul Island is an active volcano, last erupting in 2006, and it is located in the path of seasonal cyclones (December to May).

Because of its unique ecosystems, Raoul Island was declared a Flora and Fauna Reserve (now Nature Reserve) in 1934. The New Zealand government has funded the eradication of all introduced feral mammals: goats were eradicated in 1984 (Sykes & West, 1996), and rats and cats were eradicated in 2002 and 2004, respectively (Broome, 2009). The eradication of goats greatly assisted recovery of endemic plant species, rescuing several from the brink of extinction. As a consequence of the rat and cat eradications indigenous seabirds and land birds are returning to Raoul Island (Veitch, et al., 2011), significantly beginning the recovery of this ecosystem. Several terrestrial birds now occupy extensive areas of Raoul and are likely to have significant impacts on ecosystem dynamics.

However, a small suite of transformer weed species (sensu Pyšek, et al., 2004) currently impedes full restoration of ecosystem functioning on Raoul Island. The vascular plant flora of Raoul Island currently comprises 118 indigenous species and 196 introduced species (of which c.10% are transformer species). A weed eradication programme has been underway since 1972 (West, 2011) and, to date, 11 species have been eradicated (Table 1), the majority of which were transformers (West & Thompson, 2013). New incursions or detection of exotic species are evaluated for impact and eradication potential as per DOC weed-led systems (Owen, 1998). Biosecurity to prevent new incursions is a priority and weed control to protect threatened plant species in non-forested, coastal ecosystems is important.

The eradication programme is now focussed on nine transformer species that have a major impact on forest ecosystems, four of which are vines (Table 2, and see West, 1996 for more background on these species). Given that seabirds are now beginning to return to Raoul Island to breed, it is particularly important to ensure that vines, which can entangle landing seabirds as well as smother native vegetation including forest, are eliminated.

Weed eradication programmes can take a long time, and many have failed (Panetta, 2015). The Raoul Island weed eradication programme has been formally reviewed twice since it began 45 years ago (West, 1996; West & Havell, 2013). Each time, the species being targeted have been evaluated to understand impacts of the species, and effectiveness of the eradication methodology. Both reviews have resulted in changes to the management programme and revised lists of species to focus on for eradication. The latest review restricted the focus to nine species where eradication will have the biggest impact on biodiversity. Changes to staffing were also recommended, so that there would be six months overlap of some experienced staff with new staff. This recommendation has been actioned for the contracted staff but the volunteer programme (six-month term) was discontinued in 2015 and replaced with

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 435–442. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

seconded staff (three-month term), effectively halving this additional effort for weed control.

In between the two formal reviews, the programme is constantly evaluated in relation to all management on the island. For example, grape (*Vitis vinifera*) was added to the list of target transformer species before rats were eradicated because the two rat species present were preventing fruit development on the grape vines (West and Havell, 2011). The year in which eradication commenced for each of the nine transformer species is shown in Table 3.

The option of eradication of transformer species is more appealing in the long-term than ongoing control to zero-density, as eradication means that financial investment in weed detection and control can cease once the species have been eliminated. To achieve this, sufficient resourcing is required to not only achieve the goal but also reduce total costs (Panetta, 2015). The feasibility of eradication of alien plants from Raoul Island was evaluated 30 years after the programme began (West, 2002). At that time, all necessary conditions (listed in West, 2002) appeared to be met, and application to the task was what was needed.

Preventing reinvasion is entirely achievable for all nine remaining target species, given the remoteness of Raoul Island and the strict biosecurity protocols that are in place. But how well are the species being extirpated and contained within Raoul Island as eradication proceeds? Panetta (2015) describes a model for categorising species in terms of the 'technical' feasibility of eradication by taking into consideration the relative feasibilities of extirpation and containment. He notes that eradication occurs via two processes: (i) extirpation (the elimination of the target in both space and time) and (ii) containment, which is the prevention of further occupancy of space (i.e. spread).

This approach is a useful one to apply to the nine target transformer species on Raoul Island as the work is done and reported on a plot basis, and it is an advancement on the methodology proposed by Holloran (2006) for reporting progress. There are currently 13 weeding blocks comprising 153 plots of varying size (0.1–83.2 ha), covering almost 834 ha which is 28.3% of the total area of Raoul Island (Fig. 1). Plot size varies based on terrain and travelling time; typically each plot can be carefully grid-searched in one day (see West, 2002 for more detail

Table 1 Species eradicated from Raoul Island. For each species, the year eradication began and the year in which the species was last recorded are given. Eradication was formally declared in 2013 by West and Thompson (2013).

Species	Common name	Eradication began	Last recorded
Cortaderia selloana	pampas grass	1984	1993
Ficus macrophylla	Moreton Bay fig	1996	1999
Foeniculum vulgare	fennel	1969	1999
Furcraea foetida	Mauritius hemp	1974	2002
Gomphocarpus fruticosus	swan plant	1979	2002
*Macadamia tetraphylla**	macadamia	1996	2003 (2015)
Phoenix dactylifera†	date	1995	1999
Phyllostachys aurea	bamboo	1996	2001
Populus nigra	poplar	1995	2003
Senecio jacobaea	ragwort	1980	1980
Vitex lucens	puriri	1997	1997

* One macadamia seedling was found in 2015 in the same location as the original small stand of trees.
† Wild dates have been eradicated but the species is still present at two historic sites as apparently non-reproductive individuals.

Table 2 Transformer weeds currently being eradicated on Raoul Island. The juvenile period, seed persistence and dispersal mechanism of each species is used to estimate the feasibility of eradication (Panetta 2015). Species are listed in order of feasibility of eradication: most to least.

Species	Common name	Growth form	Juvenile period	Seed persistence	Dispersal	Feas-ibility	Goal
Olea europaea subsp. *cuspidata*	African olive	Tree	5 years	2.4 years[1]	bird	3	eradicate
Psidium cattleianum	purple guava	Small tree	2–3 years	6–7 months[2]	bird	3	eradicate
P. guajava	yellow guava	Shrub	1–2 years	c. 1 year[3]	bird	4	eradicate
Passiflora edulis	black passionfruit	Vine	9 months	a few weeks[4]	bird	4	eradicate
Ricinus communis	castor oil plant	Small tree	5–6 months	>19 years[5]	explosive*	6	eradicate
Senna septemtrionalis	Brazilian buttercup	Shrub	c. 2 years	>16 years[6]	explosive*	5 or 7	eradicate
Caesalpinia decapetala	Mysore thorn	Vine	4–6 months	>12 years[7]	explosive*	6	eradicate
Anredera cordifolia	Madeira vine	Vine	< 1 year	15 years (tubers)[8]	gravity*	6 or 8	contain
Vitis vinifera	grape	Vine	1 year	5 years[9]	bird	8	eradicate

*Occasional long-distance dispersal by wind, bird, water or accidental-human vectors: for Brazilian buttercup and Madeira vine this occasional longer distance dispersal has resulted in considerable range extension, therefore, two feasibility estimates are given to cover both the normal and not uncommon dispersal events. [1]Cuneo, et al., 2010; [2]Uowolo & Denslow, 2008; [3]CABI, 2017b; [4]CABI, 2017a; [5]Kammili & Jatothu, 2015; [6]Ewart, 1908; [7]no published data: this estimate is from an isolated infestation of known age on Raoul Island; [8]Harden, et al., 2004; [9]no published data found for *Vitis vinifera*: this estimate is for *Vitis aestivalis* (Haywood, 1994).

of the plot-based searching methodology). Using Panetta's model (Panetta, 2015), each plot can be evaluated to see if the species has been extirpated from it, and the distribution of a species among the plots can be evaluated to see if the species is being contained or is expanding its range. Then, the relative relationship between extirpation and containment can be evaluated for each target species to determine if eradication can be achieved (Panetta, 2015).

METHODS

On-island weed searching

Details of weed searching and removal are given in West (2002) and Holloran (2006) and here we restate briefly what the annual plan and actions are: that weeding plots should be grid-searched on the ground a minimum of once each year with plots containing the target transformer species to be searched twice. Within plots, known infestations are marked (including GPS coordinates) and specifically searched during grid-searching or between grid-searches. Finds of immature plants outside of infestations are recorded as random finds. New infestations are created when mature, fruiting plants or localised seed banks are found and, if a new infestation is large, a new plot may be created. If no target species have been found at an infestation for the period of the suspected viability of the propagule bank based upon database records, or the site has been destroyed by a landslide or volcanic eruption, the infestation is retired. GPS tracks of grid-searching are downloaded to Arc-GIS and used to identify any gaps in search coverage and to document search effort.

Feasibility of eradication

Data on the factors used by Panetta (2015) to determine feasibility of eradication were compiled from published information and, where necessary or more appropriate, from our observations on Raoul Island. The two key biological factors relevant to extirpation are the length of the juvenile period (i.e. how quickly can plants produce more viable propagules?) and seed persistence (i.e. how long can seed remain viable?). The biological factor that is most relevant to containment is dispersal modes (i.e. is spread likely to be short- or long-distance; predictable – e.g. water or wind – or unpredictable?). Evaluating the data for these three factors enables identification of eradication feasibility on a scale from most feasible (a score of 1) to least feasible (a score of 8 – see Panetta, 2015, p. 232).

Evaluation of progress towards eradication

All data on the number of individuals removed per plot for the nine target weed species from 1 January 1998 to 31 December 2016 were extracted from the Raoul Island weed database. Recording of the number of individuals in three stage classes – seedlings, adolescents (taller than 30 cm but not yet flowering) and mature (flowering and/or fruiting) – began in October 1997, so the database now holds more than 20 years of continuous data.

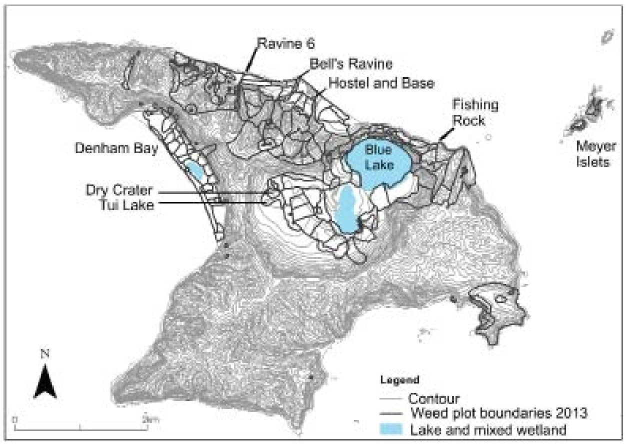

Fig. 1 Raoul Island showing places mentioned and the distribution of weed plots.

The number of times each plot was searched per year, from 1998 to 2016 was extracted from the database. Also, the number of active, retired and random infestations in each plot was summarised for the same period. This information was used to interpret the data on number of individuals per target species per plot and per year.

RESULTS

On-island weed searching

From 1998 to 2011 the mean number of grid searches per plot exceeded one a year and exceeded two in 2003 (Fig. 2). However, since 2012 the number of plots grid-searched has dropped well below a single search each year culminating in less than one third of plots being grid-searched in 2016.

Feasibility of eradication

The data for the nine transformer species targeted for eradication show a wide range of feasibility (Table 2), from feasible, e.g. African olive (*Olea europaea* subsp. *cuspidata*) and purple guava (*Psidium cattleianum*) to much less feasible e.g. Madeira vine (*Anredera cordifolia*) and grape. Species with long juvenile phase (> 2 years), short seed persistence (< 3 years) and short distance or largely human-mediated propagule dispersal score lower, and are therefore more feasible to eradicate. Conversely,

Table 3 Percentage of plots occupied by each species in 1997–2000 (from West 2002) and 1998–2016 as well as the year in which eradication began.

Species	Common name	Eradication began	% plot occupancy	
			1997–2000	1998–2016
Olea europaea subsp. *cuspidata*	African olive	1973	19.6	13.6
Psidium cattleianum	purple guava	1973	22.4	25.0
P. guajava	yellow guava	1972	11.9	8.6
Passiflora edulis	black passionfruit	1980	32.9	36.4
Ricinus communis	castor oil plant	1990	7.7	6.4
Senna septemtrionalis	Brazilian buttercup	1978	72.0	72.1
Caesalpinia decapetala	Mysore thorn	1974	18.2	20
Anredera cordifolia	Madeira vine	1995	2.1	2.1
Vitis vinifera	grape	1998	8.4	8.6

species with short juvenile phase (< 2 years), long seed persistence (> 3 years) and long distance dispersal score higher. The short juvenile phase means searching has to be more frequent; the long seed persistence means the duration of the programme is longer and is extended every time new seed is added to the soil if a fruiting individual is not found in time; the long-distance dispersal means that a greater area must be searched.

Evaluation of progress towards eradication

All transformer species

The number of active and retired infestations for each species gives a good indication of progress towards achieving eradication (Fig. 3). Five species – African olive, yellow guava (*Psidium guajava*), castor oil plant (*Ricinus communis*), purple guava and black passionfruit (*Passiflora edulis*) – have considerably more retired than active plots. Brazilian buttercup (*Senna septemtrionalis*) and Mysore thorn (*Caesalpinia decapetala*) – the two species with the greatest seed longevity – have proportionally more active plots. Control of grape began later than the other species (Table 3), hence the high proportion of active plots compared to retired. Madeira vine is the only species with more active than retired plots.

The random infestations give an indication of dispersal beyond the immediate vicinity of mature plants (Fig. 3) and the effectiveness of the programme to control weed reproduction. Black passionfruit and purple guava, both bird-dispersed, have a relatively high proportion of random finds. Mysore thorn has the highest proportion of random finds reflecting not its dispersal ability but its highly cryptic nature when growing among the tall ground ferns which grow densely in parts of Denham Bay, and its extensive original distribution.

African olive

Numbers of this species detected and removed since 1998 are very low (Fig. 4). The last mature individual was removed in 2008, and two adolescent plants from different locations in 2010 and 2011. All of these finds were from within the historic range of this species before eradication commenced and the percentage of active plots for this species has decreased (Table 3).

Purple guava

Numbers of this species were low (West 2002) but began to increase in 2008, increasing an order of magnitude in 2011, and with very high numbers recorded in 2016 (Fig. 4) from just a few infestation plots mostly within the crater around the shores of Blue Lake and Tui Lake. Most of the purple guava detected in 2015 were from new detections in the dry crater near Tui Lake, adjacent to old infestations where purple guava was last detected in 2002. More than half the numbers detected in 2016 were from this infestation. Purple guava infestations are still being found within the known historical range of the species, but the percentage of plots occupied has increased slightly (Table 3). Infestations of purple guava and buffers of up to 100 metres have been intensively searched since 2015, and, subject to resourcing, additional areas within the crater are likely to be checked. Seedlings of this species are very cryptic (look very similar to two of the endemic species) so careful searching is required.

Yellow guava

There is an increased number of yellow guava “seedling” detections since 2011 but overall the numbers are quite low (Fig. 4). The last mature individual detected was in 2008 with no further detections at that site. The seedlings recorded are generally suckers from roots: those recorded in 2011 were suckers from just two plants. A yellow guava shoot was discovered in 2015 in a crack in a concrete path close to the Hostel. This may have originated from root suckers from a relic guava root system in adjacent gardens, as ongoing persistence and lack of other finds indicates. However, it is also possible that an undetected mature plant may be present within the range of local birds. Yellow guava is active in fewer plots within its historical range (Table 3).

Black passionfruit

The number of black passionfruit being detected and removed began to increase markedly from 2004 (Fig. 4), with the biggest number found so far, in 2011, coming primarily from one infestation where eight mature vines had been removed the year before. This site is still very active. To date, despite the increase in numbers detected, black passionfruit has not materially exceeded its historic range. Although it now occupies more plots than previously (Table 3), these are plots within the bounding polygon that describes the historic range of this species.

Castor oil plant

Numbers of this species are low (Fig. 4), with the last mature plants removed in 2003 all from one site. With the exception of three adolescent plants in 2011 and 2012, all other seedlings and adolescents removed since 2004 have come from this site. Castor oil plant has not expanded beyond its historic range and has fewer active plots than previously (Table 3).

Brazilian buttercup

This species has been the most numerous since the eradication programme began. Numbers were declining

Fig. 2 Mean number of grid searches per plot from 1998–2016.

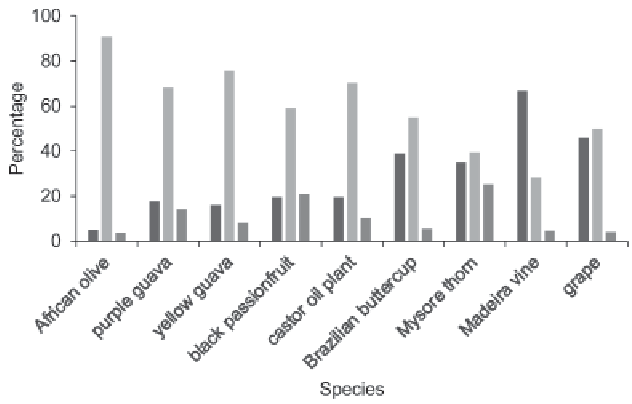

Fig. 3 Percentage of active (black bars), retired (mid grey bars) and random (dark grey bars) infestations within the weeding plots for each transformer species from 1998–2016.

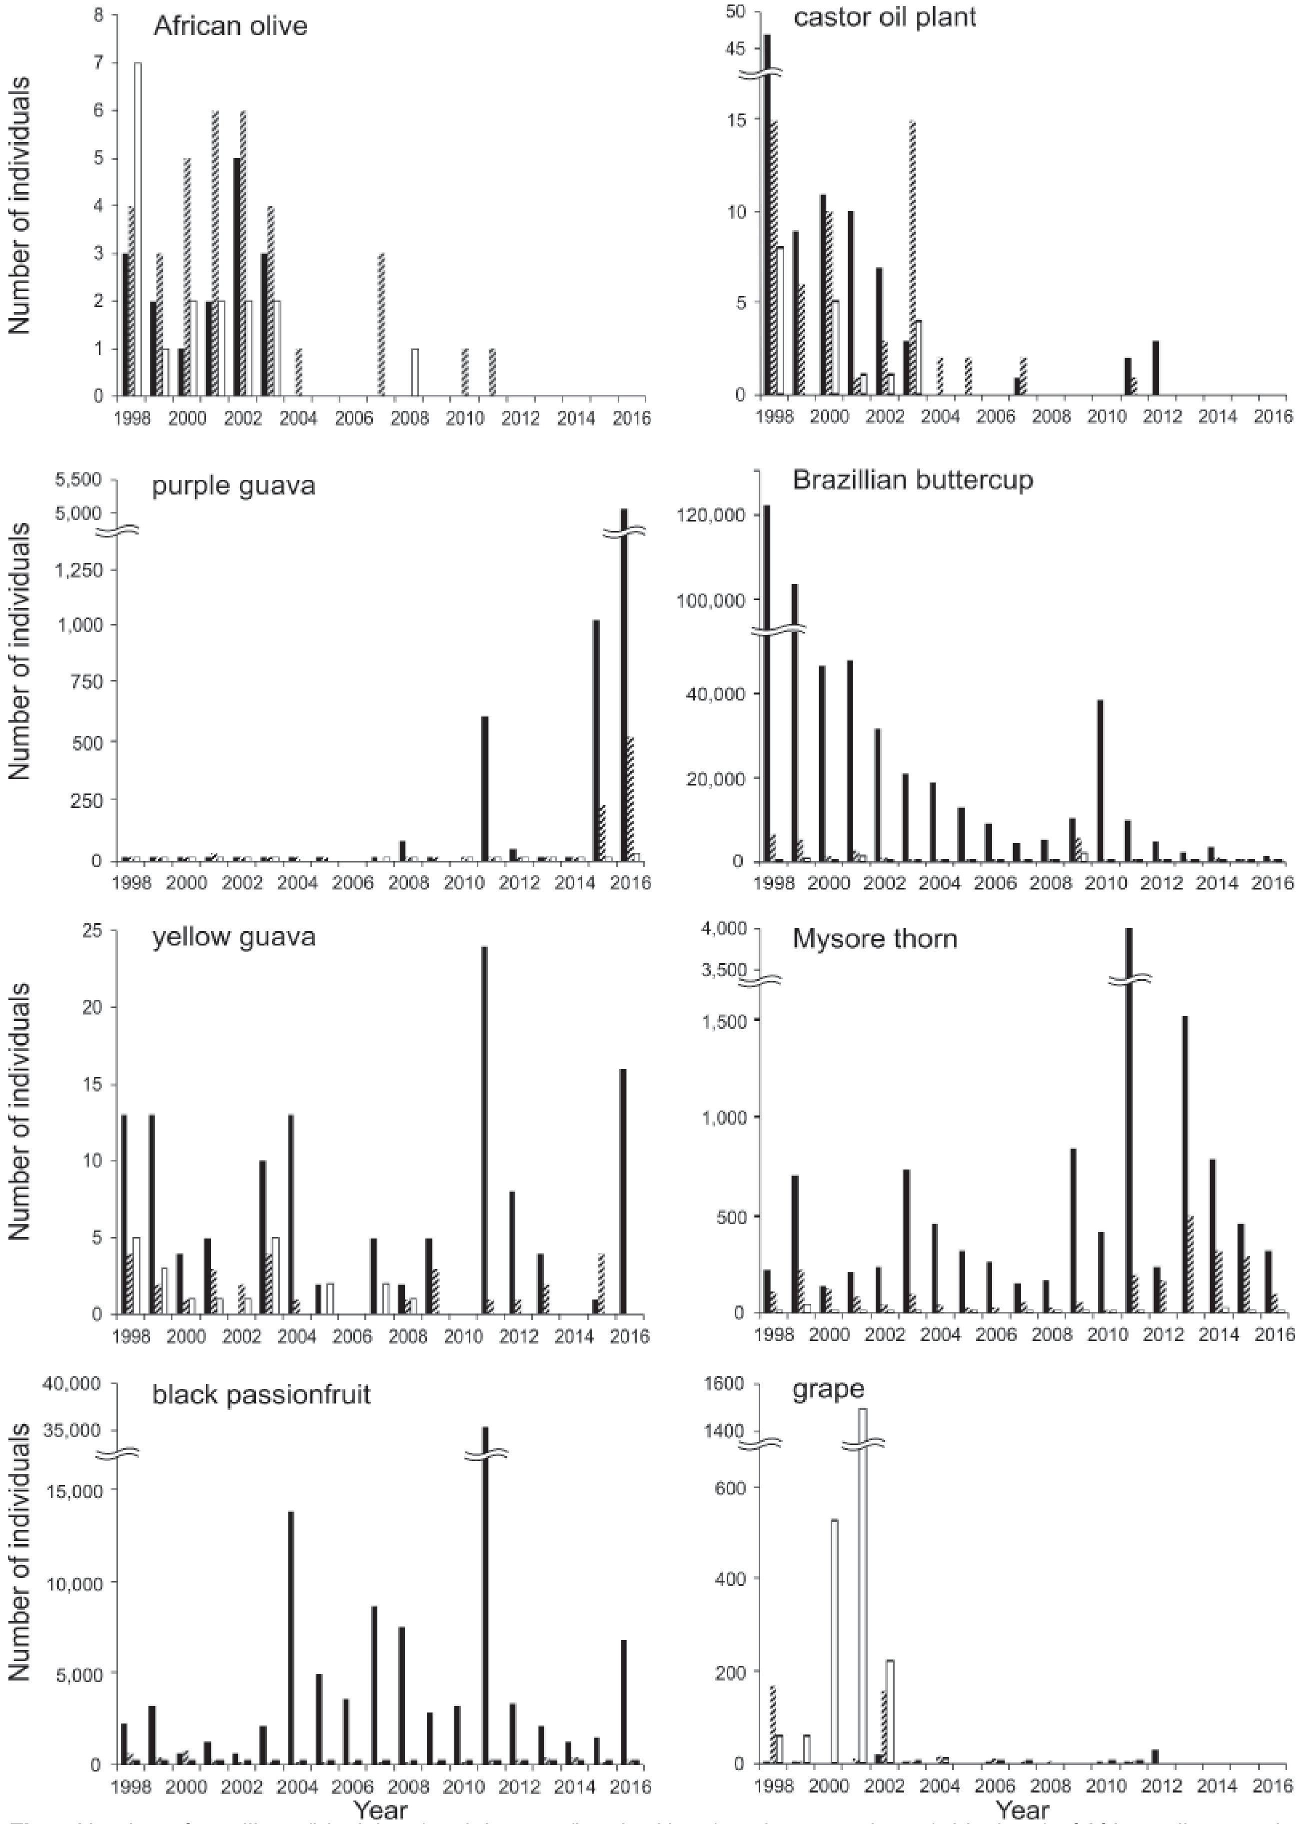

Fig. 4 Number of seedlings (black bars), adolescent (hatched bars) and mature plants (white bars) of African olive, purple guava, yellow guava, black passionfruit, castor oil plant, Brazillian buttercup, Mysore thorn and grape removed in the period 1998–2016 from Raoul Island. For Brazilian buttercup the data for the same period are for removal from Raoul Island and the Meyer Islets: this is the only one of the target species found on these islets that are c. 1 km NE of Raoul Island.

effectively until 2008 when they began to increase, reaching a new peak in 2010 – primarily seedlings (Fig. 4). In 2009, the significant increase in mature and adolescent plants is due to the discovery of three outlier populations that extended the range of this species beyond its historic range. Two of these sites – the westernmost weed plot (see Fig. 1) and a plot on the cliffs at the southern end of Denham Bay were found during helicopter surveillance. The other site, below bluffs at the northern end of Denham Bay was found during a routine search of a nearby plot at the back of the bay. Brazilian buttercup is also on North and South Meyer Islets and is the only one of the target species found off Raoul Island. This species occupies a marginally greater percentage of plots than previously (Table 3): the new plots described above have been virtually cancelled out by the retirement of some plots due to slips and the 2006 eruption.

Mysore thorn

Mysore thorn numbers have fluctuated through time but reached a new peak in 2011 as a result of the high number of mature vines found in 2010 (Fig. 4): the highest number of mature plants recorded since 2001 (Fig. 5). Mysore thorn is confined to Denham Bay now that an infestation at the head of Ravine 6 has been eradicated. Within Denham Bay, however, this species' range has increased slightly, with helicopter surveillance in 2002 and 2009 leading to the detection of two sites on the cliffs above the bay, including the southernmost site known (see Fig. 1). However, it is not these newly discovered infestations that are contributing the higher numbers of all size classes since 2010, it is a number of the historic plots on the flat and towards the cliffs north of Denham Bay swamp. Mysore thorn occupies a slightly higher percentage of plots than previously (Table 3).

Madeira vine

The weight of tubers removed in 1998 was not recorded but a file note halfway through that year mentions 60 sacks of tubers had been removed. The amount of tubers removed is overall less in the past decade than in the previous one (Fig. 6) as the more accessible plots are controlled. Various methods for killing the tubers have been trialled and used, including composting (in black bins using an accelerant), burning, desiccation followed by burning of the desiccated tubers, and freezing (the current method). Madeira vine has not expanded beyond its historic range of two locations and has the same percentage plot occupancy as previously (Table 3). Madeira vine has almost been eradicated from Bell's Ravine with only small finds in 2015.

Grape

Grape vines are now in very low numbers, with no new sites since 2012 (Fig. 4). Most of the infestation sites are in Denham Bay and three are in old settlement areas on the north side of Raoul Island, reflecting past human occupancy. The percentage plot occupancy for grape has increased very slightly (Table 3), reflecting a single mature vine found in 2011 during grid-searching in Denham Bay.

DISCUSSION

Panetta's model (Panetta, 2015) is a very useful framework to evaluate eradication feasibility but when using it, we have been very conscious of the lack of accurate data on seed longevity in the soil in Raoul Island's environmental conditions. We have observed that some of the transformer species being targeted on Raoul Island have seedling banks, e.g. African olive and black passionfruit, and others have the ability to resprout from underground roots, e.g. yellow guava and grape. It could be useful for these mechanisms to be added to the model, perhaps as propagule persistence (replacing seed persistence) given that resprouts can appear more than three years after any other stem material has been present above-ground, and seedlings can remain in a seedling bank for more than three years until a light gap is created allowing the seedlings to rapidly grow to into mature plants.

The graphs of species abundance through time (Figs 4 & 5) combined with life history data indicating feasibility of eradication (Table 2) as well as plot occupancy (Table 3) and the number of active, retired and random infestations (Fig. 3) indicate that eradication is very achievable for four species: African olive, yellow guava, castor oil plant and grape. Note that species differ in their life history traits so therefore have different eradication feasibility scores (Table 2). Grape has the highest score (least feasible) but is eradicable because the biomass of all grapes was reduced to essentially zero before the rats were eradicated (West & Havell, 2011). Dispersal of this species has not been possible because all resprouts are found and destroyed before fruits are formed.

With no detections of African olive since 2011 and estimated seed persistence of 2.4 years, it is theoretically possible to declare this species eradicated now. However, given the cryptic nature of this species and seedling persistence, our preference is to wait until at least 2021 before making this claim (if there are no further detections). Yellow guava persists as occasional suckers in just three accessible locations, presumably from relict root systems, so should be eradicable with annual checks of the locations although the timeframe is difficult to estimate. Castor

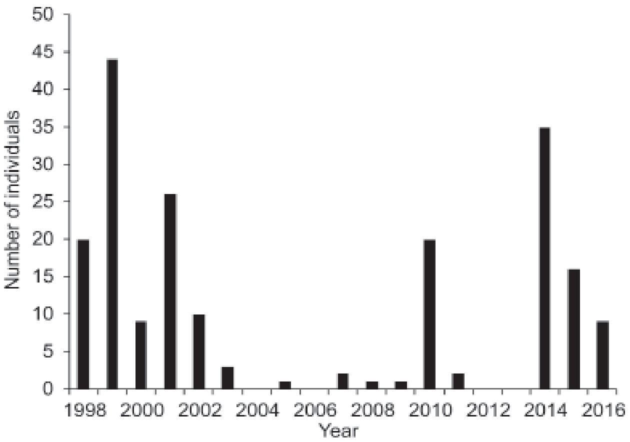

Fig. 5 Number of mature plants of Mysore thorn removed in the period 1998–2016 from Denham Bay, Raoul Island.

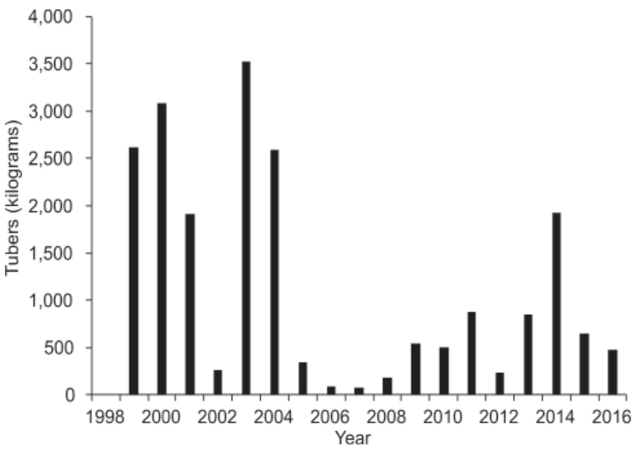

Fig. 6 Quantity (kg) of Madeira vine tubers (aerial and ground) removed in the period 1998–2016 from Raoul Island.

oil plant has seed longevity of >19 years so with the last detection of this species in 2012, and assuming no further detections, it could be deemed to have been eradicated by 2040. All grapes detected on Raoul Island so far have been resprouts from persistent root systems. Given the low feasibility of eradicating this species if it were reproducing by seed (Table 2) it is vital that fruit are never produced. All plots containing grape must be searched a minimum of once a year, ideally twice, given the short juvenile period possible for resprouts.

The feasibility of eradication for purple guava and black passionfruit is relatively high (Table 2), however, both species have been recorded in highest numbers in recent years (Fig. 4) and have a relatively high proportion of random finds (for black passionfruit there have been more random finds than there are active plots). The trend for both species indicates that the current search effort (Fig. 2) of less than one plot search per year, and the current area searched, is not sufficient to prevent seed dispersal. Black passionfruit is known to produce fruit within one year on Raoul Island, and the development of mature plants and purple guava seedlings may have occurred in the dry crater in the three years between 2012 and 2015. At the moment, both species have still been found within their historic range but, since they are bird dispersed, it is quite possible that these two species could be spreading to areas outside the current extent of searched plots (Fig. 1). All of these results indicate that grid searching for both purple guava and black passionfruit must continue until suppression of reproduction in these species is clearly demonstrated. Searching needs to be undertaken within the known range of these species and be extended into surrounding areas to detect any new infestations from bird-dispersed seeds. Uowolo and Denslow (2008) suggest the most effective time for purple guava control is at least three months after the fruiting season when the majority of seeds have germinated or died, given the short seed persistence. Another risk is the potential of large purple guava plants to sucker and reproduce rapidly after long periods of quiescence. A weed detection dog is being trained to focus on black passionfruit, both guava species and grape but is not yet ready for deployment.

Brazilian buttercup is the most widespread of the target species (Table 3). Range extensions of this species, discovered in 2009, plus its occurrence on the Meyer Islets indicates this species has rare long-distance dispersal, possibly by birds (although human dispersal can't be ruled out). In order for this species to be eradicated, detection methods need strong focus (Holloran, 2006). Any opportunities for helicopter surveillance should be taken, particularly when these coincide with the flowering period.

Although Mysore thorn is confined to Denham Bay, too many individuals are being missed in plot searches allowing considerable seed set e.g. the very high numbers of seedlings recorded in 2011 (Fig. 4). Seed germination in 2011 could also have been aided by two cyclones that affected Raoul Island in February (Atu) and March (Bune), with the latter resulting in widespread treefalls and stripping of foliage from trees. Given the rapid growth rate of Mysore thorn (Table 2) and the high proportion of random finds, the plots in Denham Bay need to be searched a minimum of twice each year and possibly with a closer spacing between observers than in the past (we suggest a minimum of 2 m). The short juvenile period plus the long seed persistence time make this species less feasible for eradication. However, because long-distance dispersal is very rare, this species is eradicable if seed banks and fruiting can be eliminated (as demonstrated by the eradication in Ravine 6). Of all the transformer species, Mysore thorn poses the greatest threat to ecosystem recovery, as shown by historic photographs and reports of Mysore thorn smothering the Kermadec pohutukawa canopy in Denham Bay (West, 1996). Landing seabirds can get entangled in vegetation: vines provide greater opportunities for entanglement and thorny vines (like Mysore thorn) less opportunity for safe escape (Arcilla, et al., 2015).

Madeira vine is the most difficult species to control on Raoul Island (West, 2002). It was last detected in its original location in Bell's Ravine in 2015 but because it can grow from tiny aerial tubers and subterranean tubers, it may still occasionally resprout in that location. However, at the main location east of Fishing Rock, this species grows on steep, unstable cliffs so tubers can be removed only from the most accessible sites and places that can be reached by abseiling safely. Herbicide is still used to knock back foliage when necessary to gain access to the herbicide-resistant tubers so they can be removed. Until a control method is developed that can kill tubers on the inaccessible cliffs, this species can only be contained rather than eradicated. Management so far has successfully contained Madeira vine.

It has been stated frequently in the literature that eradications are unlikely to succeed if the area occupied is large (Panetta, 2015). Howell (2012) identified that the only successful eradications of environmental weeds in New Zealand were those where the initial extent was < 1 ha, noting that there were other eradications of similar extent that were unsuccessful. On Raoul Island, four species currently have distributions of < 1 ha: African olive, yellow guava, castor oil plant and grape although the area to be grid-searched in the plots within which they occur ranges from 6 ha (castor oil plant) to 80 ha (grape). The area to be searched for the more abundant species – purple guava, black passionfruit, Brazilian buttercup and Mysore thorn ranges from 60 ha (Mysore thorn) to 550 ha (Brazilian buttercup).

However, Panetta's (2015) model of extirpation and containment indicates that African olive, yellow guava, castor oil plant and grape are all currently being extirpated (the rate of extirpation of managed infestations exceeds the rate of establishment of new ones) and contained, and could be eradicated with the current level of resourcing. As indicated above, breakthroughs in methodology are needed for extirpation of Madeira vine to become a reality. For the other four species, there have been more new infestations leading to greater numbers and, for Brazilian buttercup, range extension in recent years. The current level of resourcing is not sufficient to enable eradication as, based upon GPS track logs, not all known and potential areas are able to be searched within the time it takes for each species to fruit. There is also insufficient resourcing to analyse records of infestation within the Raoul Island weed database, and therefore plan the work more effectively.

There are many factors that have led to this situation. Rats (*Rattus norvegicus* and *R. exulans*) are no longer eating flowers, seeds and seedlings of plants. This effect can be seen in the results for several species, e.g. Mysore thorn, black passionfruit and yellow guava. No access to the crater was permitted for two years after the eruption in 2006 resulting in mature plants of purple guava and Brazilian buttercup, with dispersal of the former and seed added to the seed bank for the latter. Cyclones have been frequent in the past decade, resulting in large areas of windfallen trees within weed control sites that stimulates germination (good for reducing the seed bank) but also impedes access and slows down the rate of grid-searching, making weed removal harder. A formal process for retiring plots is not in place and this may have resulted in a lack of focus on areas that need more regular checking.

Health and safety requirements and biosecurity management are the factors that have most influenced the drop in the mean number of plots grid-searched (Fig. 2). Staff effort has been directed towards biosecurity management as the number of visitors to the island (including organised tour groups) has increased over the years. Health and safety requirements have increased considerably since 2006: permission must be sought to enter the crater to search the plots (the granting authority is the Operations Manager based on advice from the Institute of Geological and Nuclear Sciences which monitors seismic activity on the island); weed plots that must not be searched after heavy rain or during seismically active periods and those that require climbing gear have been identified. Staff numbers have been reduced since 2015 when deployment of volunteers for six-month periods was replaced by seconded staff for three-month periods.

These factors, combined with the lack of assistance from rats, reduced staff resourcing, plus the increased number of cyclones, has led to the increase in weed abundance, particularly for purple guava, black passionfruit, Brazilian buttercup and Mysore thorn. Health and safety standards should never be compromised but need to be compensated for by increased resourcing for the eradication of transformer weeds to be successful. The current budget for the programme is $555,000, reduced from $566,000 in the previous year. This needs to be increased to $850,000 to provide sufficient staff time to check all plots once a year plus an additional check of all plots with known Mysore thorn, grape and black passionfruit infestations (two checks a year, minimum). Madeira vine plots should be checked at the current rate of one day per week. As Panetta (2015) states "Despite the best of intentions and the highest level of professionalism, an eradication effort will not succeed if it is not adequately resourced". Increasing the budget is a wise move given that Cacho, et al., (2007) showed that total cost of weed eradication is high when low search effort was involved, but falls rapidly with increasing search effort because a more intense search effort would reduce the number of reproductive plants. This is currently the sticking point for four of the nine transformer species in the Raoul Island weed eradication programme. Whereas the bulk of the budget should be spent on Raoul Island (staff, infrastructure, materials), the off-island support resourcing is also vital and must be set at the optimal level. Remote island-based programmes require huge logistical support from dedicated teams both on and off the island.

The preceding discussion describes a number of factors that need to be considered when budgeting for success in this programme and the results described are all influenced by these. However, myrtle rust, whose impact is yet to be felt by Raoul Island ecosystems, is the latest agent of change that will need to be considered. Monitoring plots have been established to provide early indications of how this disease will affect Kermadec pohutukawa and what the flow-on effects will be. It is possible that the dynamics of the transformer weeds in this eradication programme will change, just as they have following eradication of rats and cyclones.

ACKNOWLEDGEMENTS

Thanks to staff on Raoul Island, and those on the mainland associated with the weed eradication programme for providing information for this paper. Thanks to Geoff Woodhouse, Paul Rennie and Clayson Howell for their comments on an earlier draft of this paper. A special thanks to the staff who undertake the arduous task of weed eradication on the island. Thanks, also, to the anonymous reviewers who improved this paper and to Dick Veitch for improving the figures.

Abstract The North American signal crayfish (*Pacifastacus leniusculus*) has been present in Scotland since at least 1995 and the species is now known to be present in a number of catchments. Once established, few opportunities for containment exist and eradication can often be impossible to achieve. However, in small, isolated water bodies, the application of a non-crayfish-specific biocide has provided the opportunity to remove this species permanently. In July 2011, signal crayfish were discovered in a flooded quarry pond at Ballachulish in the Scottish Highlands. This is an isolated site located ~100 km from the nearest known population and it is likely that the population was established as the result of a deliberate release of these animals 10 years previously. Experience gained from using the eradication technique at other sites in the UK led to the site being treated with a natural pyrethrum biocide (Pyblast®) in June 2012. Post treatment monitoring from 2012–2017 indicates that eradication has been successful. Monitoring of native species affected by the biocide suggests that both invertebrates and amphibians quickly recolonised the quarry pond. Eradication of crayfish using biocide is only feasible in water bodies where the entire population of crayfish can be exposed to a lethal dose and the impact on non-target species can be accepted. The technique is not appropriate for large, connected water bodies, although it may be possible to treat short stretches of canals where biocide exposure can be controlled and isolated populations of crayfish can be effectively treated.

Keywords: invasive species, natural pyrethrum, ponds

INTRODUCTION

Invasive species are the second largest cause of biodiversity loss globally through species extinction and habitat destruction (EEA, 2012). Their impact can be dramatic and often irreversible, so it is important that their spread is contained and that eradication is achieved wherever practicable. As a function of their isolation, islands may offer the best hope of locally eradicating an invasive species. Conventionally we think of islands as areas of land which are surrounded by water. However, for obligate aquatic species the reverse may be true, and it is the land which can form an effective barrier to invasion. In freshwater ecosystems, invasive non-native species can pose a major threat to native species through competition, predation and transmission of diseases (EEA, 2012) and their control in these 'freshwater islands', is therefore of particular importance.

Newly introduced species can establish rapidly and it is important to detect their presence, and take action, as early as possible. This is often not possible because, unlike terrestrial habitats, freshwaters are not easily surveyed (Boon & Bean, 2010). This means that invasive species in these habitats may not be detected until they have become fully established, often making it more expensive to remove them (Simberloff, et al., 2013).

Signal crayfish (*Pacifastacus leniusculus*) have been introduced to over 20 European countries since the 1960s. After escaping from farms in the 1970s they are now widespread across parts of England and Wales (Bean, et al., 2004). The species was first discovered in Scotland in 1995 (Maitland, 1996). In just over 10 years it had been illegally introduced into at least eight river catchments (Gladman, et al., 2009). Signal crayfish are omnivores and, through increased grazing pressure and predation, they can reduce the diversity of aquatic invertebrates and significantly alter food webs (Holdich, et al., 2014). As well as direct predation of eggs and young fish, they compete with Atlantic salmon (*Salmo salar*) and trout (*S. trutta*) for food and space and can mobilise sediment, causing silting of spawning beds (Gladman, et al., 2012; Bean & Yeomans, 2016).

Controlling signal crayfish has proved difficult and, in most situations, impossible to achieve. Several approaches have been attempted, ranging from the physical removal of animals using techniques such as trapping and electrofishing, to the construction of barriers to prevent their spread (Bean & Yeomans, 2016). Of these, trapping is often perceived as being the easiest and most effective option. In reality, however, the removal of crayfish by trapping has proved ineffective at eradicating signal crayfish because it does not remove the entire population (Freeman, et al., 2010). Where trapping has been allowed to take place on a commercial basis, either as a management tool or for the establishment of legal fisheries, it has been associated with the detection of an increased number of illegal introductions (e.g. Alonso, et al., 2000; Diéguez-Uribeondo, 2006; Arce & Alonso, 2011; Bohman, et al., 2011).

The use of biocides to control or eradicate crayfish populations is a relatively recent development. Early attempts to eradicate signal crayfish using chlorinated lime (Kozak & Policar, 2003) were not successful. However, later trials using natural pyrethrum (as Pyblast®) (Peay, et al., 2006) showed more promise in trials in Scottish freshwaters without being totally effective. O'Reilly (2015) provides a comprehensive review of the toxicity of Pyblast® and other organophosphates for signal crayfish control.

There is no single biocide available that is selective for signal crayfish only. This means that any attempted eradication using a biocide treatment would be expected to kill some, or all, of the non-target invertebrate and vertebrate fauna in the area being treated.

Signal crayfish were first detected in north-west Scotland in an artificial waterbody, a flooded slate quarry, near Ballachulish, in 2011. This species is thought to have

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 443–446. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

been present within the pond for approximately 12 years prior to its discovery there (P. Madden, pers. comm.). The nearest signal crayfish population to that discovered at Ballachulish is located over 100 km south in the River Kelvin near Glasgow. This reinforced the initial view that this species was introduced to the Ballachulish quarry pond by people; in addition, it has footpaths and a recreational area adjacent so is readily accessed by the public. The pond, and therefore the crayfish population, was isolated with no source of natural re-infestation. However the proximity of the pond to local rivers, and the potential impact that this species may have on species of conservation and recreational value, such as Atlantic salmon and trout, made it essential that the signal crayfish population was removed as soon as possible.

Study site

Ballachulish quarry pond (Ordnance Survey Great Britain National Grid Reference NN08525824) is located immediately west of the town of Ballachulish on the west coast of Scotland (Fig. 1). The area contains a large pond and a smaller waterbody located 25 m to the north (NGR NN08435835). The affected waterbody has a surface area of 18,776 m^2 and a volume of 46,000 m^3. Whilst it is relatively shallow over much of its surface area (approximately 0–5 m deep), a smaller area of deeper water, extending to a maximum depth of 13 m, is present.

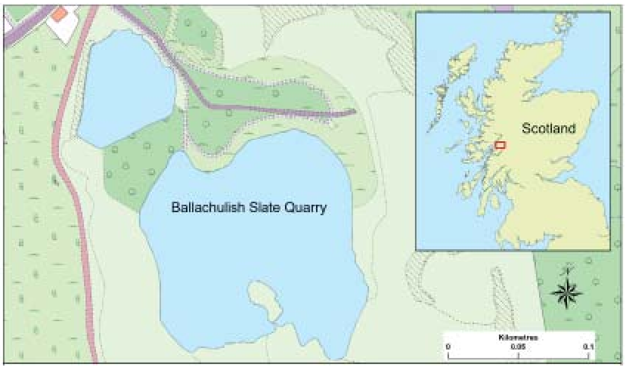

Fig. 1 The location of Ballachulish and the quarry pond relative to western Scotland.

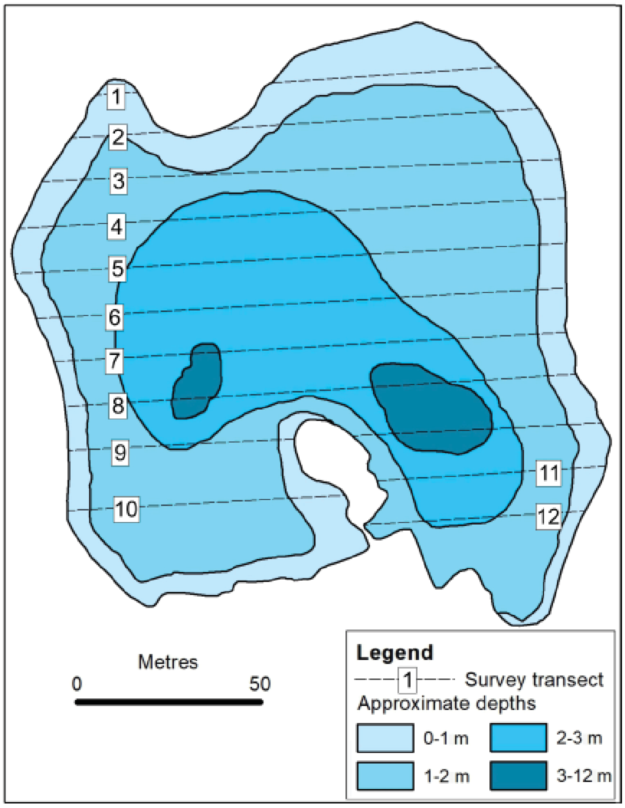

Fig. 2 Ballachulish quarry pond bathymetry.

Survey prior to any management action revealed that signal crayfish were restricted to the larger of the two ponds. The large pond also hosted a number of invertebrate and vertebrate species. Vertebrates found during the survey included fish (trout and European eel (*Anguilla anguilla*)) and amphibian species such as common toad (*Bufo bufo*) and palmate newt (*Lissotriton helveticus*).

METHODS

It was deemed acceptable, given the absence of any conservation priority species, that some mortality of native fauna would occur as a result of biocide application. The risk of inadvertently transferring juvenile crayfish in the act of translocating rescued animals to new locations meant that no attempt was made to rescue non-target species prior to the treatment taking place.

Bathymetric transects of the pond were obtained by the use of a plumb-line at 100 sample points (Fig. 2). These were used to divide the pond into compartments of equal volume. A total volume of 620 l of Pyblast® was applied to the surface of the pond by boat-mounted sprayers (Fig. 3) to achieve a target dose rate of at least 0.3 mg/l, on 12 June 2012. Water pumps and a boat with an outboard motor were used to ensure thorough mixing throughout the entire water column. In addition, backpack sprayers treated a 1 m band around the edge of the pond and the shallow margins of the pond to prevent signal crayfish leaving the water (Fig. 4). The following day, deep water sections of the pond were re-treated by spraying Pyblast® down 6 m-long rigid hoses, increasing the dose rate in the deepest areas of the pond to at least 0.4 mg/l. Mixing was achieved, as far as possible, using an outboard engine and shore-based pumps.

The effectiveness of the treatment was monitored by placing 13 sentinel cages, each containing 10 signal crayfish, of mixed sex, into the pond at different positions and depths and monitoring their mortality once the biocide had been applied. Bioassays using the freshwater shrimp (*Gammarus pulex*) as a test organism, were conducted according to the methodology described by Peay, et al. (2006). These were run on the pond water to monitor its toxicity at the point of treatment and to monitor the breakdown of the Pyblast® over subsequent days and weeks. Natural pyrethroids break down quickly when exposed to sunlight and their toxicity should reduce

rapidly. During this eradication exercise, toxicity levels, sufficient to kill *Gammarus*, persisted for 34 days.

The effectiveness of the signal crayfish removal attempt was monitored through baited Fladen-style traps set in the pond for a total of 195 trap nights in August/September each year for five years post-treatment (975 trap nights in total). Traps were set in a range of habitats and depths throughout the site to maximise the potential of capture. The ability of invertebrates to recover very quickly, in as little as 24 days, was already known from other studies (e.g. Peay, et al., 2006), therefore recovery of the pond ecosystem was assessed through amphibian surveys carried out using sweep netting and kick-sampling in late June, August, September and October 2012. Larval common toad and palmate newts were measured, aged and their general behaviour assessed to determine whether it deviated from that normally expected in undisturbed sites.

RESULTS

During, and immediately after the Pyblast® application, signal crayfish held in sentinel cages were checked intermittently to assess mortality levels and the efficacy of treatment. By the end of the first day (12 June 2011) most of the signal crayfish were dead (Fig. 5), however, those in deep water sections (as determined from the use of sentinel crayfish) were still active. Effort was focused on increasing the concentration of Pyblast® in these areas and by the third morning (14 June 2011) all signal crayfish, even in the deep sections, were dead. The annual post-treatment monitoring found no signal crayfish in the pond for five years after the treatment and in August 2017 the eradication was declared successful.

Bioassay monitoring indicated that after one month the concentration of Pyblast® in the pond was below the lethal limit for *G. pulex* and it was judged safe to re-open the pond to the public. Fig. 6 shows the speed at which the reduction in toxicity of water samples taken from the surface and 5 m depth in the pond took place following Pyblast® treatment. These data show that biocide toxicity in deeper waters took longer to drop below lethal levels than those near the surface, but confirmed that toxicity levels dropped to levels non-lethal to signal crayfish in all areas within 20 days post-treatment.

The amphibian surveys found larval stages of common toad and palmate newt in late June 2012, which strongly suggested they had survived the Pyblast® treatment. There was no difference in size or development stage between tadpoles from the treated pond and a nearby untreated pond. All amphibian larvae behaved normally and showed no physical abnormalities (see O'Brien, et al., 2013). A low level of fish mortality was observed and this included one brown trout plus a very small number of European eels and three-spined sticklebacks (*Gasterosteus aculeatus*).

DISCUSSION

Post-treatment monitoring demonstrated that the application of Pyblast® at a target dose rate of 0.3 mg/l was successful in removing signal crayfish from the pond. Monitoring also showed that a number of non-target species survived the treatment, or were able to recolonise quickly (O'Brien, et al., 2013). The pond is artificial and the presence of signal crayfish would have significantly altered its ecology, meaning that there is no recent, or pre-crayfish, baseline against which to measure ecosystem recovery. However, five years after the biocide treatment an abundant invertebrate and amphibian fauna is present within the pond, and no lasting chemical effect of the treatment is visible.

The risk of signal crayfish being spread to new waterbodies within the local area by natural or anthropogenic means has been reduced as a result of this successful eradication. There are now no known populations in the north-west Highlands which pose a threat of re-introduction to this site. This project has shown that full eradication is achievable in small, isolated waterbodies where the entire signal crayfish population can be exposed to a natural pyrethroid biocide, and the impact on non-target species is deemed an acceptable risk.

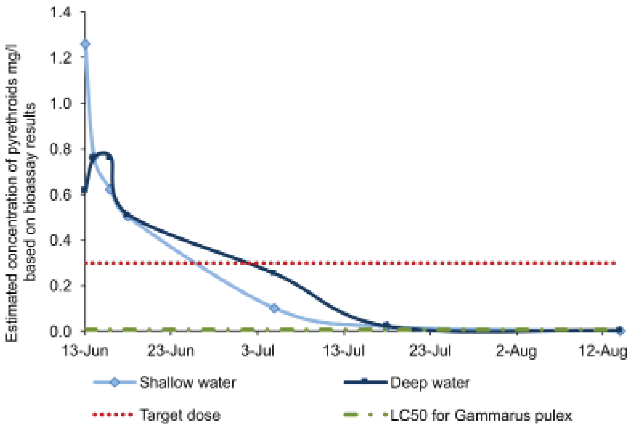

Fig. 6 Graph showing the reduction in toxicity of water samples taken from the surface and 5 m depth in the pond following Pyblast® treatment on 12t June 2012. Toxicity was estimated through a bioassay exposing *Gammarus pulex* to diluted samples and comparing to previous reference data collected on their mortality rates.

A partnership approach to dealing with signal crayfish in this location was a significant component of its success. Buy-in from public agencies and the local fisheries management sector provided the financial and physical resources required to provide adequate materials to carry out this work effectively. Ongoing promotion of a national biosecurity campaign aims to prevent future reintroductions. At an operational level, careful monitoring of sentinel signal crayfish and having a sufficient contingency of Pyblast® to supplement concentrations in the deepest areas of the pond proved crucial. The quarry pond at Ballachulish is the largest water body in the UK to date where signal crayfish have been eradicated using a natural pyrethroid. The main limitations to the wider application of this method to large waterbodies are the financial cost of the biocide (in 2012, Pyblast® cost over £50 per litre), the manpower required, the collateral damage to native biota and connectivity to outflowing rivers and streams. This trial accounted for biocide costs of >£30k alone, and with additional costs in terms of staff time and equipment hire (pumps, etc.) the total estimated figure was £73.1k. Additional costs associated with post-treatment monitoring are not included within this total. In Sweden and Norway, less expensive synthetic pyrethroids have been used (Sandodden & Johnsen, 2010), but these have the disadvantage of being more toxic and persistent in the freshwater environment. O'Reilly (2015) showed, using laboratory-based acute toxicity tests, that signal crayfish were most sensitive to Detamethrin, a synthetic pyrethroid, used in the aquaculture industry, and that juvenile signal crayfish were significantly more sensitive to Pyblast® than adult conspecifics at concentrations far lower than those used in this study (57.95 µg/l versus 0.3 mg/l). It may be possible, therefore, to use alternative biocide approaches in some situations, or lower the costs of treatment in populations which are detected at an earlier stage in their establishment. Recent advances in the detection of invasive species by environmental DNA may allow for earlier, and cheaper, identification of new populations through the expansion of surveillance networks to include a larger number of waterbodies. Environmental DNA assays have already been developed for signal crayfish (Larson, et al., 2017; Harper, et al., 2018) and a wide range of other biota (e.g. Ficetola, et al., 2008) which will allow for cheaper, and possibly more reliable, pre-and post-treatment monitoring of signal crayfish and other species to take place in future years.

ACKNOWLEDGEMENTS

This work would not have been possible without the financial support provided by Highland Council and Scottish Natural Heritage. Technical and logistical support was provided by, Fishery Trusts, Forestry Commission and the Scottish Environment Protection Agency. We gratefully acknowledge the guidance provided by Dr Stephanie Peay during this work.

Small- and large-scale eradication of invasive fish and fish parasites in freshwater systems in Norway

H. Bardal

Norwegian Veterinary Institute, Pb. 750 Sentrum, NO-0106 Oslo, Norway. <helge.bardal@vetinst.no>.

Abstract In July 2016, the European Union adopted a list of invasive alien species of concern, and at present there are two freshwater fish species on the list. Member states are obliged to prevent further spread and to perform rapid eradication when problem species are discovered at new sites, but continental EU member states have limited experience with eradication of fish. Eradications are more likely to succeed if the invasive species is confined to insular habitats. Freshwater invasives can be regarded as island invasives, since their habitats have boundaries against shorelines, saline waters, waterfalls and dams, and these boundaries make eradications possible. CFT Legumine® containing rotenone is the only legal piscicide in the EU, and Norway has used CFT Legumine® in eradication efforts for many years. Species that have been introduced outside their native range and have been successfully eradicated include minnow (*Phoxinus phoxinus*), roach (*Rutilus rutilus*), pike (*Esox lucius*), common whitefish (*Coregonus lavaretus*), and the salmon parasite *Gyrodactylus salaris*. This manuscript summarises the eradication efforts of invasive fish species and fish parasite species during the last two decades in Norway, covering eradications from such diverse habitats as small ponds, lakes, marshlands, small streams and large rivers. An estimated £100 million has been spent in the *Gyrodactylus salaris* eradication programme. Costs of invasive fish eradications are given, ranging from less than £10,000 to more than £200,000. There are no known invasive fish eradication failures in Norway in the last 20 years. A summary of the efforts in Norway can be an aid for planning control and eradication measures of invasive fish species in other countries.

Keywords: CFT Legumine, fish control, *Gyrodactylus salaris*, IAS, rotenone

INTRODUCTION

Alien invasive fish species are a global problem (Gozlan, et al., 2010). Eradication is more likely to succeed if the invasive species is confined to insular habitats. Freshwater invasives can be regarded as island invasives, since their habitats have boundaries against shorelines, saline waters, waterfalls and dams, and these boundaries make eradications possible.

The EU requires member states to rapidly implement measures, including eradications, against invasive alien species. In July 2016 the EU adopted a list of invasive alien species of European Union concern that requires control or eradication (<http://data.europa.eu/eli/reg_impl/2016/1141/oj>). This list includes two fish species, topmouth gudgeon (*Pseudorasboras parva*) and Amur sleeper (*Perccottus glenii*), and new species can be added. Transfer of knowledge is therefore essential as many EU countries have little experience with such operations. In Europe, successful eradications against invasive freshwater fish have been done in Spain (Fernandez-Delgado, 2009), England (Britton, et al., 2010) and Norway.

The Norwegian Veterinary Institute has extensive knowledge of fish eradication through their work on behalf of the Norwegian Environment Agency. A simplified way to look at historic immigration routes for freshwater species to Norway is that all indigenous freshwater fish species can be found in south-eastern Norway, while the rest of the country has very few indigenous species, making most south-eastern species, e.g. all cyprinids and pike (*Esox lucius*), domestic exotic in other parts of the country (Huitfeldt-Kaas,1918). Exotic invasive fish are North-American salmonids, imported for aquaculture and improvements of wild stocks, and cyprinids from the European continent (Hesthagen & Sandlund, 2016). One of the most severe threats to an indigenous fish species was the introduction of the salmon fluke *Gyrodactylus salaris*, which in a worst-case scenario could lead to local extinction of Atlantic salmon (*Salmo salar)* populations. Norwegian authorities have committed to eradicate the salmon fluke from Norwegian rivers, and the Norwegian Veterinary Institute is in charge of the project planning and eradication campaigns. The experiences from these campaigns against *G. salaris* are used in other operations against invasive freshwater fish species.

The piscicide rotenone has been used for fish control and eradication for more than 70 years (McClay, 2000). Rotenone is a natural product isolated from roots of tropical plants in the pea family *Leguminosae*, and it is highly toxic to fish (Ling, 2003). The rotenone product used in Europe is CFT Legumine® (CFT L). It is the only piscicide currently under assessment of the Biocidal Product Regulation (BPR, Regulation (EU) 528/2012), and thus the only piscicide legal for use in Europe. The effect of rotenone on non-target organisms has been extensively studied (Ling, 2003; Vinson, et al., 2010; Finlayson, et al., 2010a; Dalu, et al., 2015) and, even if some invertebrate taxa are very sensitive, the general findings from Norway are that most taxa recolonise treated areas within a year (Fjellheim, 2004; Kjærstad, et al., 2015).

Two different solutions of CFT L have been used in the described treatments. The first CFT L formula used contained 2.5% rotenone and the synergist piperonylbutoxid (PBO). Since PBO did not have the desired synergic effect (Finlayson, et al., 2010a), the manufacturer made a change in the product in 2012. The new product omitted PBO and increased rotenone content to 3.3%. As of 2013, all treatments described have used the 3.3% solution.

The objective of this manuscript is to present all rotenone treatments against invasive freshwater fish species in Norway the last 20 years, and a short summary of the still ongoing eradication campaign against the salmon fluke. None of the invasive fish species eradications are previously published. Only lake volumes are described in detail, but the treatment area also includes adjacent streams, pools and marshlands, to ensure that no fish survives in temporary locations. The work of treating these surroundings varies depending on the site, but the amount of CFT L used in these areas is small compared to the amount used in lakes. A map is included for the geographical location of the invasive fish species eradications (Fig. 1). Costs are included to give an idea about the cost of invasive fish eradications (Table 1). The following descriptions can be an aid for planning control and eradication measures of invasive fish species in the EU and for other stakeholders.

OVERVIEW OF ERADICATION OF INVASIVE FISH AND FISH PARASITES IN FRESHWATER SYSTEMS IN NORWAY

Salmon fluke (*Gyrodactylus salaris)* in rivers and lakes in Norway

The salmon fluke *G. salaris* is a freshwater salmon ectoparasite indigenous to the Baltic region, and an exotic invasive species in Norway that was first detected in the 1970s. *G. salaris* is one of the most severe threats against Norwegian Atlantic salmon (Anon., 2016), It has been introduced via fish transports from Sweden, and distributed in Norwegian rivers through stocking from salmon hatcheries. Norwegian Atlantic salmon populations are highly susceptible to the parasite, with up to 95 % mortality for salmon fry and parr (Johnsen & Jensen, 1991). Rainbow trout (*Oncorhynchus mykiss*) and Arctic char (*Salvelinus alpinus*) can also host the salmon fluke. It has been found in 50 rivers in Norway, and rotenone treatments aim to eradicate the Atlantic salmon from infected river systems since the parasite cannot survive without its host. The salinity of the fjords acts as a barrier for dispersion of the salmon fluke, providing defined borders for the treatment area (Soleng & Bakke, 1997). Extensive operations to preserve and re-establish local strains of Atlantic salmon and sea trout (*Salmo trutta*) are performed before, during and after eradications (O'Reilly & Doyle, 2007). Forty-three rivers throughout Norway have been treated and the salmon fluke has so far been successfully eradicated from 31 rivers. Meanwhile, 12 rivers are still under post-treatment surveillance awaiting confirmation of eradication. The rivers differ in size but eradication campaigns have included 42 km long rivers in rugged terrain (Sandodden, et al., 2018) and 10 rivers in the same fjord system in the Vefsna region, where River Vefsna had a discharge of 200 m^3/s on the day of treatment (Stensli & Bardal, 2014). Also, in the Vefsna region, the salmon fluke infested Arctic char in three lakes. In total these lakes covered more than 18 km^2, two of them 65 m deep. The Vefsna region was one of the largest rotenone treatments ever performed, for both lake and riverine systems (Stensli & Bardal, 2014). Confirmation of eradication was attained in the rivers of the Vefsna region in 2017. The lakes in the same region still await eradication confirmation because of a different procedure for eradication confirmation.

Minnow (*Phoxinus phoxinus*) in Hardangervidda National Park

The minnow is indigenous to south-eastern Norway, but has been introduced to most parts of the country. It is believed that minnow has been spread through the use of live bait and also accidentally released, mistaken as brown trout (*Salmo trutta*) fry. Minnow have been present at Hardangervidda for decades. Minnows can multiply to high numbers and food competition has had a negative impact on local fish stocks and birdlife. Minnows are not present in western watercourses at Hardangervidda National Park, a high altitude, tree-less plateau in southwest Norway, but were found up to the water divide in several places. The risk of further dispersion across

Table 1 Year of treatment, location and target species, with approximate volume of lakes, litres of CFT L used and approximate cost of treatment.

Year	Location	Target species	Volume (1,000 m^3)	CFT L volume used (l)[a]	Cost (£1,000)
1999	Hardangervidda	Minnow		137	30–50
2005	Sør-Fron	Rainbow trout	5.6	7.5	<10
2008	Lake Ålmotjønna	Roach	120	180	10
2008	Lake Alsettjønna	Common whitefish	84	90	10
2009	Lake Lille Mortetjern	Roach	2.9	4.5	10
2012	Telemark Canal	Pike		100	30–50
2013	Hardangervidda	Minnow	640	805	>100
2014	Telemark Canal	Pike		22	10
2014	Lake Vikerauntjønna	Roach	188	293	10–30
2015	Lake Klokkartjønna	Lake trout	675	670	30–50
2016	Gäddede	Several species		8	10
2016	Bymarka	Roach	2,500	4,000	>200

a) CFT L used also includes CFT L in streams, pools and marshlands surrounding the lakes.

the water divide was regarded as imminent. A successful treatment was conducted in 1999–2000 in the area around Stigstuv (Tønset & Bakkeli, 2000), which is set at the east-west water divide at Hardangervidda National Park. Fish barriers were built to create a buffer zone towards the water divide. Minnows were found in the buffer zone again 10 years later, most likely because the barriers were not working properly. In flooding periods the water level downstream from the barrier could rise and thus level out the height difference. The barriers were adjusted in 2013 prior to a new treatment of the Stigstuv area. The treatment area comprised 40 ponds/small lakes, streams and marshes within an area of 2 km^2. Total water coverage of the ponds/small lakes was 140,000 m^2, with depths of up to 4 m and average depths of 0.5–1 m. The treatment was performed during four days in August 2013 by 16 people. Target dose was 1 ppm CFT L, and a total of 225 l of CFT L was used.

In addition, Lake Hætjørna, another site on Hardangervidda, also was treated due to minnow invasion. Two new barriers had been built, one in the inlet and one in the outlet, making the lake a buffer zone without minnows. Twelve people treated the lake, ponds and marshes in the surrounding area in two days, just prior to the treatment at Stigstuv. Lake Hætjørna covers an area of 0.2 km^2, with an estimated mean depth of 2.5 m and maximum depth 8 m. The target dose was 1 ppm CFT L, and a total of 580 l of CFT L was used. No minnows were caught in hoop net surveys in 2014 and 2016. An environmental DNA survey found no traces of minnows at either site in 2016 (Fossøy, et al., 2017).

Rainbow trout (*Oncorhynchus mykiss*) in Sør-Fron

Sør-Fron is a municipality in Oppland County. Rainbow trout were found in four artificial ponds at a farm in Sør-Fron. Rainbow trout are indigenous to North-America, and have been exported worldwide for angling and fish farming. In Sør-Fron it had been released in these ponds, and netting in October 2000 confirmed their existence. Rainbow trout can host the salmon fluke and thus act as a vector for the parasite. There was risk of escape from the ponds during large floods in the nearby River Lågen. The ponds were treated with rotenone in October 2005. The volumes ranged from 350 to 3,750 m^3, and two people completed the job in one day. The target dose was 1 ppm CFT L, and a total of 7.5 l CFT L was used. On arrival, all ponds were covered with ice. Ice cover was broken before adding CFT L, and the dosage was increased slightly to compensate for the low water temperatures. Prior to treatment the number of fish was reduced through netting. There has been no programme for eradication confirmation, but there have been no later reports of rainbow trout in the ponds.

Roach (*Rutilus rutilus*) in Lake Ålmotjønna

Lake Ålmotjønna is situated in Rissa municipality in Sør-Trøndelag County. The roach is indigenous to south-eastern Norway, but alien to the Trøndelag region. It is believed that roach were released by anglers. Roach were discovered in Lake Ålmotjønna in the summer of 2007. The purpose of the treatment was to prevent further spread downstream to the large Lake Storvatnet, which could lead to a permanent foothold for roach in the region. The volume of Lake Ålmotjønna was 120,000 m^3, and average depth was 5 m. A rotenone treatment was conducted in August 2008. Two people worked for one day. Target dose was 1.5 ppm CFT L, and a total of 180 l CFT L was used. Only two dead roach were found post-treatment. Fish scale analysis revealed that the roach had been introduced at least five years prior to treatment, and apparently had not reproduced. There has been no programme for eradication confirmation, but there have been no later reports of roach in the lake.

Common whitefish (*Coregonus lavaretus*) in Lake Alsettjønna

Lake Alsettjønna is situated in Selbu municipality in Sør-Trøndelag County. The common whitefish is indigenous in south-eastern Norway and eastern watersheds, but alien to the region. Common whitefish was released in Lake Alsettjønna around 1875 as part of a wedding gift. The purpose of the treatment was to prevent further spread to the larger Lake Selbusjøen, which could lead to a permanent foothold for common whitefish in the region. Common whitefish is a food competitor of the indigenous brown trout and Arctic char and can be more effective in exploitation of food sources. It also has a large capacity for propagation. Increased rainfall in the catchment could, in the future, make the stream from Lake Alsettjønna habitable for common whitefish in flooding periods, leading it to spread to Lake Selbusjøen. A rotenone treatment was conducted in Lake Alsettjønna in August 2008. The volume was 84,000 m^3, and average depth was 4 m. Two people worked for one day. Target dose was 1 ppm CFT L, and a total of 90 l CFT L was used. There has been no programme for eradication confirmation, but there have been no later reports of common whitefish in the lake.

Roach (*Rutilus rutilus*) in Lake Lille Mortetjern

Lake Lille Mortetjern is situated in Nittedal municipality in Akershus County. The roach is indigenous to south-eastern Norway, where Lake Lille Mortetjern is situated, but fish had not been recorded in this lake before, making it ideal for amphibians. Roach are present in a neighbouring lake in walking distance, so suspicion is that it has been carried from there and released into Lille Mortetjern. Roach were discovered here in 2007. The lake is known for its rich population of amphibians. The endangered smooth newt (*Lissotriton vulgaris*), great crested newt (*Triturus cristatus*), and moor frog (*Rana arvalis*) can be found here. Since the discovery of roach in 2007, the population of amphibian larvae dwindled to a minimum due to roach predation (Kooij & Redford, 2012), and lack of recruitment threatened the long-term survival of the amphibians. For the first time in Norway, a rotenone treatment was conducted to benefit endangered amphibians. The lake is small, only 2,880 m^3, and rotenone treatment was performed in September 2009. Two people completed the treatment in one day. The target dose was 1.5 ppm CFT L, and a total of 4.5 l of CFT L was used. No mortality of amphibians was observed during treatment. The following spring, newts and frogs reproduced in high numbers (Kooij & Redford, 2012). Eradication of introduced fish in amphibian habitats can be done effectively with rotenone with apparently few negative effects on the amphibian population. It is recommended that treatments be carried out in the autumn when most adult amphibians and metamorphosed larvae have left their breeding habitat and water temperatures are still high enough for rapid rotenone degradation. No roach were detected in biodiversity surveys after the treatment.

Pike (*Esox lucius*) in the Telemark Canal

The Telemark Canal connects the coast of Telemark County with the inland by means of eight sluice stations on a stretch of 105 km. The pike is indigenous to south-eastern Norway but is alien to the Telemark region. Pike were released in the lower parts of the watercourse about 200 years ago. Pike are a voracious predator with the potential to severely decimate indigenous populations of fish. Over the last century, pike have spread upstream. Further upstream are large lakes with populations of large brown trout and river pearl mussel (*Margaritafera margaritafera*) that could be severely affected by invasive pike. Pike were found between Kjeldal and Hogga sluice, Hogga being the critical last sluice before entering the large lake system. This led to permission for rotenone treatment between Hogga and Kjeldal sluice, and the building of an electric fish barrier in the side canal leading up to Kjeldal sluice to prevent pike from being sluiced upstream together with boat traffic. The goal was to stop the pike at Kjeldal sluice, creating a pike free buffer zone up to Hogga sluice. A rotenone treatment was carried out between Hogga and Kjeldal sluice in October 2011, a stretch of about 1 km, to eradicate pike and restore the buffer zone. The river segment between the sluices was drained, and five people treated the remaining pools in one day. The target dose was 1 ppm CFT L, and 100 l of CFT L was used. An electric fish barrier was established in 2012, at the side canal leading up to Kjeldal sluice, to stop further spread.

The Norwegian Veterinary Institute conducted a new treatment at Kjeldal sluice in April 2014, this time only in the side sluice canal downstream of the area treated in 2011. The electric fish barrier in the side canal had been shut down during the winter season in 2013 due to maintenance work. Therefore, it was necessary to prevent the pike that had passed the non-functional electric barrier during winter from entering the previously treated area upstream of Kjeldal sluice before the boat sluices were opened for the season start. The side canal was 220 m long, 3 m deep and 17 m wide. One person did the job in one day, and a total of 22 l of CFT L was used. The target dose was increased to 1.5 ppm CFT L to compensate for water leaking through the sluice gates. Netting has been conducted in the rotenone-treated areas over several years, and no pike have been found.

Roach in Lake Vikerauntjønna

Lake Vikerauntjønna is situated in Trondheim municipality in Sør-Trøndelag County. The roach is indigenous to south-eastern Norway, but alien to this region. It is believed that roach had been released, and the source was other lakes with an alien population of roach in the same municipality, in Bymarka. A dense population of roach was detected in Lake Vikerauntjønna in 2013. It is located only 250 m from Trondheim municipality's main potable water source, Lake Jonsvatnet. There was a concern that roach could adversely affect water quality. The two lakes belong to separate catchments, but the risk of further spread to Lake Jonsvatnet was considered to be high due to the small distance between the lakes. Rotenone treatment was considered as the only measure that would eradicate the roach. Lake Vikerauntjønna covers an area of 0.04 km^2 with a water volume of 188,000 m^3 and maximum depth of 17 m. Treatment was conducted in September 2014 by five people in one day. The target dose was 1.5 ppm CFT L, and a total of 293 l of CFT L was used. Fish scale analysis revealed that the roach had been introduced for the first time around 2007, and possibly new introductions in following years too. No roach were detected in biodiversity surveys after the treatment.

Lake trout (*Salvelinus namaycush*) in Lake Klokkartjønna

Lake Klokkartjønna is situated in Blåfjella-Skjækerfjella National Park in Nord-Trøndelag County. The lake trout is indigenous to North-America but has been imported to Scandinavia for fish farming and angling purposes. The first records of release in Norway are from the 1970s (Hesthagen & Sandlund, 2016). In Lake Klokkartjønna the introduction could have come from source populations in Sweden, since lake trout are more common across the border, but no one knows for sure. A first finding of lake trout in Lake Klokkartjønna was recorded in the autumn of 2010. Lake trout are considered to be a threat to natural habitats, ecosystems, and indigenous fish populations. The risk of spread downstream to adjacent lakes was considered high, and permission for rotenone treatment was granted. Lake Klokkartjønna covers an area of 0.14 km^2 with an estimated volume of 675,000 m^3. Eradication was performed in July 2015, and eight people participated over two days. The target dose was 1 ppm CFT L, and a total of 670 l of CFT L was used. No lake trout have been found through post-treatment netting.

Several species at hydroelectric power plant in Gäddede

Gäddede hydroelectric power plant is situated in Sweden in Strømsund municipality in Jämtland County close to the Norwegian border. The power plant separates two lakes with different fish species due to a natural fish barrier. The upstream lake contained only indigenous brown trout and Arctic char whilst the lower lake also hosted pike, common whitefish, burbot (*Lota lota*), and rainbow trout. It was unwanted for any of these fish species to be spread upwards in the waterway. It is not possible for fish to pass upstream through the power plant, but a planned maintenance shutdown in 2016 could enable fish to pass the turbines and later rise up above the dam into the upper lake. As a precautionary measure, permission for rotenone treatment in the stagnant ponds on both sides of hydro power turbines was given. The volumes of the ponds ranged from 150 to 2,500 m^3, and eradication was performed in June 2016. Two people did the job in one day. A high dose of 3 ppm CFT L was used to compensate for fresh water leaking into the isolated ponds. A total of 8 l CFT L was used. There has been no programme for eradication confirmation. Dead fish were found during treatment in the ponds.

Roach in seven lakes in Bymarka

Bymarka is on the outskirts of Trondheim city in Sør-Trøndelag County. The roach is an invasive species in the region and was released in the 1880s to three small lakes in the same watercourse. From the 1960s to the 1980s roach were spread to three neighbouring lakes, and were found in another four lakes from 1998 to 2013. It was suspected that the roach population in Bymarka was the source of spread. When roach were found in Lake Vikerauntjønna, close to the Trondheim municipality's main potable water source, plans for treatment of the lakes in Bymarka were put forward. The main reasons were a concern for the roach to adversely affect potable water quality, a wish to permanently eradicate this blacklisted species from the region, and to contribute to conservation of natural fish stocks and biodiversity. Rotenone treatment was considered to be the only measure that could eradicate roach from these lakes. Several of the lakes have a dam, and an attempt to eradicate roach through dewatering in 2004 failed. One lake was 17,000 m^3 and 10 m deep, while the six other lakes ranged from 412,000 to 615,000 m^3, with maximum depths of 10–17 m. In September 2016, treatment was performed by a crew of 14 people for four days. A total of 4,000 l of CFT L was used and, as before, the target dose was 1.5 ppm CFT L. Populations of invasive pike in the lakes were eradicated simultaneously. No roach were detected in a biodiversity survey after the treatment.

DISCUSSION

Rotenone treatments are not without controversy, but most times invasive fish eradications are welcomed. The general public's acceptance of rotenone treatments in Norway might be a result of the absence of failure, thus strengthening the understanding for rotenone as a necessary and effective tool in the fight against invasive freshwater fish. The description of rotenone treatments does not include method, but relevant method can be found in Sandodden, et al. (2018). A standard operating procedure for the use of rotenone in fish management is given by Finlayson, et al. (2010b). For rotenone analysis, an on-site determination of rotenone has been developed by the Norwegian Veterinary Institute (Sandvik, et al., 2018).

The Norwegian Environment Agency is in the process of writing an action plan, which will identify and prioritise measures against invasive freshwater fish. This will lift the coordination of possible eradication measures from county level to national level, making top prioritised measures easier to identify. Forthcoming eradication projects are mostly for domestic invasive pike. The *G. salaris* eradication campaign will continue, and is now at an intermediate planning stage with the next eradication, at the earliest, in 2022.

Costs of treatments

Costs are not easy to describe uniformly. Eradication projects have had different levels of participation from the County Governor, and work hours are usually the main expense in these smaller eradications. The cost consists of the Norwegian Veterinary Institute's planning and preparations and expenses with treatments, including hired crew. The cost does not include pre- and post-treatment biodiversity surveys, cost of CFT L, and County Manager expenses. Eradication of *G. salaris* is not included in the table, but the cost of the eradication campaign so far is estimated to be about £100 million.

Eradication confirmation

The *G. salaris* eradication campaign includes a surveillance programme for eradication confirmation, but no parallel surveillance programme exists for invasive freshwater fish. Eradication confirmations are based on the absence of new detections by biodiversity surveys, local netting and angling. Successful restocking of indigenous fish also indicates the absence of the introduced species. Net trapping and environmental DNA surveys are other possible ways to document the outcome of a treatment but there is, at present, no national set of rules for eradication confirmation. However, there are no examples from Norway, during the past 20 years, of failed rotenone-based eradication attempts against invasive freshwater fish.

This may be because all eradications are assigned for planning and execution to a national competence group for rotenone treatment, which gives continuity-based experience and knowledge. Secondly, smaller lentic waters are less complicated treatments due to longer time for adequate mixing of rotenone and thus ensuring lethal concentration in all parts of the lake, which should leave the target fish no opportunities to accidently avoid lethal exposure. Large-scale lotic waters systems are also possible to succeed in, proven by the *G. salaris* eradication campaign.

ACKNOWLEDGEMENTS

I wish to thank all my colleagues who have participated in the described treatments, and the Norwegian Environment Agency for their role in fighting invasive species. I appreciated the constructive comments on the manuscript given by two anonymous referees.

Abstract Invasive species are of significant concern, especially in mega-diverse countries, because they cause negative effects such as loss of native biodiversity, ecological alterations, disease spread, and impacts on economic development and human health. In mainland Ecuador, information on invasive invertebrates in marine ecosystems is scarce. The objective of this study was to describe and locate the invasive species present in the rocky shores of the intertidal and subtidal zones along 10 areas (83 sites) covering most of the Ecuadorian coast during 2015–2016. Benthic macroinvertebrates communities were measured over quadrats located randomly on a 50 m transect positioned parallel to the coast in the intertidal and subtidal zone, covering an area of 1,860 km^2. Six invasive species were recorded: Arthropoda *(Amphibalanus amphitrite),* Cnidaria *(Pennaria disticha, Carijoa riisei*), Bryozoa (*Bugula neritin*a), Rhodophyta (*Asparagopsis taxiformis*) and Chlorophyta (*Caulerpa racemosa*). The areas with highest abundance of invasive species were in Jama (not a protected area), Marine and Costal Wildlife Reserve Puntilla of Santa Elena and Santa Clara Island Wildlife Refuge (protected areas). The most abundant species was *Carijoa riisei* with a relative abundance of up to 80%. It was the most aggressive of the invasive species registered in the subtidal zone, mainly in northern centre of the Ecuadorian coast. *C. riisei* is growing on native coral (*Pocillopora* spp.*)* and on sessile macroinvertebrate communities (*Pinctada mazatlanica*, *Muricea appresa* and *Aplysina* sp.) that are being affected by its invasion. This study must be taken into account by local and regional government authorities to create public policy programmes of monitoring for surveillance and control of invasive species. These programmes should focus on integration of socio-economic and ecological effects. They should be complemented by experimental design and analysis of environmental variables to provide technical information for a baseline of bio-invasion analysis along the Ecuadorian coast and Galápagos, to avoid the expansion of invasive species negatively affecting the marine biodiversity of mega-diverse countries such as Ecuador and other countries of South America.

Keywords: *Carijoa riisei*, continental Ecuador, Galapagos Islands, invasive species, macroinvertebrates, marine ecosystems, marine protected areas

INTRODUCTION

Invasive species are a cause of worldwide concern especially in mega-diverse countries because they can cause loss of native diversity, ecological alterations, increases in pests, diseases (Prenter, et al., 2004), impacts on benthic communities, impacts to the water column (Darrigran & Damborenea, 2011). Additionally, they can affect economic development and human health (Lowe, et al., 2000; Pimentel, et al., 2005). Many species are transported accidentally through anthropogenic means breaking geographic barriers that once restricted their range of expansion (Schüttler & Karez, 2008); they invade new areas, where they can settle, reproduce, spread and compete with native species.

Biological invasions, along with climate change, are key processes that feedback and affect global biodiversity. Climate change facilitates the dispersal and establishment of species which aggravates their impacts and makes their control more difficult, while invasive species can influence the magnitude of the environmental impacts by altering the structure and function of ecosystems (Mendoza, et al., 2014).

At present, there are numerous global and regional initiatives dedicated to optimising information and management of invasive alien species, including the Global Invasive Species Program (GISP), the IUCN-ISSG Invasive Species Global Information Network on Invasive Alien Species (GISIN), the Global Invasive Species programme of The Nature Conservancy (TNC-GISI) and the Inter-American Invasive Species Information Network (IABIN-I3N) (Schüttler & Karez, 2008).

On mainland Ecuador, information on invasive invertebrate species on intertidal rocky shores and subtidal zones is limited, fragmented and scattered. However, research on non-native species conducted in the Galapagos Islands (1,000 km off the coast of mainland Ecuador) has increased in the last decade, both in the terrestrial and marine environments (Campbell, et al., 2015). In 2012, the Charles Darwin Foundation (CDF), in collaboration with the Galapagos National Park Directory (GNPD), the Galapagos Biosecurity Agency (ABG), the Ecuadorian Navy and the Ecuadorian Navy Oceanographic Institute (INOCAR), initiated the Marine Invasive Species Project in the Galapagos Marine Reserve (Keith, et al., 2015).

The study of non-native species in Ecuador has mainly been done in the Galápagos Islands, due to the importance of this unique ecosystem in the world and the relative lack of scientific funding on the mainland. In the Galápagos Marine Reserve (GMR), an initial baseline study produced a list of seven non-native species in the GMR (Keith, et al., 2016). The marine invasive species team of the CDF have continued the research and applied different methodologies to learn more about non-native species in the GMR and

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 452–457. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

the Eastern Tropical Pacific (ETP) region (I. Keith, pers. comm.). The objective of this study was to identify invasive species located in rocky shore habitats of the intertidal and subtidal zones covering 1,860 km^2 of the Ecuadorian coast during 2015–2016, that could be considered as threats for Ecuadorian mainland as well as Galapagos vulnerable ecosystems.

MATERIALS AND METHODS

Study area

Fieldwork was carried out in 10 areas along the Ecuadorian coast in six protected coastal marine areas (acronym in Spanish: AMCP) and four non-protected areas. The study areas ranged from Playa Escondida (0°49'8.05" N, 80° 0'22.66" W) in the north of Ecuador in Esmeralda province to Santa Clara Island in the south of Ecuador (3°11'21.11" S, 80°27'10.21" W) in El Oro province, covering 1,478 km^2 of protected areas and 382 km^2 of additional areas on the mainland coast. This survey included the protected areas (Fig. 1) from the north of Ecuador in the Galeras San Francisco Marine Reserve (acronym in Spanish: RMGSF) (Esmeralda province); Wildlife Refuge and Marine Coastal Pacoche (Pacoche) and Machalilla National Park (acronym in Spanish: PNM) (Manabí province); El Pelado Marine Reserve (acronym in Spanish: REMAPE); and Wildlife Coastal Marine Reserve Puntilla of Santa Elena (acronym in Spanish: REMACOPSE) (Santa Elena province) to Santa Clara Island Wildlife Refuge (Santa Clara) (El Oro province). The non-protected areas (Fig. 1) were: Jama, Canoa (Manabí province), Ayampe-La Entrada (between Manabí and Santa Elena provinces) and Copé (Santa Elena province). The Ecuadorian coast has an extension of 2,900 km corresponding to 45% of open coastal and 55% of inner coastal waters (Ayón, 1988). There is a wide range of geological features along the coast, including bluffs, barriers and sandplains, estuaries and lagoons, and engineered shoreline structures (Boothroyd, et al., 1994).

The climate on the coast varies seasonally from dry season (May to November) to the rainy season (December to April). The average annual temperature is above 22°C, with maxima fluctuating between 32–38°C and minima fluctuating around 15°C (Sonnenholzner, et al., 2013). Ecuador belongs to the Tropical East Pacific (TEP) region, with two sub-regions known as Panama Bight Ecoregion and Guayaquil Ecoregion (Sullivan & Bustamante, 1999; Miloslavich, et al., 2011). The northern half of the Ecuadorian mainland coast corresponding to the Panama Bight Ecoregion extends from Azuero Peninsula of Panamá to Caráquez Bay. It is characterised as a tropical zone, covered mostly by mangroves and dense rainforest vegetation (Miloslavich, et al., 2011), with >2,000 mm/yr of rainfall and without ecologically dry months through the year (Sonnenholzner, et al., 2013). The southern Ecuadorian coast, falling within the Guayaquil Ecoregion, extends from Caráquez Bay to Illescas Peninsula in the north of Perú and is characterised by a drier climate with <100 mm/yr of rainfall (Miloslavich, et al., 2011).

Survey

A total of 83 sites were sampled from February 2015 to February 2016 along the four coastal provinces of Ecuador (Esmeraldas, Manabí, Santa Elena and El Oro). These sites were established considering aspects such as representativeness of ecosystems; areas with greater and lesser anthropogenic intervention, biological processes (reproduction hotspots, feeding areas, seabirds and sea turtle nesting sites); and sensitive habitats or areas of great ecological importance according to the requirements established in the terms of reference of the Environmental Ministry (Ministry of Environment, 2014). The composition and abundance of the macroinvertebrates present in the rocky shore in the intertidal and subtidal zones were quantified using a band-transect system parallel to the coastline.

Data were collected in the intertidal zone following the standardised protocol from the South American Research Group on Coastal Ecosystems (SARCE) (SARCE, 2012). At each site, 10 quadrats (50 × 50 cm each) were randomly placed and sampled along a 50 m transect positioned parallel to the waterline in the mid, low and high intertidal level. A total of thirty replicates was sampled for each site. The abundance of colonial organisms was estimated by percent cover and all mobile individuals (>2 cm long) were counted. Most identification of biota was done in the field, although occasional problematic specimens were collected for reference and sent to specialists for identification. For the subtidal zone, at each site the organisms were separately estimated in two transect blocks by a diver, one on each side of 50 m transect line set along a shallow depth (normally 6–8 m). Every transect block encompassed a total reef area of 50 m × 5 m. The next diver scanned the nearby transect block by swimming back parallel to the initial transect at a distance of 5 m from the transect line (Edgard, et al., 2011). This up and back procedure for two adjacent blocks was

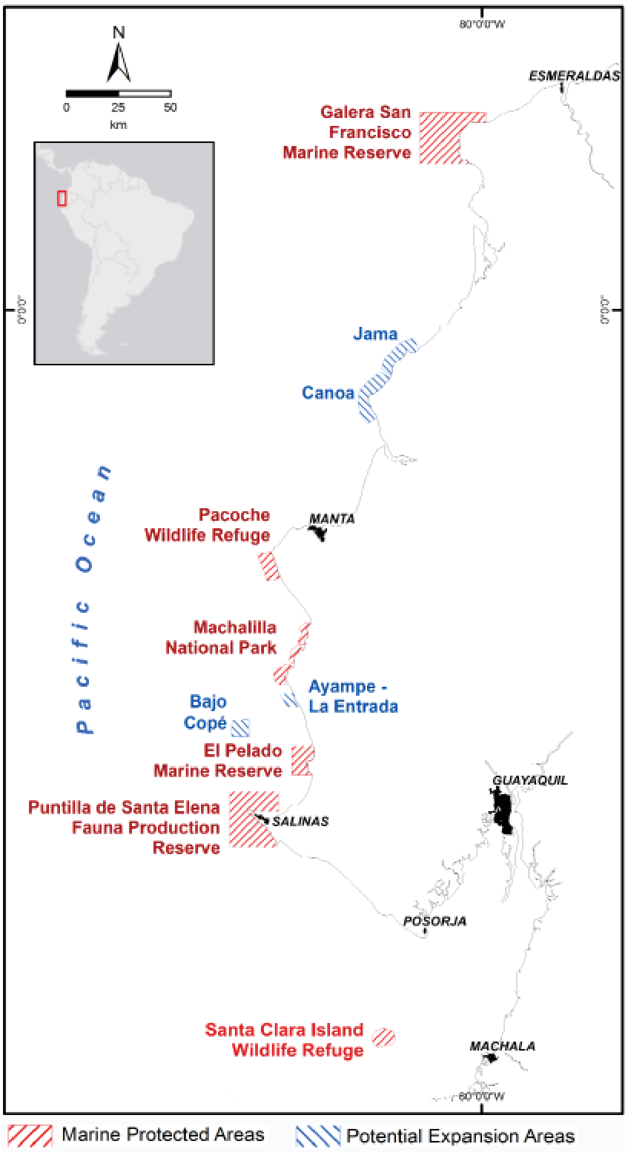

Fig. 1 Study area and location of the sampling sites on the Ecuadorian coast.

repeated along the shallower depth contour, generating a duplicate transect block data at each site. Sessile organisms were estimated by percent coverage of different taxa and grouped in substratum classes (crustaceans, cnidarians, sponges, ascidians, bryozoans, hydroids) within the transect lines. The cover was generally recorded by divers within 10 quadrats (0.5 × 0.5 m), placed sequentially every 5 m along the 50 m transect, and mobile organisms were counted along each quadrat. Digital photo quadrats were taken during the field work. We summed counts across all quadrats to create site totals.

Data analysis

To explain the biological assemblage, an X sites by Y species matrix of abundances was built to perform a non-metric multidimensional scaling (n-MDS) and cluster analysis to visualise the similarity of studied areas. For both analyses a similarity matrix was generated using the Bray-Curtis index on the fourth root transformed data to remove the weight of the dominant species (Clarke & Gorley, 2006). Further bubbled MDS analyses were performed to visually establish the differences among the abundances of *Carijoa riisei* between zones, using the statistical package Plymouth Routines in Multivariate Ecological Research (Primer). In order to determine the difference of organism abundance by province, a nonparametric ANOVA was performed, after the assumptions were not fulfilled, using the Kruskal Wallis test. In addition, to determine the difference in abundances between protected and unprotected zones, we applied the ANOSIM test using PRIMER V6 (Clarke & Gorley, 2006).

Distribution maps of species were prepared using the information collected from the fieldwork. These maps represent the relative abundance with a percent of coverage/m^2 on every site for inter-tidal and subtidal zones, with scales ranging between 0.1–50%, indicating a spatial approximation of alien invasive species location and coverage. Besides the status, invasiveness of each species was established using international databases such as: the IUCN list of 100 most harmful invasive alien species in the world (Lowe, et al., 2000); Global Invasive Species Database, ISSG (IUCN/SSC, 2014); and Invasive Species Compendium (<www.cabi.org/isc>).

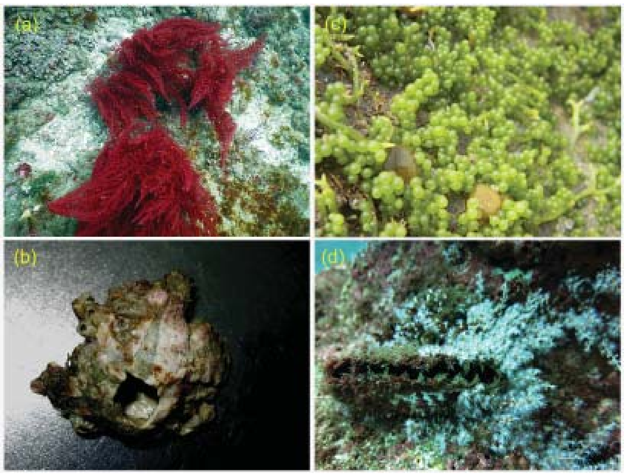

Fig. 2 Alien species found in the survey: a) *Asparagopsis taxiformis,* b) *Amphibalanus amphitrite* c) *Caulerpa racemosa*, and d) *Carijoa riisei* growing on the bivalve *Pinctada mazatlanica*.

RESULTS

A total of six alien invasive species from five phyla were recorded: Cnidaria (*Pennaria disticha*, *Carijoa riisei*), Bryozoa (*Bugula neritina)*, Arthropoda (*Amphibalanus amphitrite),* Rhodophyta (*Asparagopsis taxiformis*) and Chlorophyta (*Caulerpa racemosa*). Assemblages were numerically dominated by cnidarians. The most abundant species was *Carijoa riisei* (Table 1; Fig. 2). Invasive species were recorded at 24 sites (14 sites in the subtidal zone and ten in the intertidal zone). In the subtidal zone, the area with the highest presence of invasive species was the RMGSF in the north of Ecuador (Esmeralda province) while in the intertidal zone it was Punta Carnero site in the REMACOPSE, south-central part of the coast in Santa Elena province· (Table 1; Fig. 3).

The n-MDS of invertebrate invasive species abundance showed four groups with major similarity (60%), one group formed by Jama, REMAPE and RMGSF, the second group clustered the sites of REMAPE (south-central coast); the third group formed REMACOPSE, Ayampe, Copé and Santa Clara (central and south-central coast) and the last one grouped by REMACOPSE, Pacoche, Santa Clara, Ayampe and Canoa (Fig. 4).

Amphibalanus amphitrite, Pennaria distincha and *Carijoa riisei* were the invasive species with greatest

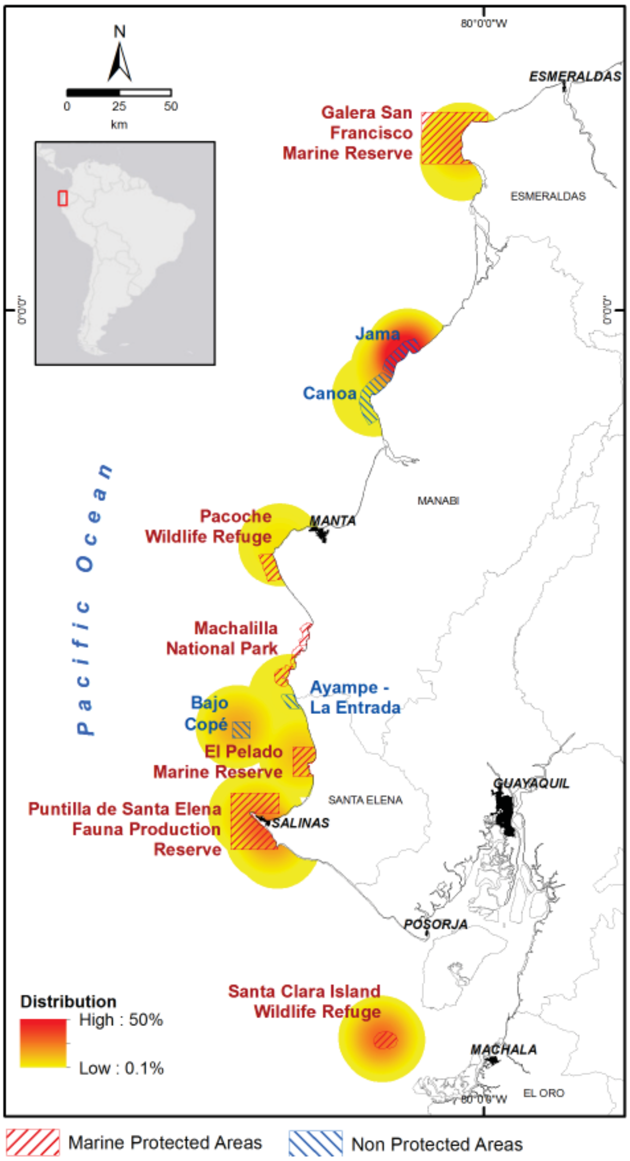

Fig. 3 Relative abundance and distribution of invasive species along the Ecuadorian coast during 2015–2016.

occurrence. Of these three, C. *riisei* was most abundant (Fig. 5) in the non-protected area located in the central coast of Ecuador (Jama) (Table 1). However, it was also recorded in the north zone of the Galera San Francisco Marine Reserve (Punta Alta, Piedra de Quingue) and in the south-central coast at El Pelado Marine Reserve (La Pared).

Statistically, no significant differences were found between the abundance of invasive species by provinces (global R=0.08, p>0.001) or by protected and unprotected zones (global R=-0.06, p>0.001).

The MAP's that presented the greatest number of invasive species were REMACOPSE (four species) and Ayampe (three species), followed by Jama and REMAPE (less than three species. Galeras San Francisco, Canoa, Pacoche and Copé recorded low benthic numbers of invasive species (Table 1).

DISCUSSION

This is the first report investigating the presence of invasive species along the Ecuadorian coast, including marine protected areas and unprotected areas, covering the coast from north to south of the country and two ecoregions in four distinct provinces. There are four species classified as macroinvertebrate invasive species worldwide, of which the majority are the cnidarians, mainly the Anthozoa class. Although the invasive species recorded are not listed in the 100 world's worst invasive alien species according to IUCN (Lowe, et al., 2000), two species (*Carijoa riisei* and *Bugula neritina,*) are listed in the Global Invasive Species Database (ISSG) and four species (*Carijoa riisei*, *Bugula neritina, Pennaria disticha* and *Amphibalanus amphitrite)* are registered by the Global Register of Introduced and Invasive Species (GRIIS).

Table 1 Invasive species recorded by provinces, areas and sites on the Ecuadorian coast, including abundance (coverage percentage) in the subtidal and intertidal zones.

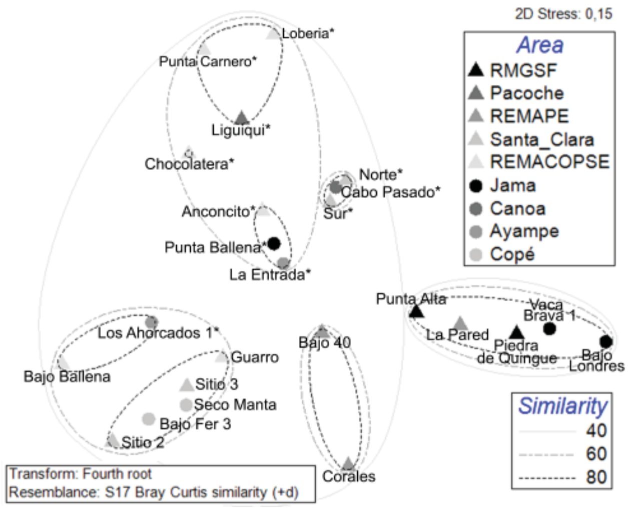

Fig. 4 Non-metric multidimensional scaling ordination, showing relative abundance of marine invasive species registered along the Ecuadorian coast during the period 2015–2016.

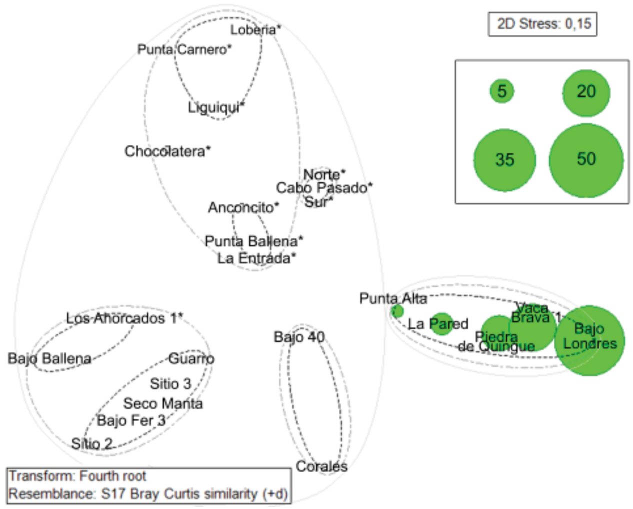

Fig. 5 2D bubble MDS configuration showing relative abundance of *Carijoa riisei*.

Carijoa riisei showed a greater abundance in the central zone of the Ecuadorian coast, mainly in Jama. This species has increased its colonisation in some areas of the El Pelado Marine Reserve in two years (2013–2015) (Cárdenas-Calle & Triviño, 2014). The invasion of *C. riisei* to new sites is probably caused by marine currents and maritime traffic. The invasive growth of *C. riisei* was noted among colonies of Pocilloporidae corals, *Pinctada mazatlanica, Muricea appresa* and *Aplysina* sp., confirming the imminent threat of this species to the sessile biota of the marine protected areas (Martínez, 2013). This species has an extensive geographic distribution in the Pacific from the Philippines, Indonesia, Australia, and Thailand, South Atlantic (Silva, et al., 2011) and Caribbean region (Kahng & Grigg, 2005; Kahng, et al., 2008;) with a variety of reproductive strategies (Barbosa, et al., 2014) including sexual and asexual reproduction, growing in different habitats, but preferring shallow areas.

Carijoa riisei has caused great impacts and damage to coral areas in Hawaii (Barbosa, et al., 2014) where it is currently considered a pest and has affected over 70% of the colonies of black corals *Antipathes dichotoma* and *A. grandis* (Global Invasive Species Database, 2017). It is considered a common invasive species from Florida (USA) to Santa Catarina (Brazil), displacing native species. It is now known to monopolise benthic surfaces under optimal conditions for its growth, from the intertidal zone to depths of >100 m (Venkataraman, et al., 2016). *C. riisei* competes successfully over black coral and invertebrates (Kahng & Grigg, 2005) and is dispersed through marine vectors (Grigg, 2003), and it is reported as a major biofouler in the Atlantic region (Concepcion, et al., 2010).

The rapid growth of the *C. riisei* colonies and their widespread dispersion in coral ecosystems has begun to generate great concern worldwide for being considered a threat to the diversity of sessile corals and invertebrates. For this reason, it is listed in the database of invasive species of IUCN (Global Invasive Species Database) and there is evidence of ecological impacts of this species in some countries of the South Pacific, as in Colombia, where high mortality of corals and octocoral coating has been reported on the island of Malpelo (Sánchez, et al., 2011).

Orensanz, et al. (2002) detected more than 40 invasive species in the Southern Atlantic Ocean, where poor knowledge of the regional biota makes it difficult to track invasions. For these reasons it is necessary to begin an alliance between national and international academics and environmental authorities (Ministry of Environment) in Ecuador to develop a strategy for surveillance and research on the ecological effects of invasive species in the coastal zones. With *Carijoa riisei* it is necessary to quantify mortality and replacement of existing coral communities in Ecuador, because this information is currently unknown, as is the habitat and biota preferences for colonisation. It is important to know its distribution, its ecological effects on native fauna, and its preferences (habitat, substrates, depths and environmental variables) to allow the establishment of substantial management actions to avoid its dispersion to other sensitive areas, such as the Galapagos Islands where it is still absent.

We found that the greatest abundance of invasive species was in the Ecuadorian central coast (Manabí), belonging mainly to the cnidarians. However, the largest diversity of species was in the south-central coast (Santa Elena). The presence of these invasive species is possibly due to the currents, ballast water and encrustations of invaders on ships. We can speculate that factors such as marine currents, rise of temperature, increase of maritime traffic, global warming and invasive breeding strategies will accelerate the augmentation of invasive alien species and the loss of diversity of corals, octocorals, sponges and other marine sessile invertebrates on the Ecuadorian coast. Four of the six non-native species found on the mainland of Ecuador (*Pennaria disticha, Bugula neritina, Asparagopsis taxiformis* and *Caulerpa racemosa*) from Table 1, are already present in the Galapagos Islands (Danulat & Edgard, 2002; Keith et al, 2016).

This study must be taken into consideration by local and regional government authorities to create public policies and programmes to monitor for surveillance and control of invasive species. These programmes have to be integrated with socio-economic and ecological effects and complemented by experimental design and analysis of environmental variables to provide technical information and a baseline of bio-invasions along the Ecuadorian coast and Galápagos. It is important to avoid or limit the expansion of invasive species that negatively affect the marine biodiversity of mega-diverse countries such as Ecuador and other countries of South America.

ACKNOWLEDGEMENTS

We thank James Mair, Emeritus Professor, Heriot Watt University for providing comments on an earlier version of the manuscript. We also appreciated the collaboration in the laboratory of Verónica Araujo, student from the Universidad de Guayaquil. We are especially grateful to the Ministry of Environment of Ecuador (Subsecretaría de Gestión Marina y Costera), the Inter-American Bank and the Global Environment Facility (GEF) for financial support. This work was part of the project "Quantitative subtidal and intertidal marine biodiversity inventories in six marine protected coastal areas and four areas of possible expansion" (CFC-001-2015).

Lessons on effectiveness and long-term prevention from broad-scale control of invasive alien species in Scotland's rivers and lochs

J.C. Horrill[1], M.K. Oliver[1] and J. Stubbs Partridge[2]

[1]Rivers and Fisheries Trusts of Scotland, 11 Rutland Square, Edinburgh EH1 2AS, UK. <chris@rafts.org.uk>. [2]Scottish Natural Heritage, Great Glen House, Leachkin Road, Inverness IV3 8NW, UK.

Abstract Prior to 2008 there were few invasive alien species (IAS) initiatives operating in Scotland on a scale required for effective control. The establishment of the Biosecurity and Invasive Non-Native Species Programme by the Rivers and Fisheries Trusts of Scotland was the first attempt to link local efforts with national IAS strategy on scales appropriate to the effective control of target species. The programme worked with 26 local fisheries trusts to produce biosecurity plans that covered over 90% of Scotland's rivers and lochs. The programme implemented a range of prevention measures, including promoting awareness of invasive species issues and the need for biosecurity among water users. Projects were established for invasive plants on most major river systems, and for American mink (*Neovison vison*) in the north of Scotland. These projects involved public/private partnerships, using a mix of professional staff and volunteers. Interactive data management systems were developed to manage input from a large number of individuals and to inform an adaptive-management approach. These control projects demonstrated that it is feasible to reduce the size and density of target populations of invasive species across large geographic areas. The key to maintaining the momentum of this control effort in the future will be to demonstrate sustainable IAS management in the longer term. This challenge led to the formulation of the Scottish Invasive Species Initiative (SISI) whose overall aim is the development of a long-term, cost-effective strategy for IAS management throughout the north of Scotland. SISI will test strategies derived from experience and information from previous control projects. Important areas that the initiative will seek to address include defining outcomes, integrating IAS management into other management initiatives, and maintaining partnership interest and cohesiveness in a challenging funding environment.

Keywords: adaptive management, biosecurity, community-based effort, giant hogweed, Himalayan balsam, IAS, Japanese knotweed, mink, rivers

INTRODUCTION

Scotland depends on the quality of its iconic natural environment for economic and recreational wealth. The high number of protected sites (1,868) and designated natural features (5,376) reflects the importance placed on natural heritage.

Watercourses are integral, defining features of Scotland's landscapes and culture. Historically, Scottish society relied on healthy rivers and lochs for food, recreation, transport and industry. Art, folklore and traditional activities have long drawn inspiration from them. Today, the economic reliance extends to whisky-distilling, salmon-farming, tourism and many new forms of recreation. In 2010, Scottish residents generated £2.3 billion from their visits outdoors (SNH, 2011). Recreational freshwater fishing is estimated to support around 4,300 jobs, contributing £79.9 million to the economy (Marine Scotland, 2017).

Within increasingly fragmented landscapes, water courses also function as corridors between habitats for biodiversity. This vital function is compromised by invasive alien species (IAS) (Also known as Invasive Non-Native Species (INNS) in the United Kingdom) for which rivers and lochs are excellent pathways into the broader natural environment. The margins and shorelines of watercourses themselves are among the most exposed to the risk of IAS spread and damage. Climate change, pollution and habitat disturbance accelerate rates of invasion, with corresponding costs for socio-economic, human and ecological well being (Forest Research, 2008; Williams, et al., 2010).

The UK and Scottish Governments have recognised the IAS threat. The Great Britain Invasive Non-Native Species Strategy (GBNNSS, 2008) is a policy and strategic response. The Scottish Environment Protection Agency (SEPA) addresses the threat through the INNS supplementary plan to the Scotland and Solway-Tweed River Basin management plans (SEPA, 2009a; SEPA, 2009b). Scottish Natural Heritage (SNH), a Scottish Government agency, has included IAS in its Species Action Framework (Raynor, et al., 2016).

Prior to high level recognition of this sort, the vast majority of reponses to IAS were small-scale and localised. Management on larger scales was confined to catchment-based control of invasive alien plant species (IAPS) on the River Tweed (Tweed Forum, 2006) and to control of American mink (*Neovison vison*) in the Cairngorms National Park and rural Aberdeenshire (Bryce, et al., 2011).

The scale of the threat, the likely severity of ecological, social and economic impacts and the prospect of rises in control and eradication costs have constituted a case for better, more strategic and systematic approaches to managing IAS. This paper reports on the results and lessons learnt between 2008–2017 from the work of 26 member organisations of the Rivers and Fisheries Trusts of Scotland (RAFTS) in partnership with government agencies and universities to address the IAS threat to Scotland's rivers and lochs. We will also refer to an ambitious project in which those lessons are incorporated to manage multiple IAS cost effectively in the long term over 29,500 km^2 of northern Scotland.

METHODS

Biosecurity planning

At the northern invasion front for high-impact IAS of the United Kingdom and Europe, Scotland was well placed to manage the threats strategically at national and local scales. On the national scale there was an opportunity to defend the IAS-free region to the north of the front, control IAS in the lightly infested catchments in northern and southern Scotland, before addressing the more impacted areas of central Scotland.

RAFTS and its 26 local Trust members created area-specific biosecurity plans in three phases between 2008 and 2010 (Fig. 1). All plans used a template designed by RAFTS in consultation with the Great Britain Non-Native Species Secretariat, Scottish Government, SNH and

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 458–465. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

SEPA. The template linked key elements of IAS policy and strategy to local action and acted as a framework for universal consistency. Plan objectives reflected the three key elements of the Great Britain INNS Strategy (GBNNSS, 2008): (1) prevention, early detection, and surveillance; (2) monitoring and rapid response; and (3) mitigation, control and eradication. Objectives and actions were also linked to related plans and initiatives such as River Basin Management Planning (SEPA, 2009a; SEPA, 2009b). This approach translated the key elements of national policy and strategy into action across relevant sectors in ways which emphasised coordination and partnership.

Funding secured for a series of projects from 2009 to 2017 enabled local organisations to coordinate and monitor the control of invasive alien plant species and American mink by professionals and volunteers (Table 1). RAFTS provided the overall coordination, strategic direction and evaluation of the activities. SNH, SEPA, the University of Aberdeen (mink) and Queens University Belfast (plants) provided specific technical support. Principal target species were the IAPS, giant hogweed (*Heracleum mantegazzianum*), Japanese knotweed (*Fallopia japonica*) and Himalayan balsam (*Impatiens glandulifera*) and the alien invasive mustelid American mink – all recognised as high-impact species for waterbodies and/or biodiversity (UKTAG, 2015).

Engagement

Engagement of key stakeholders was critical given the scale of the work, the need to obtain permissions for access and the recruitment and maintenance of the volunteer workforce. Awareness campaigns, mailshots, presentations, meetings with local environment/community groups, schools and individuals, newsletters, the websites and media were means to initiate contact with potential volunteers. Working in public areas and approaching landowners for permission also proved effective in engaging local communities.

Once engaged, stakeholders were kept informed through websites, newsletters, media and meetings and later through interactive reporting systems. Participating organisations and individuals received skills-training for efficient, effective, legally compliant surveillance and control of IAS. Formal training courses were tailored to roles in the control strategy. Volunteers were also offered informal training if they were unavailable for formal courses.

Table 1 Summary of projects implemented through the RAFTS Biosecurity and Invasive Non-Native (Alien) Species Programme with duration, description of activities and geographic scope and participating local partner organisations.

Name of Project	Duration	Description	Participating Trusts
Pan Scotland Invasive Non Native Plant Species Control	2009–2016	A series of projects for the control and eradication of invasive alien riparian plant species in northern, southern and central Scotland. Included biosecurity, awareness and training of professional staff and volunteers.	Annan; Argyll, Ayrshire, Cromarty Firth; Deveron, Isla and Bogie; Don; Dee; Esk River; Forth; Findhorn, Nairn and Lossie; Galloway; Lochaber; Kyle of Sutherland; Tweed; West Sutherland
Scottish Mink Initiative (SMI)	2010–2015	Aiming to eradicate breeding mink from 20,000 km^2 (later extended to 28,000 km^2) of north and north-eastern Scotland. The Initiative also supports awareness and local capacity building activities as well as the development of local management models for future mink control.	Cromarty Firth; Deveron, Isla and Bogie; Dee; Don; Esk; Findhorn, Nairn and Lossie; Spey, Tay, Ythan
Controlling priority invasive non-native riparian plants and restoring native biodiversity (CIRB)	2010–2014	Control and eradication of invasive alien riparian plant species in 12 catchments in southern Scotland, piloting biosecurity, awareness activities, training of Trust staff and volunteers, best practice identification and dissemination.	Argyll; Ayrshire; Galloway; Tweed Forum

IAPS densities, distribution and control

Surveys of river and loch catchments identified the location, extent and abundance of IAPS. The distribution of IAPS populations were entered into a geo-database along with estimates of abundance based on the DAFOR scale (Kent & Coker, 1992). The impact of treatment was monitored by recording distribution and abundance post-treatment. Treatments varied by species but were primarily foliar leaf spray (Japanese knotweed and Himalayan balsam), stem injection (Japanese knotweed) and physical removal (Himalayan balsam).

Initially the majority of local Trusts took a 'top down' approach to control, starting at the upstream extent of IAPS distribution and working downstream. The rationale was the reduction of potential reinfestation of treated sites from upstream populations. Later, working from the lower to the upper catchment was adopted by some Trusts when treating whole catchments. This tactic recognised that plants lower in the catchment developed earlier than those in the upper regions.

Mink control

Volunteers and paid staff relied mainly on mink rafts to detect and trap American mink. Originally conceived by the Game and Wildlife Conservation Trust (GWCT) (Reynolds, et al., 2004), the mink raft is a floating platform on which a tunnel covers a clay pad. The raft is anchored to the bank of a waterway. American mink are predominantly active within 10 m of waterways (Yamaguchi, et al., 2003), are naturally attracted to tunnels and leave footprints in the clay when investigating them. Once a mink is detected, a live-capture cage-trap is inserted in the tunnel. Captured mink were despatched humanely. Carcasses were tagged and sent to Aberdeen University to determine sex, age and provenance based on genetic profile (Fraser, et al., 2013; Melero, et al., 2015; Ruiz-Suarez, et al., 2016).

Evaluation

Stakeholder engagement and impacts on IAS populations were evaluated in 2015 as measures of success. Data recorded for stakeholder engagement included contacts, background, and time spent. Assessment of mink control recorded raft locations and status, raft checks, mink sightings and captures. The locations and extent of target IAPS were recorded using geographic positioning systems and abundance by percentage cover or the DAFOR scale.

From 2012 data recording by volunteers and professional staff used specifically designed digital tools that not only managed data but also fed back information to users. The web- and map-based interactive geo-database for IAPS management made it easy to acquire survey and monitoring data and to translate changes in IAPS treatment status and abundance to maps presented on the website. An online platform, the MinkApp was developed in collaboration with Aberdeen University's dot.rural initiative (http://www.dotrural.ac.uk/) for the recording, management and presentation of data derived from American mink control. The MinkApp used natural-language-generation (NLG) to inform volunteers by email of mink captures and sightings in their area.

Trends in mink detections and captures were used to determine whether large-scale coordinated control efforts had had an impact on mink populations. The best (least biased) impact data were derived from the checking records for mink rafts. Detection rates could be calculated from the percentage of raft checks where mink footprints were observed. Further analysis through a generalised linear mixed effects model (GLMM) was carried out on long-term mink detection data from three test catchments: the Dee, Spey and Ythan where control had been ongoing since 2006 / 2007 (Bryce, et al,. 2011; Lambin, et al., 2019). The GLMM model accounted for differences among catchments, which was fitted as a fixed effect and as an interaction with time of mink control (i.e. the effect of mink control was allowed to vary by catchment). Non-independence between multiple records from the same raft(s) was accounted for by fitting raft as a random effect.

The effectiveness of IAPS treatment was assessed by the area cleared of infestation (i.e. no regrowth occurred for a year or more), the percentage decrease in coverage and the number of sites in a low maintenance state (DAFOR ≤ 1 (Rare) = 1–10% coverage) before and after treatment. Where coverage was recorded using the DAFOR scale, the mid value for each category of the index was used. Use of DAFOR categories, although simpler to record, encompasses score ranges of 10–25% and therefore more subtle changes in IAPS coverage may not be apparent with this index.

RESULTS

Stakeholder engagement

Throughout the reporting period a total of 1,000 volunteers serviced 2,020 surveillance points for mink control (Fig. 2) and at least 391 volunteers participated in IAPS control, contributing ≥ 2,587 hours of work. Actual numbers at any given time varied, being dependent on the size of area being managed and funding availability. In 2015 there were approximately 800 volunteers participating in mink and IAPS control. Continual recruitment was necessary to offset loss of volunteers. Volunteers left because of a number of reasons. A small but significant number decided it was not really something they wanted to do shortly after recruitment. Other reasons were moving from the area, changed employment and boredom.

Volunteers participating in mink control were from a broad range of backgrounds. Residents of the area with no

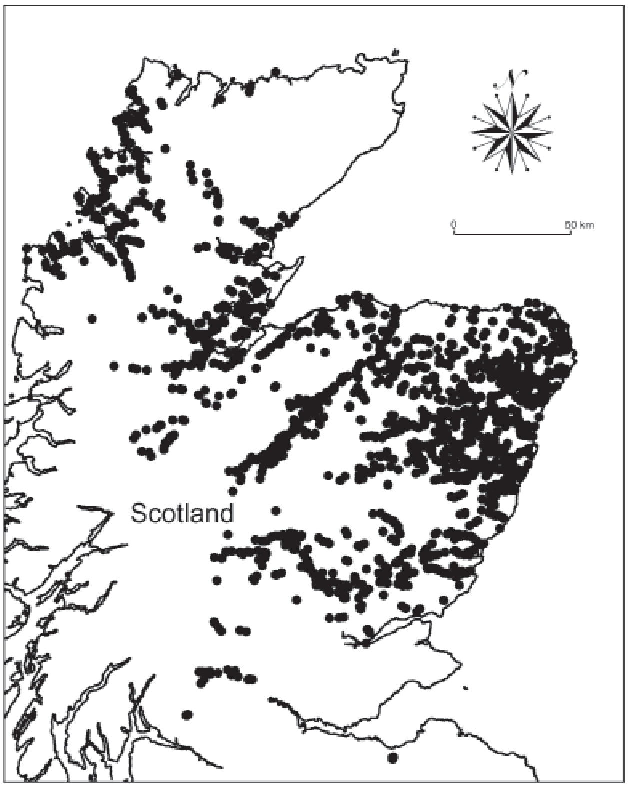

Fig. 2 Location of the 2,020 surveillance points (rafts, tunnels, traps) monitored for American mink between 2006 and 2015.

connection to the local environment constituted the largest proportion, followed by two professional groups – estate workers (game keepers and land managers) and fisheries personnel (managers, owners, guides and anglers). These three groups provided 78% of volunteers. The remaining 22% came from conservation organisations, government agencies and local councils, the tourism and leisure industry, farmers, fish farmers and University staff.

The degree to which individual volunteers engaged with control activities varied greatly, with most content with participating in surveillance e.g. checking mink rafts. However, a relatively small but significant proportion of volunteers, in terms of their contribution, received instruction for skilled activities e.g. humane despatch, stem injection and foliar spray near watercourses. These latter tasks required informal training and/or certification and increased commitment from the volunteer and host organisation.

There was only one landowner where there was issue with gaining access to land despite the large geographic area and the number of landowners involved. Access permissions were initially given verbally but insurance requirements meant that written permissions were increasingly required.

American mink

Across the entire control area, and considering all raft-check records in a calendar year, there was a steady decline, from a positive check rate of around 0.14 in 2011, to a low of around 0.02 in July 2015 (Fig. 3). The majority of the 86 positive raft checks towards the end of the study period (from a total of 2,776 recorded in the period July 2014 to July 2015) were concentrated along the frontier of the project area, which was consistent with frontier catchments receiving an influx of dispersing mink from outside of the control area and the coast.

Trends in mink captures followed those of the detection rate, with a decrease from over 280 in 2012, to only 98 mink captured in the 12 months prior to July 2015. Although mink were captured across the raft network, the areas with the highest numbers of captures reflected the optimum habitat for mink and the history of control effort. In agreement with the mink raft detection data, nearly all of the captures in 2015 were from lowland or coastal areas, indicating an overall contraction of the mink population both in range and population size (see also Lambin, et al., 2019).

The GLMM analysing how mink detection rate changes with year of mink control, showed a clear and statistically significant ($P < 0.0001$) negative relationship (Fig. 4; Table 2). Based on the fitted curves, the model predicts that

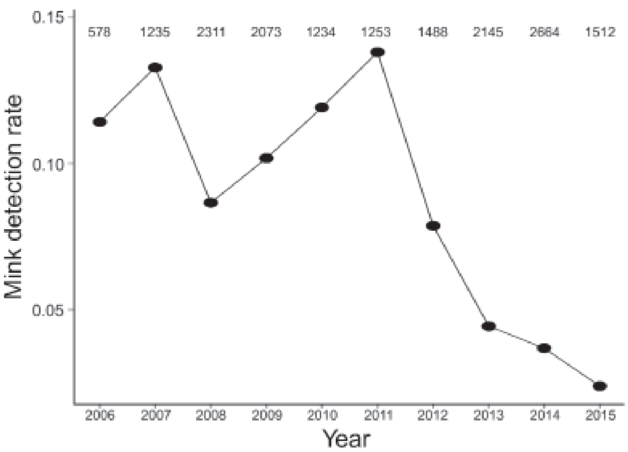

Fig. 3 Changes in the mink detection rate (number of positive raft checks / total number of raft checks) per year of coordinated mink control. Numbers above the points show the total number of checks from which the rates are estimated.

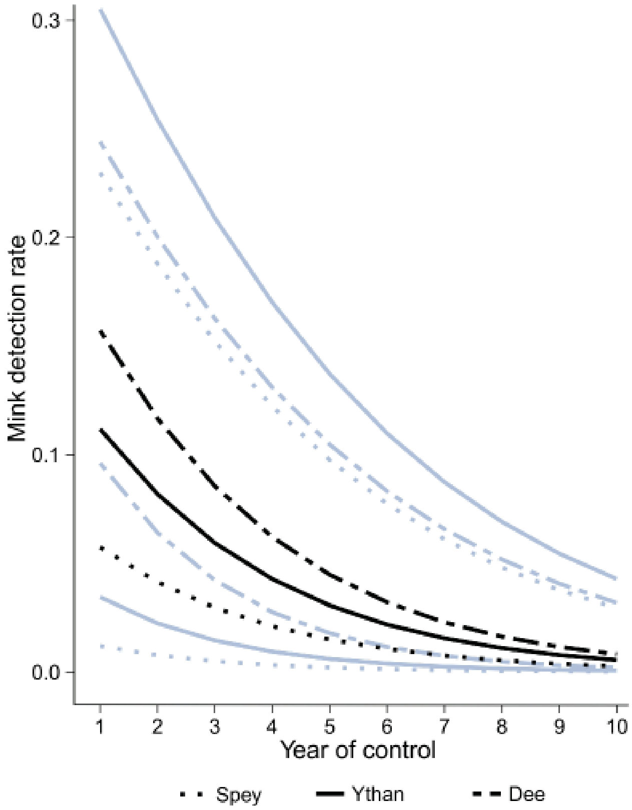

Fig. 4 The effect of control on mink detection rates (abundance) calculated by a generalised linear mixed effects model (GLMM). The black lines are fitted curves for the Dee, Spey and Ythan river catchments The grey lines areas are 95% profile confidence intervals.

Table 2 Summary table for a generalised linear mixed model (GLMM) analysing the relationship between mink detection rate (per raft check) and the year of mink control (by river catchment). Data are for the rivers Dee, Spey and Ythan. Observations is the number of raft checks. Groups refers to the number of rafts.

Observations: 9086	**Groups: 399**	**Residual d.f. 9079**	**Variance: 1.57**	**St. dev: 1.25**
	Estimate	S.E.	Z value	P value
Intercept	-1.33	0.24	-5.67	< 0.0001
Year of control	-0.35	0.05	-7.27	< 0.0001
Catchment (Spey)	-1.12	0.44	-2.58	0.01
Catchment (Ythan)	-0.55	0.30	-1.85	0.06
Year of control: Spey	0.00	0.10	0.02	0.99
Year of control: Ythan	0.15	0.06	2.54	0.01

mink abundance will be reduced to ca. 40% of the starting abundance in four years and further to around 6% of initial levels after nine years. A large amount of the uncertainty in the model's predictions (illustrated by the 95% confidence intervals [grey lines] in Fig. 5) is attributable to differences between the catchments, rather than the overall estimate of the effect of mink control (Table 2). This was particularly true of one catchment where the mink population remained high before dropping abruptly after control in the adjacent catchment.

A small number of rafts influenced trends significantly with a majority of rafts never detecting any mink footprints. All information on mink presence came from 36% of rafts (n = 357) checked at least once. In fact, only 6% of checked rafts (a mere 59) accounted for 637 (53%) of the 1,307 detections. Whilst factors such as duration of raft placement and checking frequency may influence this result, the take home message is that a small portion of the raft network does most of the work in detecting, and vis a vis removing, mink.

Invasive alien plants

The 10 river Trusts that supplied information surveyed a minimum of 2,403 km of waterways (Table 3). Their surveys revealed that IAPS were widespread (extending over ca. 1,603,821 m^2) and had become a serious threat to riparian biodiversity and activities along Scottish river corridors.

Japanese knotweed was the most frequently encountered IAPS. Trusts recorded it in all survey areas though the extent varied significantly among them (Table 3). Giant hogweed was least prevalent and abundant. Three Trusts reported it absent and a fourth discovered only one small stand. But in all other areas infestations averaged > 4,000 m^2. In Ayrshire giant hogweed had invaded 188,000 m^2 . Himalayan balsam infestations proved to be the most challenging. This IAPS had reached 699,233 m^2 of river corridor. Stands in two catchments extended over tens of kilometres.

Table 3 Summary of the area surveyed (in metres) and area recorded as infested by each IAPS for each of the 10 trusts (reported as m^2).

	Area surveyed	GH	HB	JK	Total
Annan	197,000	20	200,000	11,364	211,384
Argyll	195,000	-	-	9,198	9,198
Ayrshire	739,000	188,000	204,000	257,000	649,000
Cromarty	300,000	27,000	128,500	54,500	210,000
Dee	170,000	4,176	32,938	41,768	78,882
FNLT	103,500	72,000	62,700	88,500	223,200
Galloway	114,000	4,196	75	21,663	25,934
Lochaber	42,400	0	0	43,500	43,500
Nith	160,450	41,955	70,430	39,718	152,103
WSFT	30,000	0	590	30	620
Total	2,403,834	337,347	699,233	567,241	1,603,821

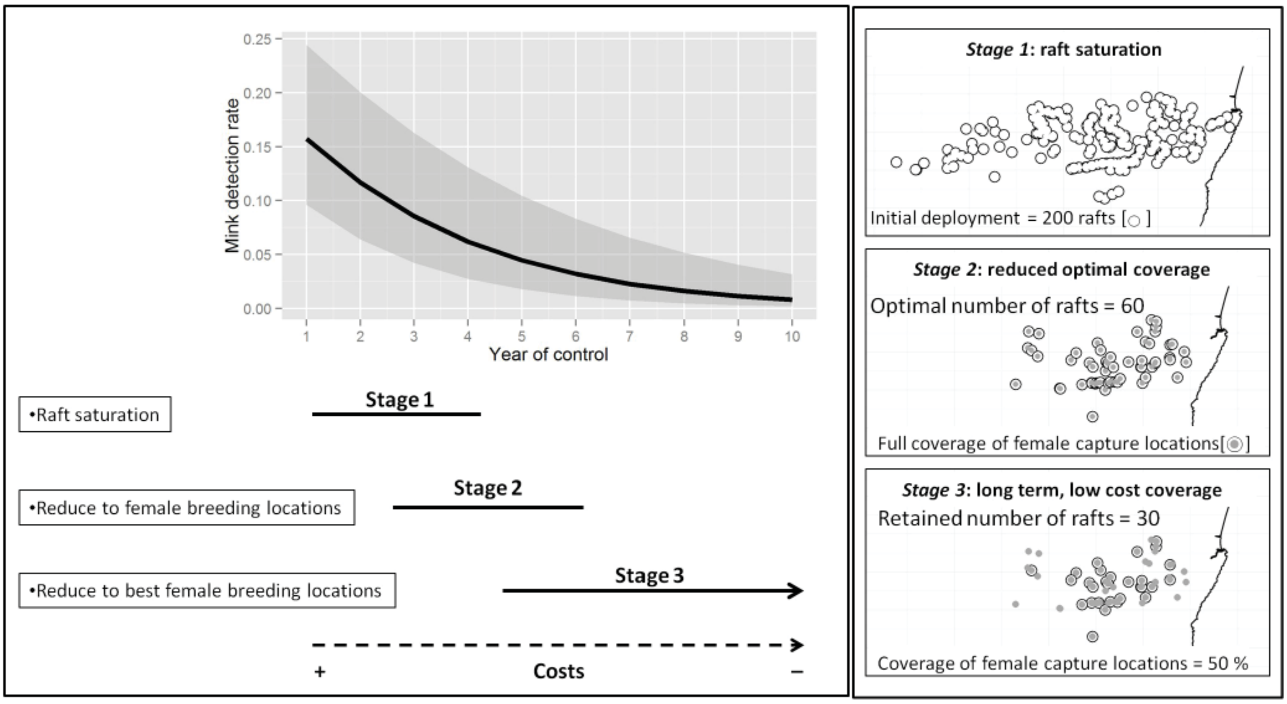

Fig. 5 Schematic of a graduated three-phase strategy for mink control (based on capture data from the River Dee, NE Scotland). In Stage 1 (years 1–4) mink abundance is at its initial maximum. The box on the right illustrates how the strategy moves from a saturated raft network in Stage 1, to cover all female capture locations in Stage 2, and only a subset of these in Stage 3.

Success in clearing areas of infestations was limited with 16%, 11% and 10% of the original area of infestation cleared for giant hogweed, Japanese knotweed and Himalayan balsam, respectively (Table 4). However, decreases in coverage between 50% and 80% were common for all three target IAPS.

The greatest decrease in coverage was for Japanese knotweed, with five areas achieving >85% decrease. Despite the reduced coverage, shoots from the sub-surface rhizome prevented sites from being categorised as cleared. Cover of giant hogweed fell by 53%–75%. However, there was mixed success in controlling Himalayan balsam (Table 4). Trusts reported that effective control of this IAPS was problematic as it is easy to miss individual plants hidden among native vegetation, or in areas of limited access. In four areas, Himlayan balsam was also anecdotally observed to quickly colonise sites that had recently been cleared of giant hogweed or Japanese knotweed. Of note, however, is that both Nith and Cromarty Trusts, using a targeted approach and a larger coordinated workforce, decreased coverage of Himlayan balsam by >82% (as well as clearing >29,000 m^2) across large areas.

Standardised percentage coverage decreased from a median of 38% (mean 33%) to 5% (mean 14%) in 447 pre-treatment sites following control. The majority of sites (327; 73%) showed improvement, 103 (23%) were recorded as having no change, and infestation levels at 17 (4%) had got worse. Around half the sites infested by giant hogweed and Japanese knotweed, and 38% of those by Himalyan balsam, were in a low maintenance state after treatment (Table 5). This was despite the reported increase of infestations of giant hogweed after the large floods of the winter of 2013/14.

Costs

The work reported in this paper was undertaken through the sequential securing of short-term (1–4 year duration) funding. Consequently funding was cyclical with periods of higher funding alternating with those of low or no funding (Fig. 6). Using northern Scotland as an example, the amount of funding secured for IAS work has increased in each subsequent funding phase, from £124,000 (1996–2005), £639,000 (2006–2009) to over £1.95 million provided in the period 2010–2015. The increased funding reflected the expanding geographic reach (from 5,000 km^2 to almost 30,000 km^2) and complexity of the work undertaken. This included the addition of IAPS control in 2009 and biosecurity, awareness, education and capacity building activities after 2010.

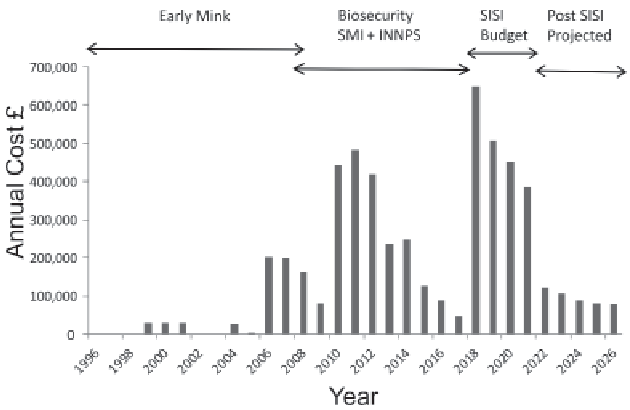

Fig. 6 Funding for IAS work in northern Scotland.

DISCUSSION

Findings and lessons for future work

The control strategies and measures for both IAPS and American mink have had a demonstrable, although variable, impact in suppressing target populations in terms of coverage and population density over large geographic areas (see also Bryce, et al., 2011; Melero, et al., 2015; Oliver, et al., 2016). The variation in results suggests there is room for improvement in strategy and local implementation.

The use of an evidence-based approach, derived from evaluation of activities and research associated with the project, provided the central core of the adaptive-management strategy. The findings were utilised to improve control strategies (e.g. concentration of surveillance in lowland areas and along migration routes for American mink, control methods for IAPS, engagement and retention of volunteers, and implementation of management efforts at an appropriate geographic scale in defensible areas for all IAS). An example of the latter is that the GLMM analysis highlighted the importance of taking a coordinated multi-catchment approach to mink control as the number of mink in a catchment depends on control both within that catchment and in neighbouring catchments.

Working over such a large geographic scale, including urban areas, with limited secured funding was made possible by the use of a large trained volunteer workforce supported by professional staff. Staff were either employed by the project or from local organisations. The latter arrangement allowed the building of capacity for volunteer management and IAPS control within the organisations. Although this approach helped to build longer term management sustainability, it sometimes resulted in competing priorities between the project and the organisation. Employing dedicated project staff avoided this conflict but did not effectively address long-term sustainability, as employment ended with the cessation of project funding.

The use of large volunteer networks rather than increased numbers of staff reduced employment costs, a significant cost. However it did not reduce liability risk for the organisation(s) that supported the network. To mitigate risk as the project developed, RAFTS increasingly used written rather than verbal permission for volunteer participation and access agreements. The information and training given to volunteers increased, particularly regarding health and safety. Organisation policies and public liability insurance was also regularly reviewed in light of volunteer numbers and their work. Changes in project management structure required revision of all agreements. One outcome of these changes was that significant numbers of volunteers expressed concern and dissatisfaction with perceived increased bureaucracy, with a small number withdrawing their participation.

Management over such a large area required the building and maintenance of coordinated partnerships with defined roles for individual partners at both local and national level (Table 6). At the local level, non-government/non-profit organisations (Trusts) provided the hub of the partnerships and collaboration. The Trusts have close ties to sectors of the local communities, particularly landowners. At the national level RAFTS was the main contact point for government agencies and universities, and coordinated the work of the local organisations. Partnership arrangements were not pre-determined but rather developed over the course of the work and in response to the varied demands of the management strategies employed. Partnerships and collaboration involved over 70 organisations, including the Scottish Government, state agencies, local authorities, universities, >50 local non-government organisations and businesses and over 800 volunteers at any one time.

Coordination was generally effective but there were instances of inconsistency of approach and in data collection among local organisations (Arts, et al., 2013). Although consistency of data collection improved with the advent of the on-line reporting systems, ensuring consistency of approach and data collection among large numbers of local organisations remained a significant challenge.

Common interest formed the basis for collaboration. Differing characteristics of communities (individuals and community organisations) within and among geographic areas of Scotland meant approaches to engagement varied. The diverse composition of the volunteer base demonstrated that IAS control, particularly of American mink, provided a common base for a wide range of community groups, some of which had a history of conflicting interest (e.g. gamekeepers and bird conservationists). Motivational factors included professional or commercial interest and a concern for the local environment – as expressed by residents who made up a large proportion of the volunteers.

Taking action and demonstrating results were important factors in retaining participating volunteers and organisations. Demotivating factors included the breaks in project activities caused by short term funding cycles and perceived increased bureaucracy. The use of on-line reporting systems provided a means to disseminate progress and results through a limited functionality for data interrogation (mink) (Beirne & Lambin, 2013) and a map interface for IAPS. These reporting mechanisms became part of an overall volunteer and organisational recruitment and retention strategy that combined a variety of awareness activities with training and legal empowerment. Successful control also influenced volunteer retention with the lack of detection of IAS leading to boredom. Maintaining interest and motivation remains a critical long-term challenge for future management (Beirne & Lambin, 2013).

Despite repeated efforts to obtain long term funding, IAS control in Scotland has relied on short term, or project specific, funding. The resultant funding cycles occur as one project has to finish before funding for the next stage can be secured. Start-stop cycles result in a loss of staff, volunteers, equipment and, as a consequence, momentum, capacity and credibility (see also Lambin, et al., 2019). Furthermore, overall costs increase as start up costs (staff and volunteer recruitment, training, control) exceed recurrent costs of established projects.

Funders' regulations also influence the work that can be undertaken. The majority of short-term funders require

Table 6 Contributions by participating institutions.

Level of collaboration	Partnership organisations
Strategy	RAFTS, GB Non Native Species Secretariat, Scottish Environment Protection Agency, Scottish Natural Heritage, national park authorities (Cairngorms and Loch Lomond),

tangible benefits for their support. These benefits are more easily expressed in terms of IAS reductions than prevention (biosecurity), where no occurrence or a 'negative' result defines success. Regulations have also prevented funding being used for rapid-response, another key element of successful IAS management. Funding for IAS management should recognise that 'negative' results indicate success both in prevention and control, have flexibility to allow for rapid response and changes in approach required by adaptive-management and be available for work over appropriate geographic- and time-scales.

Although there is still no long-term funding of IAS control in Scotland, project funding has been secured for the Scottish Invasive Species Intiative (SISI) (2018–2022). SISI aims to develop a long-term, cost-effective management system for multiple IAS across 29,500 km^2 of northern Scotland. The project builds on the experiences of its predecessors and tests more focused strategies for IAS management.

One such approach to mink control derives from the variation in the relative contribution of individual rafts to overall detection rates, coupled with the analysis from the GLMM. The model predicts abundance will be more than halved following four years of control and reduced to < 10 % after ten years. Accordingly, capture data will be used to reduce raft coverage in three stages over the same timeframe (Fig. 5). If patterns of mink dispersal and settlement are influenced by habitat quality, despite the species's mobility and generalist habits, reductions would track capture rates for females. This assumes that populations under control pressure will reoccupy optimum habitat preferentially, and that concentrations of female mink will indicate where that is. Reactive redeployment may be required in response to localised increases in mink activity. If successful, the strategy will use the best available evidence and scientific understanding to substantially reduce costs.

Protecting non-invaded areas through awareness targeted to user groups (e.g anglers and boaters) and the use of biosecurity stations and individual biosecurity kits is a key component of the project. Habitat restoration using resilient native communities will be tested as a means to reduce reinvasion risk of areas cleared of IAS.

Emphasis is placed on strengthening the capacity of local organisations, so IAS management becomes part of normal working practices. SISI will also develop means to maintain volunteer participation over the timeframes required to manage IAS. Evidenced-based adaptive management is central to the strategic approach of SISI and the project will develop interactive and map-based data-recording systems.

SISI faces some significant challenges in balancing costs with outcomes, particularly in regard to reducing introductions and spread over such large geographic areas and defining what reduction in IAS can be sustained. Effective coordination, and quality assurance, of the work undertaken by multiple local organisations is not to be underestimated.

Despite the challenges, it is envisaged that by the end of SISI the more focused control will have suppressed target populations to levels where that suppression can be affordably maintained by motivated local organisations and their volunteer networks (Fig. 6, from 2022–2026). However, post-project IAS management in Scotland will still require additional funding to that provided by local organisations and at present it is not clear how that will be provided.

ACKNOWLEDGEMENTS

Biosecurity on St Helena Island – a socially inclusive model for protecting small island nations from invasive species

J.R. Balchin[1], D.G. Duncan[1], G.E. Key[2] and N. Stevens[1]

[1]Agriculture and Natural Resources Division, Scotland, St Helena Island STHL1ZZ. [2]GB Non-Native Species Secretariat, Animal and Plant Health Agency, Sand Hutton, York YO411LZ, UK. <gillian.key@apha.gov.uk>.

Abstract St. Helena Island, 122 km^2 (47 sq. miles) is a UK Overseas Territory in the South Atlantic. It is a remote volcanic island situated in the sub-tropics 1,127 km (700 miles) from Ascension Island and 2,736 km (1,700 miles) from South Africa. Its resident population of ca. 4,500 is serviced by a single supply ship which visits up to 25 times a year. Isolation has acted historically as a natural barrier to pest arrival and border control has followed the conventional practice of protecting agricultural interests through restrictions on fresh produce, plant materials, livestock and pets. The benefits of isolation were compromised in 2016 when the first airport opened. Private jets arrive now from Africa, Europe and South America, and commercial flights started at the end of 2017. A programme of biosecurity capacity building and strengthening was established in anticipation of this air traffic. St Helena authorities introduced a national biosecurity framework and associated policy (entitled *Biosecurity St Helena*), the latter constructed through multi-sectoral consultation, and key stakeholders participated throughout in policy development. *Biosecurity St Helena* applies international standards set by the International Plant Protection Convention across the biosecurity continuum. As is typical in small island nations, human and financial resources are limited, so that the biosecurity strategy addresses mainly higher risks. Compliance is heavily reliant on public awareness. Active communication engages all community sectors in biosecurity work through education, information, advocacy and feedback. Authorities use key performance indicators to measure the effectiveness of this approach. *Biosecurity St Helena* is a model of actively socialised biosecurity for other small island nations.

Keywords: biosecurity strategy, capacity building, community engagement, inclusive planning, small island nation

INTRODUCTION

St Helena Island, a United Kingdom Overseas Territory in the South Atlantic Ocean, is a volcanic island with an area of 122 km^2 (47 square miles) and total population of 4,534 (St Helena Government, 2016). St Helena is remote and isolated, lying 1,127 km (700 miles) southeast of Ascension Island and 2,736 km (1,700 miles) from South Africa, with a sub-tropical, maritime climate. A total of 502 endemic species are currently known, comprising around one third of the total endemic biodiversity of the UK Overseas Territories and making a significant contribution to global biodiversity (Churchyard, et al., 2014). The economy is based mainly on agriculture, fishing, a small but growing volume of tourism and income from offshore employment.

Until 2016 the only regular access to St Helena was via the Royal Mail Ship (RMS) *St Helena*, calling around 25 times a year in passage from Ascension Island and South Africa. Most commodities are imported. More than 69% of the island's annual requirements for agriculture and food are sourced from South Africa, including almost all fruit, and significant quantities of vegetables.

In 2010 the UK Government announced its intention to build an airport on St Helena, conditional upon the St Helena Government's commitment to internal investment and increased tourism. Air access and expansion of the tourism sector augmented biosecurity risks to St Helena. To meet the challenge, the St Helena Government launched a programme in 2013 to upgrade biosecurity arrangements. The 2009 South Atlantic Invasive Species Strategy had already defined dedicated biosecurity capacity for St Helena as a strategic priority for the prevention of invasive species and unwanted organisms in the region (Shine & Stringer, 2010).

St Helena has a limited range of existing cosmopolitan pests and is very vulnerable to new introductions harmful to the economy, community health, environment and the new investments in tourism development (Pryce, 2015). Until now, biosecurity has relied heavily on its isolation as an oceanic island and limited modes of entry to minimise exposure to new pest threats.

The Government's Agricultural and Natural Resources Division (ANRD) reviewed biosecurity practices in in 2013 (Key, 2013) and concluded that capacity was inadequate to address the new biosecurity pressures associated with air access. Lack of biosecurity-specific legislation or overall operational framework severely compromised post-border controls and enforcement. There were no fumigation or other specialist facilities for local treatment of contaminated goods. Tellingly, the common interests of different sectors, particularly agriculture, public health and the environment were not harmonised for biosecurity purposes.

PREPARING FOR NEW BIOSECURITY MEASURES

The St Helena Government's programme to upgrade biosecurity in 2013 departed from the existing emphasis on managing agricultural and animal imports at the border. It moved biosecurity to a risk-based approach across the broader continuum of invasive pest organisms in marine and terrestrial environments. Interception measures pre-border, at-border and post-border were to be more closely integrated. Resource limitations in the small-island context argued for greater investments in pre-border controls and post-border surveillance.

Approaches to building the new biosecurity framework

The ANRD led a new policy team comprising agency representatives of Environment, Customs and Public Health; the first time this multi-sector team had been brought to the same table. Their purpose was to establish the architecture of the new biosecurity system through an overarching policy statement. The policy team recognised that understanding of biosecurity issues was essential for community buy-in and compliance. Accordingly, the team developed the new biosecurity policy in full consultation with all sectors in the community, from farmers to politicians, coupled with close participation throughout the reform process. Stakeholders were given multiple opportunities to discuss new ideas and to object to them if warranted. The policy team intended biosecurity

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 468–472. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

awareness in the community, as a whole, to benefit from these approaches.

Consultations, commencing with twelve focal groups of stakeholders in 2013, explored attitudes to the current biosecurity procedures. Despite some criticisms, all 54 stakeholders that were consulted supported the current arrangements and the need to strengthen them in anticipation of air access.

Participants in a subsequent workshop agreed on the vision for biosecurity policy and then defined strategic objectives and expected outcomes. The broader public were invited to consider the resulting policy statement. The St Helena Government endorsed the policy after it had been revised to incorporate feedback. Now entitled *Biosecurity St Helena*, the policy was launched officially in the biosecurity facility at the seaport in November 2014 (St Helena Government, 2014).

Today, ANRD is the agency lead for biosecurity. It holds the authority to approve import licences and has the principal duty to launch responses to incursions. The community relies on ANRD for government leadership in matters of compliance and enforcement of the new biosecurity legislation.

Biosecurity St Helena defined

The policy vision and principles govern the new biosecurity arrangements and are supported by the island's legal and institutional structures. The policy is the blueprint for "an effective biosecurity system of shared responsibility that protects the sustainable future of our island environment, allowing a vibrant economy, safe movement of people and goods, and enhanced livelihoods and health" (St Helena Government, 2014, page 3). Overarching outcomes are:

- Effective management of biosecurity risks to St Helena's environment, agriculture, amenities, public health and well-being, including safety;
- Effective governance of St Helena's biosecurity system through shared responsibility and roles

Biosecurity St Helena recognises that a zero-risk approach is not practical and works to reduce the risk to an acceptably low level. The policy endorses a white list and licencing approach, whereby all high-risk goods are prohibited except those for which import health standards have been developed. Import health standards specify the conditions under which goods can be imported and the treatments required in response to pest organisms intercepted or simply suspected pre-border, at the border or post-border.

Six crucial principles guide biosecurity work:

1. Leadership for effectiveness throughout the biosecurity apparatus
2. Clear communication of stakeholder roles, responsibilities, and the 'what, why and how' of biosecurity investments.
3. Shared responsibility across all sectors and interests for mutual benefit
4. Risk-based responsiveness to the probability of border challenges, potential harm and changes in the nature of threats.
5. Evidence-based decision-making supported by quality systematic research
6. Co-operation between sectors to minimise the probability of new incursions and manage existing ones.

BIOSECURITY ON THE GROUND

A multi-sector plan was developed alongside the biosecurity policy to put the new structures in place. The policy team supervised developments for the first year, and thereafter improvements were mainstreamed into the work plans of ANRD, Environment, Customs and Public Health, taking effect in the 2016/2017 financial year.

At the border

The St Helena Government recruited two full-time biosecurity officers in 2015, the first in the island's history. They work closely at the border with Customs whose warrants they also hold. Customs and Immigration officials received the same biosecurity training to ensure harmonised border security.

Import health standards apply for a range of commodities, and the island's main traders assisted the development of these standards. Inspection procedures now align with international standards set by the International Plant Protection Convention (IPPC) for phytosanitary (plant health) risks and the World Organisation for Animal Health (OIE) for zoosanitary (animal health) imports. Inspection practices are codified for consistency and transparency. Import Health Standards, application forms and general guidance are now available on-line at <http://www.sainthelena.gov.sh/st-helena-biosecurity-service/>.

The officers employ a dog trained to detect honey, bananas and citrus, to protect St Helena's disease-free bees and bananas. Likewise, citrus (commonly intercepted on incoming visitors) may introduce newly emerging diseases such as huanglongbing citrus greening. Dog handling at the border is governed by a Standard Operating Procedure written together with Customs who run their own detection dogs.

The full-time team has extended biosecurity operations on the wharf, beyond the former pre-occupation with fresh produce. Customs help with passenger and cargo profiling so that higher risks can be ranked for quarantine inspections. Profiling relies on interception data for visitors and surveys of imported cargo arriving by sea, and will be refined as data accumulates for both visitors and freight arriving by air.

Personal goods in shipping containers and vehicles shipped in break-bulk were predicted to be high risk freight. Between January 2016 and March 2017, 99 (40.4%) of 245 imported vehicles (mostly cars) were found to be contaminated with soil. Inspectors intercepted 75 live spiders in 16 (6.5%) of the vehicles. Over the same period, 23 live spiders were intercepted in four (11.8%) of the 34 incoming containers of personal goods. The spiders belonged to seven species known from the UK and South Africa. They were found mainly in the space behind vehicle wing mirrors, on the windscreen wipers, and behind the rear-mounted spare wheel on SUVs. Most spiders in shipping containers were discovered immediately inside the doors.

Soil samples collected from vehicles (typically from rear wheel-arches) were weighed, then placed in seed trays for up to two months to check for seed germination. A mixture of grasses and small dicotyledons germinated successfully from nine (9.1%) of the 99 samples but none survived long enough to identify species.

Building and operating St Helena airport

Construction of St Helena airport commenced in January 2012. Three new biosecurity pressures had to be managed

A second supply vessel now visited every six weeks or so until October 2015. The ship departed from a new port of origin and was the first vessel able to moor alongside the island at a specially constructed wharf. The normal supply vessel RMS *St Helena* barged freight ashore from an anchorage in the bay.

The new vessel discharged large quantities of construction materials, including river and dune sand.

Several hundred off-shore workers arrived (mainly from Africa and Thailand), for whom biosecurity awareness was low to zero.

ANRD negotiated quarantine agreements with the South African construction company. Consignments of sand were fumigated in Namibia and inspected on arrival in the port area. The team inspected break-bulk consignments before disembarkation from the vessel. Compliance improved to a good standard after some initial teething troubles. Only two pests were intercepted during the construction phase - flattened giant dung beetles (*Pachylomera femoralis* Coleoptera: Scarabaeidae) on open metal gantries; and ice plant, (*Galenia papulosa* Aizoaceae) in river sand. Construction staff were quick to report biosecurity issues and responded appropriately.

Border and biosecurity officials meet all inbound flights. Airport biosecurity is guided by a Standard Operating Procedure refined through preliminary test-runs with flights and arriving passengers. An x-ray scanner screens all in-bound baggage. Fresh produce is examined in a small, sole-purpose biosecurity room in the airport's cargo compound.

The Public Health Committee obliges 'disinsection' of all inbound flights, recognising known risks of introducing aerial insect vectors such as mosquitoes (Gratz, et al., 2000). Eighteen private jet and three medevac flights had been treated by March 2016. Commercial flights had not yet commenced.

Post-border surveillance

The 2013 review of biosecurity (Key, 2013) revealed serious weaknesses in post-border surveillance for pest species by-passing earlier lines of defence. Today, monitoring and surveillance behind the island's borders are structured to detect and eradicate pest intruders before they can establish. Biosecurity staff direct their attention to surveillance at the airport construction site and all other ports of entry; targeted surveillance for introduced tephritid fruit flies; and readiness to respond to pest detections.

Surveillance at the construction site has mapped every location at which shipping containers were landed or opened with the participation of the construction company. At each location, the biosecurity team installed a monitoring point comprising a covered breeze block in which crumpled newspaper and a sticky trap attract and contain unwanted invertebrates. A monitoring protocol, identification guide and reference collection assist surveillance. As construction wound down in 2016, monitoring was migrated to new sites around the two seaports and the airport. Each station will include mosquito traps in the future.

Surveillance operates pheromone-baited sticky traps for five species of economically harmful tephritid fruit flies at ten pivotal fruit-growing sites across the island.

The biosecurity team have engaged relevant stakeholders in the preparation of nine response plans for incursion emergencies. The plans address terrestrial and marine risks from a range of phytosanitary, zoosanitary and invasive non-native species. They were refined through a simulation exercise, and further exercises are planned for the future.

Engaging the community

The principle of responsibility shared universally by the St Helena community and visitors is central to biosecurity arrangements. But policy consultations with stakeholders revealed poor understanding of what biosecurity is and what the biosecurity team does. In response, a multi-sector communication strategy targeted key audiences with biosecurity messaging. The strategy adopted *Border Security* (a popular TV programme on Australian border security services) as its brand but switched later to *Biosecurity St Helena* to align messages with the new biosecurity policy. *Biosecurity St Helena* branded pens, shopping bags and mugs were a popular means of reinforcing the messages. Outreach comprises a programme of press releases, articles in the local print and radio media, activities with local primary and secondary schools, and visits by groups to observe biosecurity inspections at the wharf. Councillors, government officials and airport officials were among the first groups invited. The outreach programme continues as a core element in the biosecurity team's work plan. New stakeholders involved in air access readily embraced the messaging, which focused on collective responsibility for protecting the island for the future.

Site visits were very productive; feedback was positive from visitors who were not previously aware of the wharf facility or only generally familiar with the biosecurity team's functions.

The public are actively encouraged to be vigilant for new invasive non-native species. In March 2015, a public awareness campaign comprising press announcements and leaflets invited the public to report unusual tracks, signs, weeds or invertebrates. Reporters are rewarded with a gift of branded promotional goods.

Sustaining external support for *Biosecurity St Helena* is a priority. Biosecurity reaches well back into the supply chains through visits to overseas agents and suppliers who are expected to comply with stringent, time-consuming or costly quarantine requirements often for commodity quantities small relative to their normal trade volumes. Face-to-face contact with suppliers and South African Cape Inspection Service aims to translate their goodwill into co-operation, especially for frequently imported high-risk goods such as South African, produce and plant propagation materials.

Measuring success

A comprehensive database records imports and interceptions. Another holds baseline data for all taxa of native and introduced species, together with a reference collection of pest species known on the island. ANRD uses these data to measure biosecurity outcomes and assess threats based on empirical evidence.

Even so, establishing meaningful indicators to measure biosecurity effectiveness is a challenge. The number of interceptions is a commonly used metric, but one open to confounding interpretation: does an increase in the number of interceptions indicate (i) a decrease in effectiveness (i.e. more introductions arriving owing to poorer pre-border measures) or (ii) an increase (more interceptions owing to better inspection practices)?

To resolve this ambiguity, ANRD uses five key performance indicators based on the notion of tolerance thresholds for interceptions. Once a threshold is exceeded, the biosecurity team investigates likely causes and applies appropriate remedies.

The indicators relate to passenger, fresh produce and cargo pathways arriving by sea (Table 1). Table 2 shows the biosecurity performance results for the 2016 calendar year. None of the thresholds was exceeded in any indicator.

Table 1 Tolerance thresholds used as measures of biosecurity performance for three main risk-pathways on St Helena Island.

Pathway	Threshold	Notes
Percentage of passengers arriving without a quarantine-risk item in their baggage	No more than five in every 100 passengers arrive with prohibited goods such as honey, fruit, nuts	Includes passengers and crew on RMS *St Helena* and private yachts, but excludes day-visitors on cruise ships
Percentage of fresh-produce lots[1] inspected which do not conceal a quarantine pest	No more than five in every 100 lots inspected have a quarantine pest (dead or alive)	
Number of quarantine pests detected at the border as a percentage of the total number of imported shipping containers and uncontainerised vehicle of any type	No more than three quarantine pests detected for every 100 units	
Number of quarantine pests detected post-border as a percentage of the total number of imported shipping containers and uncontainerised vehicle of any type	No more than two quarantine pests detected post-border for every 100 units	
Number of animals breaching border biosecurity requirements as a percentage of total animal imports Breaches include identity issues, disease, or incorrect paperwork	No more than five in 100 animal imports fail to satisfy requirements	

[1]A "lot" is defined as the total amount of any one type of produce which are clearly from the same source.

Table 3 lists commodity types by passengers' reasons for visiting. The 'other' class of passenger was most likely to arrive with prohibited goods. This class includes construction workers possessing few or no English language skills and therefore less likely to have understood the biosecurity arrival information provided on the ship. Fresh produce was most frequently seized, typically apples, pears, oranges and other citrus picked off the breakfast table in the ship before disembarkation.

DISCUSSION

Biosecurity compliance and enforcement can be challenging in small, isolated communities if stakeholders are not willingly engaged through knowledge of need and benefit. Socialising the processes of building a strong biosecurity system through active participation is particularly important. *Biosecurity St Helena* is a relatively short and succinct blueprint which could have been constructed quite quickly. Instead, the St Helena Government chose purposefully to pursue a process of intensive consultation which extended preparation over a period of nearly a year. Thus, the drafting process was considered as important for social acceptance as the resulting document. Local priorities and concerns are now reflected in the language and layout of the plan.

Most importantly, *Biosecurity St Helena* demonstrates the benefits of political will to integrate agricultural and environmental interests for biosecurity purposes. Limitations on human resources common to small island states have been largely overcome on St Helena by close co-operation between biosecurity and customs officials.

Table 2 Results for five key performance indicators for the 2016 calendar year in which the RMS St Helena, 186 yachts and eight cruise ships visited.

Indicator	Threshold	2016	Data
Percentage of passengers arriving without a quarantine-risk item in their baggage	95%	98%	3,930 passengers arrived 469 items confiscated from 60 passengers, of which 76% were fresh produce, 1% honey, and 24% other items
Percentage of fresh-produce lots inspected which do not carry a quarantine pest	95%	97.4%	62 phytosanitary import licences issued" 366,085 kg fresh produce and 16,050 kg seed potatoes imported 536 lots inspected
Number of quarantine pests detected at the border as a percentage of the total number of units imported	3	1.1	1,023 containers and 250 vehicles imported 14 interceptions, of which 4 were tephritid larvae, 8 Lepidoptera larvae and 2 other taxa
Number of quarantine pests detected post-border as a percentage of the total number of units imported	2	0.1	1 interception: a chafer beetle
Number of animals that breach border biosecurity requirements as a percentage of total animal imports	5%	0%	42 animal import licences issued

Table 3 Goods seized from passengers (n = 60) by purpose of visit in 2016. Some passengers imported more than one type of risk item.

Purpose of visit	Type of items seized		
	Honey	Fresh produce	Other produce
Returning resident	0	12	7
Tourist	0	5	3
Government worker	1	4	3
Other	1	18	10

Extending sea-port biosecurity vigilance to high-risk shipping containers and vehicles revealed their prominence as vectors for harmful hitch-hikers such as spiders. This had not been known before.

Two main weaknesses remain in the island's biosecurity framework. First, new biosecurity legislation has been delayed by other priorities in the Attorney General's Office. In the meantime, existing statutes and regulations are neither harmonised nor aligned with international biosecurity expectations, so that *Biosecurity St Helena* lacks explicit legal mandates for compliance and enforcement. Warnings must substitute for fines and other legal sanctions, a shortfall which is disadvantageous to the new system.

Second, import risks are not yet assessed systematically or comprehensively. The new biosecurity policy requires all produce or risk material not on the white list (i.e. not subject to agreed import health standards) to be submitted for import risk assessment (IRA) but, in common with many small island nations, St Helena lacks the domestic technical expertise to apply the international guidelines on pest risk analysis (IPPC, 2017). Biosecurity officers cannot refer to specialist networks for advice on risk likelihood and impact, assessments of which are required at each level of the IRA process. They are often too busy to attempt these formal assessments themselves. Yet, under pressure of requests to import new commodities, St Helena's biosecurity officers regularly have to make such decisions.

Pragmatic guidelines for IRA are being applied in the interim. Risk evaluation for familiar commodities can rely on levels of confidence acquired through practical experience and knowledge of their points of origin. For example, fresh produce from South Africa, vehicles from Ascension Island, UK or South Africa, and selected plant propagating materials from the UK or South Africa are relatively well known and already have import conditions defined for them. These conditions must be revised if the risk profile alters through, for example, a change in pathway or reports of a new pest or disease in the country of origin. For commodities of these sorts, the biosecurity team assess new risks using simple web-based resources such as the CABI Invasive Species Compendium (<https://www.cabi.org/isc/>) and CABI Crop Protection Compendium (<https://www.cabi.org/cpc/>).

Biosecurity St Helena does not have risk assessment measures in place for unknown pathways or commodities such as novel plant or animal species imported for propagation or breeding. These are highly concerning and challenging to address.

The key factor for success in socialising biosecurity is considered to be the amount of time and effort committed to listening, talking and responding to the community, from farmer to government official, and utilising a range of communication media. No attempt was made to directly tackle the few more resistant individuals with arguments. It was found that time and peer pressure were in most cases sufficient to bring them round, and compliance was high.

In conclusion, St Helena Island faces increasing pressures from invasive species and is typical of small island nations in having too few resources to cope. Despite this, it has risen to the challenge and has in place a model for autonomous biosecurity by a small island nation. What has made this possible – and what compensates so significantly for chronic resource stresses – is the decision to engage business and local communities in developing *Biosecurity St Helena* and sustaining it day-by-day. Harmonising of public services has been highly effective. Recognising that a solely official approach to *Biosecurity St Helena* would lack necessary resilience and buy-in, the socialising of biosecurity is what makes *Biosecurity St Helena* a model for other small island nations.

ACKNOWLEDGEMENTS

The authors would like to acknowledge the St Helena community for being part of protecting the island's future. We are also grateful to the anonymous reviewers of this paper for their invaluable comments and suggestions for improving the text.

Proactive planning and compliance for a high-priority invasive species rapid response programme

Abstract The California Channel Islands (USA) are home to numerous endemic taxa and provide refugia for many Californian coastal species. Over recent decades, land managers have made considerable progress in eliminating alien invasive mammals and non-native invasive plants and ants. The California Islands Biosecurity Group aims to protect that investment, by coordinating and finding economies of scale in efforts to prevent invasive species introductions, detect incursions, and to respond rapidly and successfully to incursions that do occur. The highest priority is the prevention or early detection and elimination of *Rattus* introductions to any of the rat-free islands or islets in the archipelago. The rapidity of a response to a suspected incursion of rats could be hindered not only by the time required to detect it and mobilise the field effort, but also by the time required to secure regulatory permissions to implement the pre-planned actions. To address these issues, we are proactively obtaining necessary permits and developing strategy that could allow response action within 36 hours of a known or suspected introduction of *Rattus*. Our process includes developing a flowchart to aid managers in determining the appropriate management response, which considers seasonality, location, and potential non-target taxa at the incursion site. Completing the necessary compliance process proactively, and maintaining a ready stock of the materials needed to equip a management response, reduces the time between detecting an incursion and being able to respond to it and thereby increases our ability to protect the conservation value of – and investment in – these islands.

Keywords: biosecurity, California Channel Islands, eradication, planning, rapid response, rat introduction

INTRODUCTION

The extraordinary ecological, economic, and cultural damage invasive alien species can cause on islands, and the high costs and challenges of controlling or eradicating these species, has led many island managers to place greater attention on efforts to prevent biological invasions in the first place (Ruiz & Carlton, 2003; Broome, 2007; Rout, et al., 2011; Bassett, et al., 2016). Biosecurity programmes are designed to proactively prevent invasive species from arriving on an island, detect introductions quickly, and prevent non-native species from establishing on islands via rapid response actions (Broome, 2007; Russell, et al., 2008a; Russell, et al., 2008b). The ability to rapidly detect and respond to incursions is important for a variety of reasons, including that small populations are less expensive and more tractable to eradicate than large ones; some invasive species may not be eradicable at all with existing methods once even a small population has become established. The question of "how rapid does rapid need to be?" is to some degree determined by the biology of the invader. The urgency of detecting and responding to an invasive plant versus an insect or a rodent may vary, for example, because their population growth and patterns of spread may be different. Understanding those differences is important for allocating scarce management resources, as costs of surveillance are likely to increase if finer temporal scale data are needed to provide adequate detection. Costs of interventions may also increase as infestations increase in area and become more established.

This paper focuses on one critical window of time in a biosecurity strategy: the period between detecting a potential incursion and responding to it with management actions. Specifically, we provide a biosecurity programme case study from an archipelago of islands in the United States which has identified priority invaders and invasion scenarios, proactively planned responses, and sought environmental compliance permits in advance so that planned actions can be carried out quickly if an incursion is detected. Risks of rat invasion on islands are often high, because rats are common stowaways on large boats. If they successfully invade and establish populations on some islands, then they may not be eradicable with existing technologies for a variety of reasons, including the potential that available treatment options may pose unacceptable risks to populations of non-target native species. Meanwhile, animals at very low abundance can be difficult to detect (Morrison, et al., 2007; Russell, et al., 2008a). Further compounding that challenge in the context of biosecurity is that some species (e.g. rats) may be unusually mobile and wide-ranging and exhibit other unexpected behaviours in novel environments, and when their numbers are low (Russell, et al., 2008a). Thus, if a rat is detected or suspected (e.g. if there was a shipwreck of a vessel known to be infested), there may be little time to respond in a localised area with relatively high confidence that the animal remains within the project area. A variety of factors can limit response time, ranging from technical (e.g. determining the specific methods which would be most effective under the particular circumstances of the incident), to operational (e.g. getting necessary materials to the incident location), to administrative (e.g. who would make decisions within the institutions with jurisdictions over the proposed response). Environmental review and compliance processes are time consuming for land managers and, combined with required public comment periods in the national permitting process, limit the ability to respond rapidly. Here, we describe how the California Channel Islands Biosecurity Working Group has taken steps to improve the ability of conservation managers to respond quickly to a rat incursion and improve their chances of eliminating it. The most important of these steps are the advance completion of required environmental review and permitting, and the staging of materials necessary for a response to a potential rat incursion.

SITE DESCRIPTION

The Channel Islands encompass eight islands ranging in size from 250 ha to 25,000 ha, as well as numerous islets around them, all of which are within 100 km of the southern California mainland (USA). Five of the islands are included in Channel Islands National Park (Park). The US Navy owns one of the islands in the Park (San Miguel);

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 473–477. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

The Nature Conservancy owns 76% of the largest Park island (Santa Cruz); and the National Park Service owns the remainder. Four of the five Park islands are rat-free, as is an islet separated from the fifth island by just 700 m. The islands provide important nesting habitat for seabirds, including five with either state or federal designations, and one federally threatened shorebird (McChesney & Tershey, 1998; Howald, et al., 2005; CDFW, 2017a). They are home to 14 federally threatened plant species and 23 endemic animal species. The three largest islands in the Park are home to the island fox (*Urocyon littoralis*), which was recently removed from the endangered species list (USFWS 2016). The islands have been the focus of significant conservation and restoration efforts over recent decades to remove the most destructive introduced invasive species, including pigs, goats, sheep, horses, donkeys, rabbits, rats, cats, and ongoing efforts are underway to eradicate Argentine ants (*Linepithema humile*) and 32 weed species from Santa Cruz Island (Morrison, 2007, Morrison, 2011; Cory & Knapp, 2014; McEachern, et al. 2016; Boser, et al., 2017).

In order to protect the investments made and the significant biological and cultural values of these islands – and the broader archipelago in which they sit – the California Islands Biosecurity Working Group (Group) was established in 2012 (Boser, et al., 2014). The Group is composed of biologists and managers from the federal agencies, non-profit institutions, and partners that own and or have management responsibility or investment in the island resources. The Group meets quarterly in person or by phone to share updates on obstacles, technological and logistical advances to improve biosecurity, and to suggest improvements to current biosecurity practices and education programmes for professionals, visitors and resident populations. A central organising principle of the Group is that even though there are discrete islands with various jurisdictions across the archipelago, a coordinated and collaborative approach to biosecurity enhances effectiveness and achieves a myriad of efficiencies (Boser, et al., 2014; Matos, et al., in press). To accomplish an economy of scale on biosecurity priorities and to ensure that group objectives are met, the landowning entities jointly fund a full-time position to lead the implementation of group objectives. Staff biologists for the U.S. Navy, the National Park Service and The Nature Conservancy form sub-working groups to deliver results to jointly relevant projects including camera traps to detect invasive species, checks of boats and planes departing for the islands, and development of educational materials and messaging. A top priority of the Group is preventing the establishment of rats on rat-free islands, because of the well documented threats rats pose to island ecosystems, including on the California Channel Islands (Atkinson, 1985; Campbell & Atkinson, 2002; Jouventin, et al., 2003; *Howald, et al., 2005;* Towns, et al., 2006; Jones, et al., 2008; Banks & Hughes, 2012). However, given current available technologies, significant advance preparation would be required if we were to mount a timely and effective response to a rat incursion.

THE URGENCY OF RESPONSE

A comprehensive biosecurity programme will include measures to prevent incursion, as well as plans to respond to an incursion should one occur. The rapidity of the response action needs to be tailored to the species of concern. For rats, field work conducted by Russell, et al. (2008a) assessing the behaviour of collared individual rats introduced to a rat-free island indicated that most stayed within the introduction area for 2–3 days, but after that time could rapidly move away from that site. We interpreted their data to indicate that if a pregnant rat or a small population of rats were introduced to an island, there would be a very narrow window of time to take action in a localised area, and expect with some certainty that the rat(s) would be near the introduction point (Russell, et al., 2008a; Russell, et al., 2008b). For incursions on large islands (e.g. an island like 250,000 ha Santa Cruz Island), once rats have dispersed from the introduction point, we may consider them not possible to remove with current technologies, or consider that impacts to non-target species on an island-wide scale may be too great. Only a few islands larger than 10,000 ha have successfully completed a rat eradication (Howald, et al., 2007), the largest effort being recently conducted on South Georgia Island at approximately 390,000 ha (pers. comm, T. Martin 2017), and each of these used broadcast rodenticides. While rodenticides are currently the most effective tool to eradicate rat infestations (Kaudeinen & Rampaud, 1986; Tershy, et al., 1997; Howald, et al., 2007), they can have substantial non-target impacts on native species (Kaukeinen & Rampaud, 1986; Brown, et al., 1988; Eason & Spurr, 1995; Eason, et al., 2002; Howald, et al., 2010). This underscores the importance of having confidence that a suspected rat infestation remains contained within an area small enough so that risks to non-target native species are acceptably low if rodenticides are utilized. Quick deployment and response following an introduction increases that confidence. Efforts to collect data if rodenticides are used would include genetic analysis of target carcasses collected during post-treatment actions, collection and toxicology analyses of non-target carcasses discovered for at least one year, and a comparison of non-target population data pre- and post-treatment for at least five years.

One programme planning goal for the Group is to have the ability to react to an incursion within 36 hours. In the United States, however, environmental review and compliance documents permitting action that may impact non-target species, such as rodenticide use in conservation areas with sensitive or endangered species, can take months to years to complete. Given the importance of both the environmental review process and the need for a rapid response after an incursion, we sought to undertake the planning and permitting processes in advance, so that if an incursion does occur we are prepared to react appropriately and quickly.

ENVIRONMENTAL REVIEW AND COMPLIANCE

The United States' 1969 National Environmental Policy Act (NEPA) established a framework for protecting the environment from ill-considered actions by ensuring that federal agencies of the United States integrate environmental values into their decision-making processes before taking federal action. The Channel Islands National Park and the U.S. Navy islands are federal properties and therefore an environmental review must be completed before actions that could impact their environments, such as rodenticide use, could be taken. A NEPA document contains assessments of alternative actions (referred to as Alternatives) which could be implemented to achieve a stated objective that are created in consultation with subject matter experts. Further, the analysis chapter reviews the impacts of alternatives on the natural and cultural resources within the action area. A "preferred alternative" is selected by the lead agency after the document is released for public review and comment, revised if necessary, and one alternative is selected for implementation by the lead agency.

Prior to undertaking the environmental review process and structuring an environmental compliance document, we reviewed other scenarios that require proactive planning such as emergency scenarios where human life or property is at stake. In California, the Department of

Fish and Wildlife has published a California State Oil Spill Contingency plan (CDFW, 2017b) that outlines and permits actions required for rapid responses to oil spills. Similar to a rat introduction on an island, the location of the oil spill is not known during the planning process, so planning efforts must include and address a variety of contingencies that may be utilised depending on the timing and location of the spill. In rat response planning and compliance documents, we similarly need to evaluate locational- and seasonally-dependent scenarios. This includes a thorough assessment of how proposed actions may impact specific biological and cultural resources on the five islands included in the action area.

Although this proactive document must plan for the introduction event in an unknown location and time, it must nonetheless provide enough detail that the proposed response actions can be thoroughly assessed by the public and subject matter experts. Due to the ambiguity around the time or location of an introduction, and the biological or cultural resources that may be present at the site at any given time, the alternatives in a proactive compliance document must be structured differently than is typical in NEPA documents. The preferred alternative must encompass all feasible response actions, from the most minimal actions such as deploying remotely triggered cameras, to setting rodent traps, and/or broadcasting rodenticide. Proactively permitting each of these actions would allow managers to appropriately scale their response and utilise the tools that are appropriate under the specific circumstances at that time and place. The creation and use of a flowchart which directs decision-makers to recommended actions based on the known resources in a proposed project area and season allows the managers of the incident to quickly identify a recommended response. If agreed to by all consulting agencies prior to the emergency, the flowchart could be used to rapidly recommend response actions so they can be approved and quickly enacted. A contact list, similar to those used in incident response plans, must be created prior to an incident to maximise the likelihood of rapid action.

Depending on the proposed action and the resources in the affected area, additional federal and state laws may apply. In the California Channel Islands, the protected status of resident bald eagles (*Haliaeetus leucocephalus*) and numerous protected migratory birds require managers to adhere to regulations in the Bald and Golden Eagle Protection Act (1940) and the Migratory Bird Treaty Act (1918). The status of Channel Islands National Park as proposed wilderness under the Wilderness Act (1964) requires agency staff to complete an assessment of impacts to "wilderness character" in a process structured similarly to a NEPA review. The California Environmental Quality Act (1970) is similar in scope to NEPA, and a California Environmental Quality Act compliance document is required if the project is conducted on state lands or if a project uses state money. The federal Endangered Species Act (1973) and the California Endangered Species Act (1970) lists endangered and threatened species and additional permitting may be required if these species are present in the affected area. The sheer scope of the assessments and review that must occur to adhere to federal and state laws designed to protect natural resources illustrates the need to develop a functional tool to proactively gain consensus on the need to take emergency actions to protect the resources these laws were designed to protect.

CONSIDERATIONS IN PRE-STAGING MATERIALS

The compliance document must describe and accommodate assumptions about how tools needed to respond to a rat incursion could be staged for rapid deployment. For instance, if a potential action described in the environmental review document calls for the use of a conservation rodenticide, we could consider a brodifacoum-based conservation pellet designed for use on islands by Bell Laboratory which has been shown to be effective at eradicating rats from islands (Kaudeinen & Rampaud, 1986; Tershy, et al., 1997; Howald, et al., 2007). This specialised bait must be ordered months before it could be used, because it is only manufactured every few months. The rodenticide loses palatability after one year, so the bait must be properly disposed of and reordered annually. The type of bait packaging we might use would depend on the planned staging and deployment method approved in the compliance document, whether it be broadcast deployment and thus must be loaded into a hopper on the mainland and slung out to the island preloaded or packaged for transport by boat and loaded into a hopper on the affected island. For implementation to go smoothly, contingency contracts for services need to be in place prior to any incursion. A rapid deployment of rodenticide to an incursion site is dependent on all technical and logistical parts of an operation being pre-approved and permitted.

ASSESSMENT OF NON-TARGET IMPACTS

The permitting documents required in the United States include a description of projected impacts on non-target species, services such as transportation, and systems such as air and water quality. These anticipated impacts can range from "none" to "major" (the latter typically defined as population-level impacts). Monitoring programmes for bald eagles, peregrine falcons (*Falco peregrinus*), island foxes, island scrub-jays (*Aphelocoma insularis*), island spotted skunks (*Spilogale gracilis amphiala*), and seabirds are implemented annually on these islands, providing us with data on the distribution and abundance of these species on each island. Based on this detailed information, we can annually estimate how many individuals and what percentage of the population we could expect to be impacted by response actions and then use this information to recommend appropriate minimisation measures. The estimates can assist managers in assessing the risk of taking a specific action rather than taking no action at a site. For instance, the 2016 fox density estimate on Santa Cruz Island is approximately 10 foxes per square kilometre (unpublished data, A. Dillon, Colorado State University). If an area of 60 ha is treated, with the possibility of an additional 40 ha within a 200 m buffer zone, the impacted area may be as large as one square kilometre and approximately 10 foxes may be impacted by broadcasting bait. The island's total fox population is estimated to be 2,100 foxes (unpublished data, A. Dillon, Colorado State University) and thus we could expect that action to impact 0.5% of the total population. However, we could require minimisation measures that could include fox trapping in the affected area immediately before treatment to remove as many individuals as possible for translocation to lower density areas of the island. Island foxes are easily trapped using box traps, and we expect we could remove as many as 5–8 foxes from the affected area with just one night of trapping. Similar calculations using known home range data and population estimates for raptors could be used to determine worst-case scenarios if rodenticide is to be broadcast and also if bait stations are to be used. These estimates would also include risk of transient birds entering the treatment zone, possibly in response to availability of contaminated carcasses. The output of that analysis may assist managers in deciding on the best tool to use after an incursion at a specific site. We are likely to assume 100% mortality of the native mouse population in the project area and a buffer zone if broadcast rodenticide is used. These calculations and considerations must be built into an action flowchart which could be used by managers and federal agencies to assess the ecological cost of a broadcast baiting response action relative to the likelihood and ecological cost of a rat population establishing on the island.

CONCLUDING REMARKS

The benefits of proactive planning and rapid response to biodiversity protection and ecosystem function are clear-cut. Substantial evidence exists which suggests that if rats establish themselves on new California Channel Islands, they would have population-level effects on seabirds (Howald, et al., 2005) and potentially many of the listed plant species (Corry & McEachern, 2009). The approach we used to increase the ability to undertake rapid response – via proactive environmental review and compliance and having at the ready the necessary materials to respond – could be followed for other islands in the USA and, with appropriate modifications, for islands in other nations.

Although we have made substantial progress in our ability to respond rapidly to a rat detection, we still face a significant limitation in our ability to detect new incursions in a timely manner. This is due in large part to the size, ruggedness, and inaccessibility of the Channel Islands. Although we have a camera array at sites of suspected higher risk of incursion, the frequency at which we can retrieve data from these cameras, and process the images they capture, represents an important weakness in our current programme. We are hopeful that with emerging technologies – in particular mobile and networking technologies – we will be able to retrieve these data in real time (Pimm, et al., 2015). Advances in machine learning and image recognition (Lillesand, et al., 2014) also can be applied to speed up processing of images and flag suspicious images promptly to managers.

Rapidly developing technologies may play another role as we adaptively improve our planning documents. Specifically, we are considering the effect of emerging molecular methods of rat control on how we might assess risk and uncertainty, especially with regards to evaluation of non-target impacts. For example, even though rats, if established, would have negative impacts on many native species of the islands, the most successful tool currently used to eliminate rats on islands, rodenticide, has impacts to a broad array of non-target taxa (Kaukeinen & Rampaud, 1986; Brown, et al., 1998; Eason & Spurr, 1995; Eason, et al., 2002; Howald, et al., 2010). Alternative technologies such as gene drives that produce "daughterless" offspring may be available for use on invasive mammals in the relatively near term (Regalado, 2017). Such technology has already been developed for some species of insects (Gantz, et al., 2015). While there remains uncertainty about whether such technologies could accomplish eradication objectives, or would be suitable for use in low-density populations, substantial progress has been made towards advancing the technology in the past two years (Committee on Gene Drive Research in Non-Human Organisms, 2016; Regalado, 2017). Clearly, there are numerous and complex ecological, ethical, philosophical, and policy issues associated with field application of these technologies and identifying and resolving those issues will present new planning and permitting considerations, constraints and timelines. However, given the pace of developing technologies, and the known concerns with existing technologies, biologists should weigh current ecological costs of action against the likelihood of future technologies becoming available and the possibility that their use would ultimately provide better ecological outcomes. For example, a rapid response using existing technologies might be advisable – even in the face of non-target impacts – if catastrophic and irreversible damage to native species, such as extinction or a severe reduction in genetic diversity, were deemed likely to result before new rat-control technologies could be available for use, even under optimistic scenarios.

The proactive planning and permitting approach we outline can be applied broadly to conservation challenges that require the ability to respond rapidly to foreseen episodic or biologically threatening emergencies. We recognise that in island ecosystems, that experience high extinction rates and frequent state changes, managers must be nimble and quickly direct management actions for the preservation of biodiversity. The model we outline to proactively invest in planning, reviewing, and permitting essential biosecurity response measures, will improve our ability to protect the native biota of islands in the USA, if not worldwide.

ACKNOWLEDGEMENTS

We thank the members of the California Islands Biosecurity Working Group for their input into this project and their dedicated work to promoting a culture of biosecurity on the California Islands.

How do we prevent the obstacles to good island biosecurity from limiting our eradication ambitions?

Abstract Island pest eradication and biosecurity spring from the same imperative. Yet in practice biosecurity is often subordinated to the demands of eradication in planning processes so that it is not well prepared at the outset and is poorly sustained in the aftermath. Why is this when, by any logic, eradication should not proceed unless the means are in place to safeguard treated islands from renewed pest invasions? We draw on New Zealand's conservation experience to explore key reasons why biosecurity tends to lack the muscle and stamina required to protect eradication investments and their priceless biological pay-offs. We take biosecurity to be an unassailable good and discuss remedies to the challenges it must overcome if shortfalls and failures are not to become brakes on eradication ambitions. We think that eradicating pests from islands is essentially a technical business and is thus the easier part of the pest-free equation. In contrast, the problems associated with keeping islands pest-free in perpetuity are inherently more human than technical, though the latter are taxing enough. Certainly, biosecurity's work is more open-ended, less glamorous and not so dramatically rewarded. A primary concern is that the complex social dimensions of biosecurity are usually neglected. We attribute this to limited investment in social psychology tools and our habit of relying on biologists to manage behaviour-change in island visitors of all kinds. As a result, biosecurity effort can be distorted by an over-determined emphasis on surveillance and incursion response—an unduly reactive strategy but more familiar technical ground than quarantine which is inherently human-oriented. Our discussion of what works and what does not for these issues does not claim to offer universal remedies. In addition to protecting existing assets competently, our aim is to prepare biosecurity to serve tomorrow's eradication ambitions, particularly those on the testing new frontier of pest removal from inhabited islands.

Keywords: behaviour-change, complacency, improvement, priority, social psychology

INTRODUCTION

In recent decades, we have witnessed an expansion in the scale and biogeographic reach of projects to eradicate invasive organisms from islands (Howald, et al., 2007; DIISE, 2015). This diversifying of effort has consolidated eradication as a requisite measure in island restoration strategies. Successes have given comforting cues to funders and sponsors contemplating eradication as a conservation investment (see <www.milliondollarmouse.org.nz>). Eradication ambitions are clearly intensifying worldwide as operational experience accumulates and scalable advances in tools and methods overcome technical constraints on feasibility (<www.iucn.org/theme/species/our-work/invasive-species/honolulu-challenge-invasive-alien-species/commitments-towards-achieving-honolulu-challenge>; <www.predatorfreenz.org/>).

The rise of eradication as a restoration tool argues for a closely correlated strengthening of biosecurity functions (Russell, et al., 2007). These two lines of work define the mutually dependent parts of the pest-free equation. Without effective quarantine, surveillance and invasion response in place to minimise the likelihood of pests recolonising, it is reckless at best, and futile at worst, to proceed with eradication. If island stewardship lacks good biosecurity, defence of very substantial resource investments and biological pay-offs becomes a lottery in which pest organisms dictate the odds.

Biosecurity is arguably more potent than eradication as a restoration tool since most subsequent conservation investments make sense only if the island remains pest-free. Thus, biosecurity is the cornerstone, not an adjunct, of eradication work (see the panel below). Yet, however its priority is framed, we see uncomfortable signals in rates of pest invasion and reinvasion on protected islands (Clout & Russell, 2006; DIISE, 2015; Vincent, 2017) that biosecurity's practices and mind-sets have not advanced adequately to meet eradication's expectations of them.

Recurrent or not, some invasions will have been inevitable. Near-shore sanctuaries will always be vulnerable. Nor can we always predict the behaviour of animal pests or the distances over which they can travel by their own means (Veale, 2012). But other lapses will have had preventable causes: inadequate resourcing, limited preparation, hesitant follow-through, blind spots in coverage, poorly developed tools and practices, cultures of complacency, or simply outright neglect. These problems signify that operational planners have not given biosecurity the priority it requires.

These shortfalls are amenable to remedy because they arise from judgments humans make. Uncorrected, they result in biosecurity which is more often than not poorly sustained once eradication work concludes. Until the limitations in current practices are addressed, poor biosecurity will frustrate eradication ambitions.

Island restoration experience in New Zealand confirms these conclusions. In this paper, we discuss key reasons in the New Zealand context why biosecurity tends to lack the muscle and stamina of its indivisible eradication twin. These issues relate more to the social and psychological dimensions of biosecurity than to the technical challenges we face in upgrading our tools and methods, though they, too, are taxing enough.

In eradication literature, appeals for effective island biosecurity regimes focus overwhelmingly on the mechanics of pest interception. If mentioned, awareness-raising through educational outreach is usually promoted as the means to invoke helpful biosecurity behaviour in island communities and other public audiences (see for example, Boser, et al., 2014). But a growing body of empirical studies shows that heightened awareness does not necessarily alter behaviour (McKenzie-Mohr, 2013). The cryptic attitudinal barriers to biosecurity uptake are rarely assessed in public audiences (Bassett, et al., 2016) or indeed within the ranks of conservation practitioners. These social matters have immediate bearing on biosecurity's effectiveness.

We conclude our appraisal of obstacles to good biosecurity with a brief review of the measures we are

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 478–483. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

taking to address them. Though the problems are likely to be common to most biosecurity contexts, we do not claim to offer universal remedies. Our overall aim is to protect today's pest-free islands more effectively and to prepare biosecurity to serve tomorrow's eradication ambitions, particularly those on the new frontier of permanently inhabited islands. Here the social challenges are amplified and more diverse.

THE NEW ZEALAND CONTEXT

New Zealand's Government has overall responsibility for funding pre- and post-border biosecurity. The Ministry for Primary Industries (MPI) takes the lead under the Biosecurity Act 1993 to manage pest threats to human health, the economy and environment (<http://www.mpi.govt.nz/law-and-policy/legal-overviews/biosecurity/>). Under this influential Act MPI can delegate biosecurity duties to other central and local government agencies.

In the day-to-day division of biosecurity labour, the Department of Conservation (DOC) has customarily acted as the sentinel and conscience for protection of biodiversity values. Obligations to protect valued islands from invasive pests are explicit in its own mandating legislation, the Conservation Act 1987 (<http://legislation.govt.nz/>).

Today, DOC has biosecurity obligations to more than 400 pest-free islands. Up to 240 of these have been cleared historically or in more recent times of pest organisms (DIISE, 2015). Others have never been invaded. Tenure varies from public land administered by local or central government to fully freehold.

This trusteeship of recognised sanctuaries and others in-the-making extends from the Kermadec Islands in the sub-tropics to Campbell Island in the high southern latitudes. Islands at the extremities are generally well protected by isolation and strict controls on access. Conversely, others closer to New Zealand's main landmasses are within easier reach of humans and commensal pests.

Nationwide, about 85 of DOC's 2000 staff contribute in some way to island biosecurity. Typically, the majority operate part-time as gate-keepers screening traffic to and between pest-free islands. A small but growing number are also handlers of pest-detection dogs—graduates of DOC's rigorous certification programme (DOC, 2015). Rangers residing full-time on New Zealand's signature pest-free islands are obligate biosecurity gate-keepers.

Within DOC, island biosecurity operations are supported in three ways. Two national advisors lead a well-defined improvement programme discussed shortly in this paper. They negotiate for social and technical research too. Specialist community rangers organise public outreach throughout the country. And eradication veterans on DOC's Island Eradication Advisory Group (IEAG; Broome, et al., 2011) act as conscience, critics and confidants for biosecurity affairs.

Codifying of New Zealand's island biosecurity standards and practices first commenced in earnest in the late 1990s, when the rising number of pest-free islands under watch (Russell & Broome, 2016) required a more systematic approach to the work. In addition to validating biosecurity as a specialist function in its own right, the Standard Operating Procedures and Manual of Best Practice (DOC, 2008) of this time strove for national consistency and a persuasive culture of vigilance. Beforehand, biosecurity had been left in the hands of collegially isolated, largely untutored conservation practitioners.

ISSUES AT HOME

In 2012, DOC reacted to a disquieting rise in the number and costs of pest invasions on protected islands by launching a penetrating review of DOC's biosecurity fitness (DOC, 2012). The report into practices, attitudes and capacity testified to a contagious culture of complacency over invasion risks in many parts of DOC's jurisdiction (Broome, 2013). Biosecurity arrangements lacked coherence and firm, visible leadership.

Recommendations for remedy drew on examples of good practice still in place and were formalised into a determined programme of improvement (Broome & Kennedy, 2014). This acquired national priority through high-level sign-off in DOC.

The programme is still in train today. It aims to normalise a vital culture of vigilance in every part of DOC's structure. It seeks, for island biosecurity, the unqualified functional priority given to fire-fighting and Health & Safety, along with comparable prerogatives and resourcing.

In addition to confronting unfamiliar new pest threats such as the arrival of myrtle rust on public conservation lands (<www.doc.govt.nz/our-work/biosecurity/myrtle-rust/>), the upgrade programme is adjusting to new complexities in an evolving social environment. First, contemporary trends in the socialising of island management compound invasion risks by partitioning control, subordinating the biological significance of sanctuaries to other values or by condoning independent rights of access. Second, co-management agreements between DOC and owners, other regulatory agencies or communities are increasingly common. Third, many pest-free islands are passing into iwi (Maori) ownership through Treaty of Waitangi redress for colonial seizures of land. And it is business as usual for DOC itself to promote the rare biota on near-shore islands as a reason for the public to visit or camp as they wish (see for example, <www.doc.govt.nz/parks-and-recreation/places-to-go/auckland/hauraki-gulf-marine-park/visiting-islands-and-marine-reserves/>).

LINES OF IMPROVEMENT

The action plan addresses cultural, capacity and technical issues (Broome & Kennedy, 2014). Its original lines of improvement have been directed internally to ensuring that pest animals, weeds and —in special cases— pathogens did not reach islands through DOC's very frequent traffic to them.

National advisors

The two national advisors appointed to guide all aspects of the upgrade programme are extraordinary roles in the DOC structure. These sole-purpose appointments signal serious intent to make progress. The advisors are authorised to think beyond the action plan to explore emerging needs and new lines of improvement. Their operating mandate extends across all functional divisions in DOC.

Practitioner networks

The advisors have created three regional networks through which biosecurity practitioners can interact more readily with their own kind. The networks aim for peer-mediated migration of knowledge and standards across internal boundaries. Staff exchanges strengthen trust and linkages between all three networks. External associates in local government and NGOs frequently attend annual workshops.

A declared imperative is to build a strong biosecurity collegiate nationwide. Invoking the powerful unifying benefits of collegial interaction promotes horizontal accountability to peers (rather than vertically to managers) and is intended to lift productivity under conditions of capacity shortage at the workface.

Pest-detection dogs

DOC is augmenting its pest-detection dog programme through a formative partnership with New Zealand's Kiwibank (<www.doc.govt.nz/about-us/our-partners/our-national-partners/kiwibank/>). Gaps in capacity revealed through internal review (Vincent, 2015) are to be filled

Truisms for the eradication–biosecurity partnership		
Biosecurity is eradication's cornerstone	Eradication investments will come to nothing without confident biosecurity already in place	
Ask two feasibility questions before proceeding	Can the pest be eradicated? Can the island be defended from reinvasions?	
Poor preparation has a long legacy	If biosecurity is not prepared well at the outset, it will likely be sustained poorly in the aftermath	
Anticipate long lead times	Biosecurity's social and technical complexities require longer preparatory timeframes	
Biosecurity requires people of the Right Stuff	Eradication experts may not have the skills to manage biosecurity on its very different horizons and time-scales	
Quarantine is the best investment. Period.	Quarantine puts biosecurity on the front foot, where it is strategically and tactically most potent	

with new handlers and dogs trained to detect more types of organisms. Dog work will now take priority for handlers with mixed conservation duties. New full-time handlers will rove nationally to points of need. The programme has recently acquired its own national advisor and manager, appointments intended to empower the work through a more autonomous occupational structure.

Best-practice prescriptions

One national advisor acts as the go-to keeper of best-practice knowledge. S/he will codify all aspects of New Zealand's island biosecurity work through updated operational prescriptions and standards. We intend to share these prescriptions with the global community. Codes of practice will be living guides amended as new knowledge is acquired from experts, research or field experience. Learning from informal experimenting in the field is a further source of new knowledge, one traditionally overlooked.

Pragmatic biosecurity plans

Outdated island biosecurity plans in all DOC regions are to be revised. We are piloting a simplifying short-plan format (Kennedy, 2016a; 2017) designed to hasten updates and approvals. The new format restricts plans to defining briefly what has to be done (activities, rules, standards and roles), without long explanatory narratives. Thus, plans will act strictly as operational blueprints, not as textbooks or technical manuals. 'How-to' prescriptions prepared independently of plans will instruct rangers in the technical details of biosecurity tasks. The revised plan for Maud Island (Caldwell & Higgott, 2017) exemplifies the new approach.

CIMS-based incursion responses

We have recently adopted the Co-ordinated Incident Management System (CIMS) as the standard mode of response to pest invasions (Corson, 2018a, b). CIMS clarifies response roles and organises support for ground operations by co-ordinating inputs from relevant experts. We assemble technical advisory groups (TAGs) as needed to guide CIMS decision-makers on appropriate measures. Biosecurity novices are apprenticed to CIMS teams for training on the job.

Upgrade of quarantine facilities

We are ranking DOC's 38 quarantine facilities for complete renewal or internal refits in coming years. These secure stores at mainland points of departure and island landings are the primary pivot-points for movements of DOC people and freight. Facilities on the mainland also function as biosecurity's public face. Design principles (Kennedy, 2016b) are awaiting translation into new architectural and construction standards as part of the best-practice review.

Peer-review of biosecurity practices

Systematic audits of local biosecurity practices and culture have resumed (see for example Kennedy & Chappell, 2013; Kennedy & Trainor, 2016; Broome & Corson, 2017). Experienced practitioners lead the reviews, usually assisted by a novice. Audits are our most decisive means of detecting lapses in standards and propagating successful practices. As peer-reviews, they strengthen mutual trust in DOC's biosecurity ranks. Reviewers, themselves, are instructed by the process of critique and counselling. Currently, audit recommendations are not yet binding.

As expected, these and other lines of operational upgrade have had to compete for resources and priority within a complex organisation attending to demands on multiple conservation fronts. Obstacles to progress associated with biosecurity's social dimensions were under-estimated.

UNEXPECTED OBSTACLES TO GOOD BIOSECURITY

Managing human behaviour is unavoidable in the business of keeping islands pest-free. In contrast, eradication is more a technical discipline and therefore the easier part of the pest-free equation.

DOC's internal biosecurity arrangements cannot be intensified successfully, nor can they be sustained in perpetuity, if biosecurity behaviour is not normalised in organisational thought and practice. The same applies to public traffic to islands. By necessity then, we have extended our upgrade programme to invoke beneficial behaviours in public audiences whose multiple forms of contact with pest-free islands are less within DOC's control.

Of the two broad classes of audience (professional and public), our colleagues have proven to be the more resistant to the right behaviours. This is perplexing, since they are closely invested in conservation and should be acutely aware of invasive pest threats to insular biota. Yet compliance with expected behaviours still appears to be more obligatory than voluntary.

Expert mind-set

We observe an ‘expert’ mind-set at play in our colleagues. It reasons that as conservation specialists they are best placed to judge risk and thus how much they need to comply with rules. Treating compliance as discretionary translates biosecurity from an essential good into a nuisance (rationalised perhaps as an intrusion on professional judgement). Ough Dealy (2016) reports a similar 'experts-know-best' phenomenon in dog owners landing their pets illegally on pest-free islands in New Zealand’s far north. Biosecurity’s logic is not sufficient on its own to alter this mind-set.

Colleagues resist further through arguments that there is little point in DOC staff submitting to quarantine checks when the public can visit the same islands without doing so. This surprisingly prevalent thinking underwrites pressure to reduce quarantine standards (authors, pers. obs.). Its disabling logic supposes that biosecurity can extinguish all risk. We argue instead that it can only minimise the probability of pest incursions. So, if some of an island’s visitors are guaranteed pest-free, the risk is reduced accordingly.

Image problems

Biosecurity is inherently prone to neglect. It has a poor image. In contrast with the heroic character of eradication operations, biosecurity work is less glamorous, inherently open-ended and not so dramatically rewarded. Reputations are simply not made in the business. Arguably then, biosecurity does not appeal to practitioners motivated vocationally to make a demonstrable difference for conservation (Kennedy, 2003).

Perversely, biosecurity is a casualty of its own success. When everything works as it should, nothing happens. This is particularly penalising in today’s over-determined goal-directed working environments. For resource-stressed colleagues in DOC, intercepting very few invasive pests, year after year, argues for shifting effort from biosecurity to more obviously productive work.

We find as a result that our field and management staff are inclined to treat biosecurity as an insurance policy on which it is safe to avoid paying the premiums. Too often, they subordinate biosecurity to lower but more immediate priorities. Even financially punishing biosecurity failures (for example, the > $NZ200,000 mouse invasion of Maud Island; Broome, et al., this issue) have had only a limited chastening effect on this habit.

OVERCOMING ATTITUDINAL OBSTACLES IN DOC

We are in a stronger position to legislate compliance with this captive audience. Traffic to islands is governed by behavioural rules applying to all DOC staff, our associates and our freight. Quarantine inspections are obligatory (see for example, Hiscock, 2016) and must be allowed for in operational timetables. At points of departure, authorised biosecurity gate-keepers are mandated (regardless of their occupational rank) to prohibit travel until quarantine standards are met.

Ultimately, normalising biosecurity will be achieved in this audience by playing on the powerful human instinct to conform to peer-pressure. This influence on attitudes and behaviour is a defining quality of collegiality, itself articulated through peer-mediated understanding of common purpose, values and identity. DOC’s biosecurity networks are a resolute first step towards this goal. Creative celebrating of successes and champions will help. Loss of occupational autonomy under DOC’s line-management arrangements is a barrier to progress (Kennedy, 2003).

OBSTACLES TO BEHAVIOUR-CHANGE IN PUBLIC AUDIENCES

Island biosecurity in New Zealand is faltering most conspicuously in its managing of public access to pest-free islands. DOC is still seriously under-invested here, most obviously because the tools of social psychology are not yet used adequately by DOC itself or trusted by biologically-minded practitioners.

Problematic messaging

In piecemeal approaches or hesitant use of creative messaging, outreach strategies reflect their uncertainty on how to bring behaviour-change about. Neglecting outreach as a quarantine measure because of its social uncertainties denies biosecurity a powerful range of interventions. A distorting emphasis on surveillance and response is likely to result, particularly as these activities are more comfortable technical ground for practitioners unskilled in modifying public behaviour.

For instance, three years after cats and rodents were eradicated from Great Mercury Island (1,872 ha) in New Zealand’s southern Hauraki Gulf, on-island surveillance and response regimes are in place (Collins & Corson, 2016) but quarantine lacks any coherent messaging strategy to manage visitor risk. As a result, biosecurity to manage the differing forms of public contact with the island is dangerously off-balance and inherently reactive.

In the absence of insights from social research, the customary response is to fall back on orthodox messaging through signs and pamphlets. Typically, this relies on a mix of appeals to protect natural values and prohibitions on unwanted behaviour, all conveyed in alienating official language. We are not confident that this messaging or its media are effective. Much of it amounts to shouting at audiences.

Branding is similarly problematic. In 2009, Auckland Council and DOC launched the *Treasure Islands* brand (<www.treasureislands.co.nz>) to engender biosecurity behaviour in the hundreds of thousands of public and commercial travellers to 44 pest-free islands in the Hauraki Gulf Marine Park. Uncertain of its effectiveness, brand design was under constant review (Jack, 2011). Variations were visible everywhere, from bill-boards to bait stations, pamphlets to piers. Later surveys of biosecurity awareness in island residents and visitors showed limited knowledge of the brand as it had been communicated (Auckland Council, 2010a, 2010b; Lysnar, 2016). Fraser, et al. (2016) concluded that face-to-face conversations with ferry passengers were a more effective means of outreach.

We consider that the finer-scale insights of qualitative social research studies are more likely than quantitative to determine which messages and media will prompt target audiences to become willing biosecurity actors—to quarantine their personal gear before departure. Social research shows already that those messages will likely resonate with audiences’ own reasons for visiting islands, not with our notions of nobility in conservation values or biosecurity need (see McKenzie-Mohr, 2013).

Biosecurity’s unwitting social offences

Invoking the quarantine habit in public audiences faces cryptic psychological barriers. We regard credibility as a crucial issue. As with our sceptical colleagues, visitors arriving on controlled pest-free islands are disinclined to believe that they have a mouse or a rat in their bag when asked to check (Tyrrell, 2012). This is a pivotal moment at which biosecurity’s legitimacy is questioned along with the gate-keeper’s sanity.

Winning the contest for credibility is made more difficult in that emptying bags and pockets in the company of strangers can be socially awkward, particularly in the congested conditions of an enclosed quarantine room. At worst it may be regarded as an intrusion on personal privacy.

Remedies for this and many other unwitting social offences seem intractable to practitioners who are suspicious of the arcane social sciences. This is yet another barrier to overcome. In fact, remedies will be more likely in the hands of social psychologists; they can no longer be left to chance or to force of personality in biosecurity gate-keepers.

ADDRESSING THE CHALLENGES

DOC's investments to strengthen island biosecurity have had to extend beyond the internal focus of its original action plan. Thinking and initiatives are advancing along the following lines.

Biosecurity's functional identity and appeal

We see potential to lift biosecurity's functional appeal and effectiveness in-house by giving the work its own occupational structure, dedicated line-manager and credentials. This thinking recognises that biosecurity is a specialist field in its own right, entitled to greater operational autonomy, its own leadership prerogatives and requiring operators uniquely suited to its distinctive modes of work. Not all field ecologists have the necessary manner or motivations. Discrete occupational identity breaks with today's unhelpful assumption that biosecurity is merely an adjunct function of eradication and other specialist work.

Audits of readiness

Biosecurity readiness for eradication operations and ongoing quarantine would benefit from more determined auditing. An expert group resembling the IEAG appeals as a means for authoritative scrutiny. The two should operate in parallel, even if they share experts from time to time.

Testing our own attitudinal barriers to good practice

We see immediate value in social research to investigate the attitudinal barriers to biosecurity uptake in our own colleagues. Likewise, we are learning to test the assumptions we make routinely about who our public audiences are, what they understand and what motivates them. Inexpert assumptions here make unreliable stepping-off points for changing public behaviour.

Seeing the improbable

We are adopting the principle that our colleagues and public alike must see for themselves before they will accept the improbable. This means replacing talking and preaching with evidential photos, videos, eye-witnesses and stories. In the quarantine inspection room on Matiu/Somes Island in Wellington Harbour, for instance, incoming visitors can see and handle a sobering collection of pest organisms intercepted in bags and pockets.

Measuring the costs of failure

The time and dollar costs of incursion responses are now recorded more carefully using new reporting templates to prompt for essential information (Kennedy, 2015a). These data are collated to argue for better resourcing and priority. Each incursion is treated as an experiment from which lessons are now extracted more systematically (Kennedy, 2015b; Kennedy, 2016c). All reports are added to DOC's comprehensive database of island incursions (Vincent, 2017).

Making biosecurity sexy

DOC's pest-detection dogs are now employed more purposefully as our ambassadors and champions. Their unique ability to convey biosecurity messages by their very presence surpasses the best of human efforts. Contact time with public audiences of all types is now built into work schedules.

Social research

We have commenced two qualitative social research projects designed to find ways of stimulating beneficial behaviour in island visitors. Both use community-based social marketing methods (CBSM; McKenzie-Mohr, 2013) and are intended to generate solutions applicable throughout New Zealand.

The first project is searching for effective ways to convince recreational boat users to leave their pet dogs at home. Dogs landed with families picnicking on pest-free open-access islands in New Zealand's far north are killing endangered kiwi chicks crèched there for conservation purposes (Ough Dealy, 2016; Ough Dealy & Greig, 2017). Findings from this modest inaugural study have confounded most of our assumptions about the target audience and its motivations to take dogs ashore illegally (further information is available from the authors).

The second study aims to persuade recreational boat users to check their vessels and gear for pests before they leave home. This study will test our hypothesis that willingness to check at home will be greater than at the launch ramp where time and other pressures intrude. Consistent with CBSM methods, this study has attempted to isolate specific behaviours for change while exploring the character of the target audience (Harbrow, 2017).

Conversing with audiences

Though still only a concept, we aim to converse with rather than talk at public audiences. Experiments with more relaxed, colloquial language on conventional signage have been contemplated but not yet launched. Likewise, we are considering the head-turning potential in non-conventional signage (say, 3-D models of rodents) as a means of distinguishing our biosecurity messages from the walls of rectangular 2-D bill-boards island visitors expect to see at departure points.

We have also adopted the principle of conversing continuously with audiences well in advance of their arrival at departure points. Visitors of all kinds travelling to controlled-access islands receive information ahead of time on how to prepare for their quarantine inspection. YouTube videos (<https://youtu.be/yXNOpfW7PPQ>) are used too. Bounce-back messages on booking sites are under consideration. Open-access islands present greater difficulties. Here, a progression of messages along approach routes, conversing by various media, would avoid the unsatisfactory situation of today where visitors are confronted with conditions on travel at the last moment, when they are least able or prepared to comply.

Reaching back into supply chains

Following the lead of Morgan, et al. (2014), we regard it as imperative to check freight for pests early in the supply chain. We award pest-free warrants (<www.doc.govt.nz/parks-and-recreation/places-to-go/auckland/hauraki-gulf-marine-park/know-before-you-go/treasure-islands/pest-free-warrant/>) to businesses guaranteeing to supply pest-free goods or services. These businesses are used and publicised as preferred suppliers. Not only is quarantine at source more efficient but it safeguards biosecurity gate-keepers from pressures to pass suspect goods or freight for shipping under operational urgency at departure points.

CONCLUSION

Advances of these kinds are intended to make good on biosecurity's duties to its eradication partner. They spring from lessons learnt during determined upgrading of DOC's island biosecurity performance. We recognise now that biosecurity must be the cornerstone of island restoration work, not a secondary function of pest eradication or other conservation investments. Its effectiveness is not assured, however, unless it is respected as a highly specialised discipline, resourced accordingly and trusted to credentialed practitioners attuned to the particular demands of quarantine, surveillance and response. We have become acutely conscious of the need to address the discipline's complex social dimensions. These have been neglected at home historically because biosecurity work was usually left to field ecologists unfamiliar with social research tools. Biosecurity cannot avoid managing human behaviour if it is to acquire its necessary reach and balance. More systematic programmes of social investment are needed to address the obstacles to good biosecurity today. They will be outstanding preparation for the future in which the formidable social challenges of eradicating pests from populated islands, or indeed from entire countries (e.g. Predator Free New Zealand 2050) will demand more sophisticated tools and thinking than we possess now.

Abstract Mexico's National Strategy on Invasive Species (2010) and the National Strategy for the Conservation and Sustainable Development of Islands (2012) embrace its steady and positive 20-year trajectory on island restoration. Mexico has come halfway to having all islands free of invasive mammals. To sustain these results in the long-term, biosecurity became a priority. To implement these national strategies, the National Commission for Knowledge and Use of Biodiversity (CONABIO) and the National Commission for Natural Protected Areas (CONANP) integrated a participatory programme to develop the country's capacities for managing invasive alien species (IAS). With funding from the Global Environment Facility (GEF) through the United Nations Development Programme (UNDP), and private donors, the IAS programme is now under operation. Grupo de Ecología y Conservación de Islas, A.C. (GECI), a professional Mexican NGO, is implementing the programme on islands, along four lines of action: (1) island biosecurity; (2) environmental learning and capacity building; (3) control and eradication of IAS; and (4) monitoring to assess ecological recovery. While promoting the importance of biosecurity amongst all social actors, the focus is on long-term formal implementation, culture and everyday life. The methods therefore vary: workshops with authorities, integration of specific biosecurity protocols, and art and conservation activities with the local communities, particularly with children and young adults. The experience to date shows that enforcement by authorities and integration of the subject by local fishermen communities and island users are two key factors in sustaining the valuable and tangible results achieved to date over the long term.

Keywords: biosecurity, conservation, early detection, eradication, prevention, rapid response

INTRODUCTION

As one of the world's megadiverse countries, Mexico acknowledges the importance of safeguarding its biodiversity and over 10,000 endemic species (Llorente-Bousquets & Ocegueda-Cruz, 2008). Invasive alien species (IAS) pose the most important threat to biodiversity worldwide (Reaser, et al., 2007; Towns, 2011), and have caused 67% of the extinctions of Mexican vertebrates (Aguirre-Muñoz, et al., 2011a). Consequently, a National Advisory Committee for the Strategy on Invasive Species (CANEI, for its Spanish acronym) was created in 2008. It is comprised of governmental and academic institutions, as well as non-profit civil society organisations. Coordinated by the National Commission for the Knowledge and Use of Biodiversity (CONABIO), the CANEI developed the "National strategy on invasive species: prevention, control and eradication" in 2010. Its vision is to address the problems of IAS, by creating efficient prevention, early detection and rapid response systems, as well as a legal framework to mitigate, control and eradicate these species (CANEI, 2010).

The nearly 4,000 Mexican islands, as do most of the islands around the world, host a disproportionate amount of the country's biodiversity (Whittaker & Fernández-Palacios, 2007). They are hotspots of endemism richness, with 14 times more endemic species than the mainland (Aguirre-Muñoz, et al., 2016a). In recognition of the need to protect this biodiversity as well as the livelihoods of island communities, the Mexican government has included all islands in the National System of Natural Protected Areas (Aguirre-Muñoz, et al., 2017a) with the recent decree of the Islas del Pacífico de la Peninsula de Baja California Biosphere Reserve (DOF, 2016). Therefore, the formulation of the National Strategy for the Conservation and Sustainable Development of the Mexican Island Territory (2012) was an important step forward. This national strategy sets priorities to work on three tactical lines – sovereignty, conservation and sustainable development – through four transverse lines of action – knowledge, public policies, inter-institutional coordination and financing (CANTIM, 2012).

ISLAND CONSERVATION IN MEXICO

The history of island conservation in Mexico delivers a restoration success story. Through to 2017, 60 populations of 11 invasive mammal species have been eradicated from 39 islands, which represents over 59,000 ha restored (Aguirre-Muñoz, et al., 2018). Thanks to these efforts, at least 147 endemic taxa of mammals, reptiles, birds and plants are protected. Furthermore, 227 highly vulnerable seabird colonies are recovering from the impacts of IAS (Aguirre-Muñoz, et al., 2016b). A growing network of collaborating federal government agencies, e.g. the National Commission for Protected Areas (CONANP), CONABIO, the National Institute of Ecology and Climate Change (INECC), and the Department of the Environment and Natural Resources (SEMARNAT), academic institutions, local communities, fishing cooperatives, civil society organisations and donors (national and international) has been fundamental to achieving success. Working in close collaboration with the multiple partners, Grupo de Ecología y Conservación de Islas, A.C. (GECI) has implemented all but two of the island eradications in Mexico and is currently executing other eradication projects on several islands. GECI is a Mexican civil society organisation, which works with an interdisciplinary and comprehensive approach toward the restoration, conservation and sustainable development of islands (Aguirre-Muñoz, et al., 2011b).

GECI's goal, as outlined in the IUCN's Honolulu Challenge, is to remove invasive mammals from all islands of Mexico by 2030 (IUCN, 2017). To achieve it, we need to eradicate a further 70 populations of invasive mammals from 34 islands. To do so, we aim to eradicate invasive mammals following restoration priorities, including where

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 484–488. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

endemic species are vulnerable, eradications are feasible and risk of reinvasion is lower (Latofski-Robles, et al., 2014). Therefore, the implementation of a National Programme for Island Biosecurity – the policies, measures and actions to protect island biodiversity from IAS by preventing their arrival and establishment (Roberts, 2003; Russell, et al., 2008) – is vital to ensure that successes achieved remain in the long term, and that the investment in conservation measures, such as eradications, has the highest return rates (Broome, 2009). Implementing biosecurity will also further Mexico's achieved international commitments, in line with Aichi Biodiversity Target #9 which states: "By 2020, IAS and pathways are identified and prioritised, priority species are controlled or eradicated, and measures are in place to manage pathways to prevent their introduction and establishment" (CBD, 2010). Additionally, new restoration projects will benefit from building biosecurity capacities beforehand. Thus, biosecurity becomes a transverse line of action amongst all of GECIs restoration projects (Aguirre-Muñoz, et al., 2016b).

FORMULATING THE NATIONAL ISLAND BIOSECURITY PROGRAMME

Islands significantly contribute to the country's megadiversity. They harbour 8.3% of all vascular plant and terrestrial vertebrates (CANTIM, 2012). They also support the livelihood of more than 200,000 people, most of which rely on the valuable marine resources that thrive in adjacent waters. However, some islands have faced the negative impacts of IAS, particularly mammalian predators, for centuries. The introduction of such problematic species to islands in Mexico has been mainly due to anthropogenic reasons, either intentionally or accidentally. Before the 20th century, introduction of IAS was mainly related to the harvesting of marine mammals and guano mining. Nowadays, the sources of introductions have diversified and include commercial and sport fishing, as well as tourism related activities (Aguirre-Muñoz, et al., 2011b). At first, restoration projects were all about solving the problem already at hand, eliminating the IAS; however, as we free islands of their IAS, we must change our way of thinking and become proactive in preventing reintroductions or new introductions. In order to halt the introduction of IAS, intentional or accidental, we need a society that is aware of the root causes and problems associated with the loss of biodiversity and the ecosystem services it provides. We need the social construction of a new paradigm, of everyone feeling a sense of privilege every time we visit an island and acknowledging that the conservation of such a special place is in our own hands.

Therefore, GECI's restoration projects are accompanied by an environmental learning and outreach campaign that is designed for that specific island and its local community's characteristics. We seek to boost the local community identity, by publicising the island's biodiversity, as well as its endemic or more charismatic species. We produce and distribute different outreach materials (e.g. posters, photographic catalogues, wristbands, colouring books, puzzles, etc.) that showcase the island's uniqueness and what you can do to protect it. We also give varied talks to different sectors, such as schools, universities, fishing cooperatives and tourist operators, about the restoration project and the outcomes expected. Moreover, we learn about the way local communities understand, interact with and feel about their environment through their artistic expressions. We provide the opportunity for youngsters to express their connection to nature through music, painting, drawing and story-telling workshops, and have documented beautiful results.

GECI's efforts to make island biosecurity a subject matter and common topic amongst island users and managers became systematic with the nationwide project to implement the Strategy on Invasive Species in Mexico. With funding from the Global Environment Facility (GEF) in coordination with the United Nations Development Programme (UNDP), the CONABIO and the CONANP lead the inter-sectorial project to implement this Strategy. Implementing biosecurity protocols and building capacities on managing IAS are two priority actions established in the Invasive Species Strategy (CANEI, 2010). The project is implemented in priority areas of conservation and focuses on preventing the arrival and establishment of IAS through prevention measures, early detection systems and rapid response (Born-Schmidt, et al., 2017).

The project began the planning stage in 2012, and GECI, who is coordinating the island programme, started by identifying priority protected areas for implementation and setting action guidelines. The lines of action, with a 2015–2018 implementation horizon, are: 1) Biosecurity: development, implementation and evaluation of biosecurity protocols, creation of biosecurity committees; 2) Environmental learning and outreach: producing outreach materials, developing awareness campaigns about IAS, building capacities for local groups on early detection and rapid response; 3) Restoration: management of the IAS, as well as native species present; 4) Monitoring: documenting ecosystem responses to eradication of IAS (Aguirre-Muñoz, et al., 2013). Six priority protected areas are our pilot project areas where the biosecurity project is currently being implemented (Table 1, Fig. 1). The project is being replicated in the Gulf of California, in a group of islands known as the Midriff Islands.

DESIGNING AND IMPLEMENTING ISLAND BIOSECURITY PROTOCOLS

In order for biosecurity to fulfil its purpose, we need to analyse and take into account all the particular activities that different sectors carry out on the island. Consequently, we decided on a "bottom-up" strategy to create site-specific biosecurity protocols in an adaptive and participatory manner (Aguirre-Muñoz, et al., 2013). With every sector involved in the protocol design from the beginning, they provide the information needed to make an informed risk analysis and detect critical control points (González-Martínez, et al., 2017). Furthermore, by being involved, the communities are more likely to approve and adopt prevention measures that need to be carried out in everyday life and with a long-term vision.

Biosecurity protocols are documents where all the components of biosecurity are detailed; so that each stakeholder understands what will be implemented, and how he/she is involved. The main components of biosecurity are prevention, early detection and incursion response (Russell, et al., 2008). The key behind prevention

Fig. 1 Map of the islands and their coastal areas of influence for the Biosecurity Programme.

Island	Location	Previous eradications	IAS present	Local community
Isla Guadalupe Biosphere Reserve	Pacific Ocean (260 km off the coast of the Baja California Peninsula)	rabbit & donkey (2002) horse (2004) goat (2006) dog (2007) cat (in progress)	Plants 47 Reptiles 0 Birds 5 Mammals 2	100 people, comprising a fishermen's camp, a Navy Station and GECI´s station.
Isla Cedros – Pacific Peninsula of Baja California Biosphere Reserve Islands: Cedros & San Benito Oeste	Pacific Ocean (25 km off the coast of Baja California Sur Peninsula)	Cedros: dog (in progress) San Benito Oeste: rabbit & goat (1998) donkey (2005) cactus mouse (2013)	Cedros: Plants unknown Reptiles 0 Birds 4 Mammals 6 San Benito Oeste: Plants 9 Reptiles 0 Birds 4 Mammals 0	10,000 people comprising a fishermen's cooperative, the Navy Station, and the salt exporter.
Archipiélago de Revillagigedo National Park Islands: Socorro & Clarión	Pacific Ocean (480 km off the coast of Baja California Sur)	Socorro: sheep (2010) cat (in progress) Clarión: sheep & pig (2002)	Socorro: Plants 47 Reptiles 1 Birds 5 Mammals 2 Clarión: Plants unknown Reptiles 1 Birds 5 Mammals 1	Socorro: 40 people at the Navy Station Clarion: 15 people at the Navy Station
Isla Espíritu Santo – Gulf of California Islands Protected Area	Gulf of California (25 km off the coast of Baja California Sur)	cat (2017/absence confirmation stage) goat (in progress)	Plants 5 Reptiles 0 Birds 0 Mammals 1	No permanent settlement, however during fishing season around 90 people camp there. Highly visited tourist spot.
Banco Chinchorro Biosphere Reserve Islands: Cayo Centro, Cayo Norte Mayor & Cayo Norte Menor.	Caribbean Sea (30 km off the coast of Quintana Roo)	Cayo Centro: black rat & cat (2015) Cayo Norte Mayor & Menor: black rat (2012)	Plants 6 Reptiles 1 Birds 2 Mammals 0	Cayo Norte Mayor: 12 people Navy Station Cayo Centro: 3 people CONANP station, 100 people fishermen's camps. Tourist visitors.
Arrecife Alacranes National Park Islands: Pérez, Pájaros, Muertos, Desterrada & Chica.	Gulf of Mexico (140 km off the coast of Yucatan)	Pérez: black rat (2011) Muertos & Pájaros: house mouse (2011)	Plants 5 Reptiles 0 Birds 1 Mammals 0	Pérez: 15 people from the Navy Station and CONANP station. During fishing tournaments around 40 camp.

is to set as many obstacles as possible throughout the pathways of introduction, to reduce the probability for IAS to get to the islands. Early detection means a surveillance method through detection devices, such as traps, to determine if there is an incursion. Surveillance is a long-term strategy that requires funding and local capacity building. Finally, an incursion response plan, in case an IAS is detected or suspected, aims not only to confirm the incursion but also to eliminate the IAS (Moore, et al., 2010). Biosecurity protocols contemplate, at least, the following aspects: 1) Identifying the main potential IAS; 2) Identifying possible pathways and vectors of introduction; 3) Establishing prevention measures on the mainland; 4) Establishing early detection systems at disembarking sites; 5) Establishing an incursion response plan; 6) Establishing stakeholders responsibilities (PII, 2013).

Since 2014, we have held workshops for the participative formulation of biosecurity protocols for our pilot areas (and others). We invite local authorities (CONANP, SEMAR, port authorities), fishermen and tourist operators, and we go through all stages of biosecurity and discuss the sites most visited, frequency, and type of transportation. Afterwards, we vote on prevention measures and where to implement them. Additionally, we do a field practice about surveillance and early detection devices commonly used.

To date, we have six unique, specific, updated, island biosecurity protocols, created in a participatory manner. The protocols contain priorities for prevention measures and the most cost-effective and site-specific tools and methods. Protocols are currently under review by the corresponding authorities (Latofski-Robles, et al., 2017). Protocols were formally validated through workshops with the Advisory Council for each island. Furthermore, we strive to create Biosecurity Committees that are a subgroup of said Advisory Councils. These Committees will be in charge of implementation, evaluation and updating of the protocols, as well as fundraising for biosecurity to continue in the long run.

ISLAND BIOSECURITY AT WORK

The most relevant component of biosecurity is prevention. However, all stakeholders need to communicate and coordinate in order for it to be effective. Prevention is closely linked to outreach and environmental education campaigns (Parkes, 2013). An analysis of costs from the Mexican island experience, overwhelmingly demonstrates the importance of investing in biosecurity prevention measures. Recent rodent eradications in Mexico, show that, on average, it costs 20 times more to perform an eradication project than to prevent the arrival of IAS (Aguirre-Muñoz, et al., 2017b).

Early detection is of critical importance to discover any elusive individual that managed to escape the prevention measures. Thus, it also helps to evaluate the prevention strategy. Local capacity building, strong partnerships and straightforward communication between local communities, island managers and other stakeholders (e.g. tourist operators) is critical for a swift and effective incursion response. Furthermore, the *ad hoc* design and wide distribution of outreach materials for each island is vital to raise awareness of the problem of IAS.

As our National Biosecurity Programme unfolds, we have had two effective incursion response events that have successfully stopped the establishment of rodents in Arrecife Alacranes. This is a positive sign that the outreach campaign and workshops are having an effect, and that people are now aware that islands should be IAS-free and their involvement is needed to achieve that (Latofski-Robles, et al., 2016; Matos, et al., 2018). Much has been learnt from incursion events, and the lessons must be adopted nationwide to strengthen prevention measures and community involvement.

INSTITUTIONALISING BIOSECURITY

Building capacity amongst protected area managers and users regarding island biosecurity methods and techniques is crucial to protect the islands from the impacts of IAS. The threat of IAS is considered as important in most of the protected areas management plans; however, preventing their accidental introduction is not commonly featured.

The first step toward building biosecurity capacities for the Mexican islands was the "Island Biosecurity Workshop for managers, park rangers and users of protected areas" in 2014. It was held by GECI with funding from the US Fish & Wildlife Service and the CONABIO. Twenty-six people from all island protected areas in Mexico, gathered in Ensenada, Baja California for three days, during which we discussed biosecurity measures and practiced with early detection devices in Todos Santos Sur Island. Representatives from all agencies regarding islands came together. There were people from CONANP, CONABIO, the Mexican Navy, and the SEMARNAT Office for Wildlife (DGVS). We also analysed the challenges and opportunities to implement biosecurity protocols, prevention measures and early detection systems (Méndez-Sánchez, et al., 2014).

Moreover, GECI has had a solid collaboration history with the Mexican Navy (Secretaría de Marina, Armada de Mexico). They are invaluable partners in the conservation of the Mexican islands, always providing their support on projects (Aguirre-Muñoz, et al., 2017b). We have also had talks with their central offices about the need to adopt biosecurity measures in every port and for all ships. During our restoration projects, we give talks to personnel at SEMARs stations at the islands, but we also strive to provide training, so that there is always at least one person who knows about surveillance methods and early detection techniques on all islands with Navy stations.

The successful two-decade trajectory of island restoration in Mexico contributes to meet the country's goals in sustainable development and conservation (Aguirre-Muñoz, et al., 2016a). The National Biosecurity Programme must become a formally recognised, institutionalised, inter-agency, inter-sectorial agreement for it to be effective. We need to establish collaboration arrangements with several agencies, such as CONANP, SEMAR, SEMARNAT, the Federal Agency for Environmental Protection (PROFEPA), and port authorities. Once we are all working hand in hand, the restoration efforts for Mexico's island biodiversity will be reinforced and protected over the long term.

RECOMMENDATIONS AND LESSONS LEARNT

Outreach and environmental learning campaigns are of the utmost importance, and hence need to be permanent and not just for short periods of time. Only then, will people become aware of the problem and actually adopt the habits required to prevent the accidental introduction of IAS.

Working with the Protected Areas Advisory Council is the best strategy to strengthen biosecurity protocols. It also helps the project to become integrated with the area manager's work.

Communities that recently participated on an eradication project are more likely to be interested and active in keeping the island free of IAS.

Incursion response cases may have economic costs that are not specifically budgeted for, so the creation of a national biosecurity fund for emergencies is an important step forward.

Early detection alerts are a way of evaluating if the outreach campaign is working, so that even if it turns out to be just a false alarm, we now know people are aware that they should report if they see something different.

We need to sign and publish institutional collaboration agreements between government agencies in order to reinforce biosecurity measures and make sure all stakeholders comply with them.

ACKNOWLEDGEMENTS

Formulating the biosecurity protocols is the work of many people and agencies. We would like to thank CONABIO, SEMAR, and CONANP and each protected area's Advisory Council for their collaboration. The network of funding for biosecurity continues to grow; we thank the GEF, UNDP, Alianza WWF- Fundación Carlos Slim, Marisla Foundation, The David & Lucile Packard Foundation, USFWS and GIZ.

Achieving post-eradication biosecurity on South Georgia

M.G. Richardson and J.P. Croxall

South Georgia Heritage Trust, Verdant Works, West Henderson's Wynd, Dundee, DD1 5BT, UK. <mikerichardson@btinternet.com>.

Abstract The world's largest island rodent eradication programme to date was carried out on South Georgia between 2009 and 2018 (baiting on island in 2011, 2013 and 2015) by the South Georgia Heritage Trust (SGHT). A comprehensive survey in 2017/18 found no signs of rodents. Although SGHT planned and executed this eradication under permits issued by (and with collaboration from) the Government of South Georgia and the South Sandwich Islands (GSGSSI), the scale and complexity of the multi-year project was not conducive to prior agreement on post-eradication biosecurity to prevent rodent re-invasion. Thus by 2013, two years after initial baiting, biosecurity measures for rodents remained inadequate, relying mainly on rodent detection boxes on vessels and at the island's main point of entry. The more substantive post-eradication biosecurity measures implemented by other administrations were absent. In late 2014, after more than three years with no rodent sign, there was unambiguous evidence of a rat within the island's settlement. This coincided with a vessel berthed alongside a nearby jetty. Between 2015 and 2017, SGHT formally submitted recommendations to the GSGSSI on enhanced biosecurity provisions. Some of these recommendations have been implemented but arguably the most important, relating to vessel berthing and secure handling of imported cargo, remain to be addressed effectively. We summarise what remains to be done, recognising the logistic and financial challenges involved, but conscious that, until all measures are in place, there is significant risk of re-infestation of South Georgia by invasive rodents, compromising a decade of work (and funding) by multiple stakeholders.

Keywords: baiting, poison, rodents, sub-Antarctic

INTRODUCTION

Tentative plans for the possible eradication of rodents from the sub-Antarctic island of South Georgia date back to 2000 (S. Poncet, pers. comm.). The subsequent success of the eradication programme on Campbell Island (McClelland & Tyree, 2002; Towns & Broome, 2003) encouraged the Government of South Georgia and the South Sandwich Islands (GSGSSI) to undertake a feasibility study of the practicalities of a large-scale (island-wide) eradication of rats and mice on South Georgia (Christie & Brown, 2007). However, due to resource limitations at the time, the Government opted not to proceed.

Nevertheless, the small UK charity (NGO) South Georgia Heritage Trust (SGHT) agreed to take up the challenge and started to develop fundraising and project management structures and initiatives to address this. GSGSSI accepted the involvement and lead role of SGHT in principle and practice, subject to the project conforming to the relevant legislation and permitting processes.

In 2009, SGHT established a Steering Committee (SC) to oversee the management of the whole operation. The SC comprised Trustees from SGHT and the Friends of South Georgia Island (FOSGI), key GSGSSI officials (Chief Executive and Environmental Officer), representatives of British Antarctic Survey (BAS), and the SGHT Project Director (Prof. Tony Martin of the University of Dundee). The SC met quarterly from 2010 to 2015 and its main roles were to ensure the effective execution of the plans for the acquisition and shipment of equipment, vessels, helicopters and staff, and that all documentation required by the regulatory authorities (mainly GSGSSI but also the UK's Civil Aviation Authority (CAA)) was submitted on time. A list of all such documentation can be found at <http://www.sght.org/newsletters-and-publications/>.

From 2010, there followed three phases of baiting using brodifacoum poison bait distributed by helicopters. Each baiting phase was spaced two years apart (2011, 2013 and 2015) to allow both for further fundraising between baiting seasons and for evaluation of methods and results before proceeding further. This work is reported on elsewhere (Martin, 2015; SGHT, 2016; Martin & Richardson, 2017).

In the 2017/18 austral summer, a comprehensive monitoring survey, organised and led by SGHT in collaboration with GSGSSI, was undertaken to determine the results of the eradication project. The five-month survey deployed over 1,500 inert devices (chew-sticks, tunnel and camera traps and analogous devices) and, augmented by trained rodent-detection dogs (which travelled 2,420 km), covered a minimum of 8,600 ha across 120 sites. No signs of rodents were detected, allowing the conclusion that the eradication phases had been successful.

This paper aims to review the rodent-related biosecurity status of South Georgia before and during the eradication project and to summarise proposals to enhance this in the light of events during the project, and after its successful conclusion. It highlights the remaining measures to be implemented to minimise the risk of inadvertent re-introduction of rodents.

RODENT BIOSECURITY AT SOUTH GEORGIA PRIOR TO 2014

The need for biosecurity measures to be integral to any eradication efforts on South Georgia was recognised back in 2007, with a governmental report stating then that: *'First and foremost, an effective and robust biosecurity regime needs to be in place on South Georgia before eradication is attempted'* (Christie & Brown, 2007).

Although SGHT submitted Biosecurity Plans to GSGSSI for each of the three phases of baiting, those plans dealt with biosecurity solely in relation to the operational requirements of the project itself – for example, the importation into South Georgia of materials needed for the baiting operation, or the movement of equipment, including helicopters, within the island. The wider issue of South Georgia's biosecurity (the responsibility of Government), was not addressed in discussions between SGHT and GSGSSI either before or during the earlier years of the eradication project. In hindsight, this lapse was the result of both organisations trying at that time to cope with the considerable challenges of the baiting operations. Faced

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 489–493. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

with what was clearly going to be a multi-year, complex operation it would have been difficult in the initial 'proof-of concept' stages of the project to have developed a realistic and pragmatic prescription for post-eradication biosecurity. In consequence, biosecurity arrangements were held, at least in respect of rodents, under relatively rudimentary provisions. For example, the governmental Biosecurity Protocols of 2013 and 2014 (GSGSSI, pers. comm. 2013 and 2014) did little more than stipulate the need for rat guards on vessels, the deployment of rodent bait boxes (a requirement for yachts only), and the requirement that all vessels be inspected for the presence of rodents.

Despite what, in retrospect, was a deficiency in project planning, the HR Project progressed well. By mid-2014 (more than three years after the initial baiting) the Phase 1 area (c. 14,000 ha) had been tentatively declared free of rodents, and a relatively extensive survey in March of that year by SGHT detected no signs of rodents in the 60,000 ha. of the more extensive Phase 2 area.

Deficiencies in the biosecurity provisions became evident on 23 October 2014 when the unambiguous signs of a rat were seen in newly fallen snow at King Edward Point (KEP) – the administrative centre of the island in the heart of the Phase 1 area. The Government rapidly set in train its contingency plan for just such an incident. Brodifacoum bait was spread by hand out to an arc perimeter of 1.5 km from the sighting and many more rat traps were placed around the KEP base area. In the event, no more sign of this animal was seen; nor was a corpse found. This was unfortunate since, through DNA analysis, the origin of this lone animal could have been determined (see Piertney, et al., 2016). The presumption was that the rat succumbed to the poison bait.

The origins of this one known rat could only be speculated on. It could have been a survivor (or offspring of a survivor) from the 2011 baiting phase. However, this is unlikely in the most inhabited part of South Georgia where there had been no rodent signs in the preceding 3.5 years since baiting. Alternatively, it could have been imported in one of the small vessels based at KEP from another part of the island yet to be baited or swam ashore from a vessel anchored offshore. The latter scenarios are not impossible but seem implausible. Given the coincidental timing, the most probable source for this rat was from one or other of two vessels that had recently tied-up alongside the nearby KEP jetty. Records showed that one vessel had visited a number of times between 5–22 October whilst another vessel had arrived on 22 October and was still moored alongside the jetty the following day at the time of the incident (GSGSSI, in litt. to SGHT).

The general conclusion was that this latter vessel was the most likely source of this incursion. The Government concurred through a statement that "*the rat was most likely to have originated from a ship tied up at KEP in the previous days, though it was impossible to prove this*" (GSGSSI, 2015 in litt. to SGHT).

Whatever the means of introduction, this rat had managed to evade all prevention and detection measures in place at the time – bait boxes and traps deployed both on the vessels and extensively around the base area. Its presence was only detected due to recent snow cover.

RODENT BIOSECURITY AT SOUTH GEORGIA SINCE 2014

Although this incident apparently involved only a single animal, SGHT assumed that it would rapidly trigger a major Government-led review of biosecurity arrangements, in order to implement more robust measures. However, it was mid-2015, following completion of the last phase of baiting, that the Government requested SGHT input to an apparent major review of South Georgia's biosecurity arrangements. The SGHT response, submitted in late July, was a series of 10 recommendations to enhance island-wide biosecurity (Table 1).

These recommendations were based on the fact that, with aircraft unable to operate into South Georgia, the re-introduction of rodents to South Georgia could only come about via shipping. That is: by shipwrecks on the coast, or by animals swimming ashore from a vessel; gaining access along mooring warps or down gangplanks; or coming ashore in cargo or luggage. Although none of these potential introduction pathways can be ruled out, the greatest risk of a rodent re-introduction to South Georgia is most likely to be via one or other of the last two routes.

SGHT's recommendations included the requirement to maintain an adequate supply (at least three tonnes) of in-date brodifacoum bait at KEP, the need for a series of pre-baited box traps (which would be inspected frequently) around the base area, and the deployment of effective rat-guards on vessels moored alongside.

The Trust's four main recommendations are shown in bold in Table 1. These were: the use of rodent-detection dogs at ports in the Falkland Islands and on vessels destined for South Georgia; prohibiting the mooring alongside of vessels except for tightly prescribed activities; the erection of rodent-proof fences around offloading jetties in South Georgia; and the construction of rodent-proof containment areas at KEP within which shipping containers and other large-scale cargo could be held, and unpacked, in a biosecure manner.

Totally eliminating the risk of a rodent reintroduction to South Georgia cannot be guaranteed. However, SGHT was of the view that comprehensive implementation of its recommendations would very substantially reduce the risk of rodents either getting to South Georgia in the first place or, if that failed, at least preventing their escape from the immediate surroundings of the cargo unloading/ handling areas at KEP/Grytviken. The recommendations were considered by SGHT to be necessary, realistic, practical, cost-effective (especially in terms of the cost of mounting a subsequent eradication operation) and based on international best practice.

The presumption was that these proposed provisions would be included within a new, strengthened governmental Biosecurity Plan. Instead, the Biosecurity Handbook, published in December 2015 (GSGSSI, 2015) simply re-stated the existing provisions. It took no account of the SGHT recommendations. This caused SGHT to re-state its case to GSGSSI in January 2016 and again in February 2017 (SGHT, 2016; 2017 in litt. to GSGSSI). Unfortunately, we are unaware of any substantive change in biosecurity practices at South Georgia, with one important exception, relating to the trial use of rodent-detection dogs (see below).

IMPLEMENTATION OF BEST PRACTICE BIOSECURITY AT SOUTH GEORGIA

GSGSSI's policy, in principle, over biosecurity is rightly predicated (as is best practice) on the concept that: *"The most effective way of dealing with biosecurity is to have pre-border measures in place...the aim is to prevent an alien reaching the island, not try and deal with it on arrival"* (Christie & Brown, 2007). Furthermore, in its five-year Strategy Paper (GSGSSI, 2016) the Government advocated that *"Biosecurity protocols should be reviewed on a regular basis and best practice adopted"*

Table 1 Biosecurity recommendations* submitted to South Georgia Government (GSGSSI) – 2015/16 and 2017.

Recommendation	Implementation
Vessels/cargo checked by rodent-detection dogs (in Falklands) then during transit to, and on arrival at, South Georgia.	Trial underway in 2018
Vessels (other than yachts) must be prohibited from mooring alongside except when unloading/loading cargo or other strictly prescribed activities; then for minimum time only. In all other circumstances vessels must either anchor off or moor to buoy.	Only partial
When moored alongside, or to the shore, all mooring warps must have effective rat guards fitted.	Yes, though design of guards needs further attention
When moored alongside, gangway ashore must only be in place when necessary, and for minimum time.	?
Rodent-proof fence must be constructed around every dock area (KEP/ Grytviken)	None
No loose cargo (other than personal effects) must be offloaded. All cargo must be carried in sealed shipping containers which must be (a) fumigated, and (b) contain rodent bait stations.	Only partial
A rodent-proof containment area suitable for shipping containers must be constructed at KEP. Containers must only be opened and unpacked within the containment area.	Under consideration. Construction potentially starting 2019; completion 2021?
In the event of known or suspected rodent incursion, pre-planned response action must be activated immediately. Must include setting of traps and spreading poison out to stipulated radius from incursion.	Yes
A network of pre-baited trap boxes must be installed permanently around any dock area and checked frequently (daily when vessel moored alongside).	Yes
Suitable quantity (minimum 3 tonnes) in-date brodifacoum bait must be held at KEP as contingency. Such bait must be replenished as appropriate.	Yes, but whether in date is unknown

* Recommendations in bold are the most substantive ones.

In relation to the recommendations of SGHT (Table 1) and practices prevailing at the closest analogue operation, that following the comprehensive and successful eradication programme on Macquarie Island (Springer, 2016), we review the current situation at South Georgia below:

a) Pre-border measures: cargo checking on embarkation and in transit

In its most recent policy statement (GSGSSI, 2017), pre-border biosecurity measures in relation to rodents rely principally on the use of rat-guards on vessels, requiring rodent detection boxes to be carried onboard vessels and the use of bait stations within cargo shipping containers. However, even taken together, we contend that these measures are unlikely to be effective. For example, despite GSGSSI having trialled a number of rat-guard designs, none to date has proved capable of coping with the harsh weather conditions prevailing in South Georgia.

At Macquarie Island, the deployment of rodent-detection dogs is now routine. Dogs check all cargo twice before it departs Australia and then again during passage to, and on arrival, at Macquarie where the environs of the research station are then also subject to survey by dogs. With financial assistance from SGHT, GSGSSI embarked in early 2018 on a trial deploying rodent-detection dogs at embarkation points in the Falkland Islands and on ships destined for South Georgia. This is a very welcome initiative which, it is hoped, will be converted into a permanent procedure.

Nevertheless, the most likely pathway for a rodent to gain access to South Georgia is from vessels moored alongside a jetty at KEP/Grytviken either via offloaded cargo or by simply "jumping ship".

b) Vessel mooring

At Macquarie Island, the risk of further rodent invasion is reduced still further by there being no harbour or jetty facilities on the island. This means that, unlike South Georgia, all cargo transfers from ship to shore are performed either by helicopters or amphibious lighters, enabling more stringent biosecurity checks to be made. Vessels anchoring well offshore, beyond the swimming distance of rats, reduce the risk that any shipborne rodents may gain direct access to the island through their ability (documented in both the UK and Falklands) to swim up to 1–2 km between, or out to, islands. The Macquarie situation has the added advantage that ship movements are confined largely to transits between Tasmania and the island. This again enables far greater biosecurity control.

At South Georgia, in contrast, whilst ships depart to South Georgia from a variety of locations (e.g. South American ports), those that are currently allowed to tie-up alongside at KEP are invariably governmental vessels arriving from the Falklands, where the embarkation ports are known to be infested with rats and lack fully appropriate facilities for biosecure handling of cargo. SGHT has recommended that the practice of mooring alongside, the most likely route for a rodent incursion, should be prohibited, except for cargo handling and other closely prescribed activities (such as undertaking necessary mechanical repairs to a vessel or for safety). The current criteria allowing alongside mooring include activities such as the "transfer of personnel, or "allowing for crew rest periods". Given the biosecurity risks that alongside mooring poses, convenience per se should not be a valid justification for continuation of this practice. This is particularly so given that the many thousands of tourists who visit South Georgia (and KEP/Grytviken) annually do so from vessels anchored offshore.

c) Cargo-handling ashore

Biosecurity handling facilities at KEP are currently restricted to a single shed where small-scale cargo can be unpacked and checked within a confined space. There are no facilities, in the form of a rodent-proof fenced area, within which large-scale cargo (i.e. shipping containers) can be stored and then opened securely. Such a facility, coupled with rodent-proof fencing around the jetty areas at KEP/Grytviken, would provide some measure of constraint for any rodent that either managed to escape from a vessel or survived inside a shipping container.

It is evident that the rodent incursion of October 2014 was of an animal that had apparently circumvented both shipboard measures and the numerous traps and bait boxes around KEP. Those measures, at least then, had proved wanting.

BIOSECURITY COSTS AND RISKS

It is important to contrast the respective costs of eradication and biosecurity. Investment in the eradication project by SGHT has been considerable, with direct costs of around £7.5 million, rising to c. £10 million when indirect costs are included. Over 80% of the project costs have been raised through charitable donations and sponsorship; although GSGSSI provided extensive staff and logistic assistance throughout the project it made no other contribution to direct costs. In contrast, we estimate that the capital costs of the additional recommended biosecurity measures are unlikely to exceed £0.5 million. In December 2016, SGHT offered to fundraise to help pay for those capital costs.

SGHT recognises that implementation of the more substantive measures would come with additional costs (including ongoing maintenance costs), alternative risks, and the need for specific design considerations to meet South Georgia's harsh conditions. For example, any rodent-proof structure on the island must be able to withstand extremely high wind loadings, ice and snow accumulation as well as the attention of other wildlife such as southern elephant seals (*Mirounga leonina*).

Even significantly reducing the practice of alongside mooring would not entirely eliminate risk. The alternatives are either anchoring offshore or mooring to a suitable buoy. Large vessel buoyage is no longer available at South Georgia and its provision and maintenance would be both expensive and not without liability for the regulatory authority (GSGSSI). Vessels at anchor can also be at risk. Weather conditions at South Georgia can change at short notice and be severe. In March 2000, three long-lining fishing vessels were driven ashore one night in Cumberland Bay in extreme weather conditions. One managed to re-float; the other two were completely wrecked on an inshore reef. Whether there were rodents on either of those vessels, and whether they escaped ashore is not known but the incident emphasises that some risks of rodent re-introduction will always remain. This makes it even more imperative to address those risks which can be mitigated or eliminated.

CONCLUSIONS

The South Georgia Habitat Restoration Project has been the largest island rodent eradication yet undertaken. The overall effectiveness of the three seasons of baiting over five years with brodifacoum has recently been confirmed following a comprehensive monitoring survey in the 2017/18 season. This found no signs of rodents in any of the baited areas, leading to the conclusion that the eradication programme has been successful. Concurrently, the increase in the numbers and distribution of some breeding birds (including endemic species) since baiting, has already been dramatic.

Notwithstanding that result, two major lessons can be taken from this important project; one highly positive, the other less so. On the former, large scale eradications (e.g. Campbell Island (McClelland & Tyree, 2002) and Macquarie Island (Springer, 2016)) have usually relied on the extensive resources of governments. In contrast, the South Georgia project has demonstrated that, through extensive fundraising and competent project planning and implementation, even relatively modest or small-sized NGOs can take on the challenge of large-scale eradications.

The downside of the South Georgia operation has been the lack of a close synergy between eradication and biosecurity. Again, previous large eradications have had the benefit of intra-governmental co-ordination with often the same governmental agency (e.g. New Zealand's Department of Conservation or the Tasmanian Parks and Wildlife Service) having responsibility for both elements. The problems in the case of South Georgia were complicated by the fact that two organisations, of highly contrasting status, undertook or were responsible for the eradication and biosecurity elements.

To ensure that these two equally important aspects are taken forward in close harmony, we make the following recommendations for future rodent eradication projects. That:

- adequate biosecurity measures must be in place before, during and after eradication;
- in those instances where responsibilities for eradication and biosecurity may reside with different organisations, agreement must be reached in advance between those entities; and that:
- such agreements should set out the respective responsibilities, objectives and timetables for both parties before eradication is allowed to commence.

Experience from South Georgia has shown that in the absence of any such prior agreements, eradication and biosecurity may get out of step either in their timing or effectiveness – or both. Such a situation creates a potential risk that the considerable investment in eradication and its corresponding environmental benefits may be jeopardised subsequently by inadequate biosecurity provisions.

ACKNOWLEDGEMENTS

As Chair of the SC, MGR would like to thank all members of that Committee, not least the Project Director, Prof. Tony Martin of Dundee University. We would also pay tribute to the Island Foundation, Prof. Frederick Paulsen and the Paulsen Foundation, without whose massive generosity, particularly in start-up costs, the whole project could never have commenced. Fundraising also relied in a large part on FOSGI (the US counterpart of SGHT). Our thanks go also to all staff involved throughout the near-decade of the project and to the hundreds of donors, large and small, individuals, trusts and foundations, who have helped bring this eradication project to a successful conclusion.

Beyond biodiversity: the cultural context of invasive species initiatives in Gwaii Haanas

Abstract Haida Gwaii is a remote island archipelago located off the north Pacific coast, approximately 100 km from mainland British Columbia, Canada. The southern part of the archipelago, Gwaii Haanas, is designated a National Park Reserve, National Marine Conservation Area Reserve, and Haida Heritage Site, and is cooperatively managed by the Government of Canada and the Council of the Haida Nation. Haida Gwaii has been the site of many invasive mammal introductions including rats, racoons and deer. It was also where the first successful North American rat eradication took place, on Langara Island in the 1990s. Since then, a number of invasive mammal eradication and control projects have taken place in Gwaii Haanas. Most recently, a project to eradicate invasive deer on six islands began in 2017 and is ongoing. The conservation gains from eradications are well documented in various systems around the globe, but the cultural context in Gwaii Haanas is unique. The Gwaii Haanas experience presents an example of how active restoration can move beyond biodiversity to develop IAS projects that are also culturally meaningful.

Keywords: cooperative management, cultural resource, Gwaii Haanas, Haida Gwaii, traditional knowledge, traditional use

INTRODUCTION

Invasive alien species (IAS) are a significant driver of declines in species and ecosystem services worldwide (Pejchar & Mooney, 2009). In Canada, IAS negatively affect 22% of endangered species (Wilcove, et al., 1998; Venter, et al., 2006). Although invasion science spans the fields of social science, ecology, economics and conservation biology (Simberloff, et al., 2013), it rarely considers the cultural context in which invasive species eradications take place. For example, the impacts of IAS on cultural practices including the harvest of traditional foods and medicines are not usually considered.

In this paper, we describe IAS management in Gwaii Haanas, a land-and-sea protected area located in northern North America that is cooperatively managed by the Council of the Haida Nation and the Government of Canada. The Gwaii Haanas experience shows how cooperation between indigenous and federal governments in IAS initiatives allows projects to expand beyond biodiversity to become culturally meaningful as well.

STUDY AREA

Haida Gwaii is an archipelago of over 350 islands located approximately 100 km off the coast of British Columbia, Canada. Gwaii Haanas is a 5,000 km^2 protected area in the southern third of Haida Gwaii. It is known for its diverse ecosystems, distinctive flora and fauna, rich marine life, and living Haida culture.

Gwaii Haanas first garnered international attention in 1985, when the Council of the Haida Nation (CHN) led a non-violent blockade on Athlii Gwaay (Lyell Island) to protest against logging in the area. The CHN declared Gwaii Haanas (terrestrial and marine) a Haida Heritage Site in the same year. Soon after, the Government of Canada designated the Gwaii Haanas terrestrial area a National Park Reserve, and cooperative management of the land began in 1993 when the two governments signed the *Gwaii Haanas Agreement*. In 2010, the CHN and the Government of Canada signed the *Gwaii Haanas Marine Agreement* (2010), which committed the two governments to cooperative management of the Gwaii Haanas marine area. In the same year, Gwaii Haanas was designated a National Marine Conservation Area Reserve by the Government of Canada.

Gwaii Haanas is cooperatively managed by the Council of the Haida Nation and the Government of Canada through the Archipelago Management Board (AMB). The AMB is made up of equal representation from the Haida and Canadian governments and is responsible for all aspects of planning, operation, management and use of Gwaii Haanas. Decisions are made by consensus and based on the constitutions of both nations (Canadian Constitution Act, 1982, Haida Nation Constitution, 2014).

ECOLOGICAL CONTEXT

Haida Gwaii is ecologically significant in a global context. Supporting approximately 1.5 million breeding seabirds of 12 different species, it is the nesting location for one half of the entire global breeding population of ancient murrelets (*Synthliboramphus antiquus*) and for one fifth of the world's breeding Cassin's auklets (*Ptychoramphus aleuticus*) (Harfenist & Cober, 2003). Many of these important seabird breeding areas are situated within Gwaii Haanas.

There are 10 extant native mammals in Haida Gwaii, including the genetic sub-variant black bear (*Ursus americanus carlottae*). Currently, there are 12 introduced terrestrial vertebrates on Haida Gwaii, including two rats (*Rattus rattus* and *R. norvegicus*) and the Sitka black-tailed deer (*Odocoileus hemionus*), which have been the focus of recent eradication efforts in Gwaii Haanas.

Although Gwaii Haanas is protected in legislation, seabird habitat quality has continued to decline as a result of the impacts of IAS such as rats, raccoons (*Procyon lotor vancouverensis*) and Sitka black-tailed deer. Indeed, introduced species have been identified as the main threat to ecological integrity in Gwaii Haanas (AMB, 2018). Impacts from deer browsing include simplification of the

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 494–496. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

forest structure and lack of regeneration of culturally and ecologically important species such as western redcedar (*Thuja plicata*) and yellow cedar (*Chamaecyparis nootkatensis*) (Pojar, 2008). Rats have had similarly devastating impacts on seabirds. For example, some islands that previously had murrelet colonies numbering up to 8,000 breeding pairs, are now effectively at zero (Rodway, et al., 1994).

HAIDA CULTURAL CONTEXT

Archaeological evidence of human habitation in Gwaii Haanas goes back more than 12,000 years (Fedje, et al., 2011). It is estimated that perhaps more than 30,000 Haida lived in villages and seasonal camps across the archipelago. Following European contact, diseases such as smallpox and influenza reduced the Haida population to as low as 550 and the remaining people gathered in two villages. These villages have since developed into the present-day towns of Old Massett and Skidegate. The current Haida population estimate is 5,000, and approximately half live on Haida Gwaii.

The Council of the Haida Nation is mandated to steward the lands and waters of Haida territory on behalf of the Haida Nation, including the perpetuation of Haida language, culture, art and traditional ways, for future generations (Haida Nation, 2017). No treaty was ever signed for Haida Gwaii and, in 2002, the Haida Nation filed a legal case with the Supreme Court of Canada for the title to Haida Gwaii. This case challenges the idea that Haida Gwaii is owned by the Canadian government.

While this ownership dispute is resolved in the courts, Gwaii Haanas continues to be managed by the AMB. This is possible because the dispute over title to Gwaii Haanas is explicitly laid out in the *Gwaii Haanas Agreement* (1993), which also describes how the two parties will set aside that disagreement in order to focus on shared objectives concerning the care, protection and enjoyment of the archipelago.

IAS PROJECTS IN GWAII HAANAS

Haida Gwaii was the first place in North America to carry out a successful rat eradication, on Langara Island in 1995, and remains the world's largest bait station-based eradication. The Council of the Haida Nation provided direction, and several Haida community members worked on this eradication, which used bait station transects throughout the 32.7 km^2 Island.

In Gwaii Haanas, rats were removed from four islands through the SGin Xaana Sdiihltl'lxa (Night Birds Returning) project (2009–2016). All were successful, and today three islands remain rat free and one has been reinvaded. The origin of the reinvasion is unclear but genetic testing results show that it is not related to rats from the adjacent island or those that were present prior to the eradication in 2011. In 2017, a deer eradication project, Llgaay gwii sdiihlda (Restoring Balance), began on six islands in Gwaii Haanas. This project is currently in progress and aims to restore the forest understorey community that has been decimated by deer browsing.

With the deer population reduction, there is evidence of recovery including culturally important plants such as:

- Ts'uu (western redcedar – *Thuja plicata*) – construction, carving;
- Kayd (Sitka spruce – *Chamaecyparis nootkatensis*) – roots, pitch, construction;
- K'aang (hemlock – *Tsuga heterophylla*) – fish hooks, food;
- Ts'iihlinjaaw (devil's club – *Oplopanax horridus*) – medicine;
- SGiidllGuu (huckleberry – *Vaccinium parvifolium*) – medicine, berries;
- Hldaan (blueberry – *Vaccinium alaskaense* and *V. ovalifolium*) – wooden pegs, berries;
- Sk'idGan (salal – *Gaultheria shallon*) – berries.

A HAIDA PERSPECTIVE ON IAS

Invasive species on Haida Gwaii have a direct impact on Haida culture, including:

- Loss of culturally significant plants and animals including western redcedar, a species important for carving, weaving and house building;
- Lack of opportunity to access medicinal and edible plants;
- Loss of opportunities to pass on knowledge of traditional harvesting teachings between generations; and
- Loss of traditional food sources such as fruiting plants, seabirds and seabird eggs.

These losses affect Haida citizens' ability to exercise their rights and practice their culture.

The primary objective of the Council of the Haida Nation (CHN) is to achieve legal title to Haida Gwaii and the surrounding waters. However, the CHN also works to achieve conservation gains in Haida Gwaii. For example, Land Use Orders and forest management based on ecosystem management principles have been implemented to protect culturally significant areas and to ensure Haida values are maintained in areas where logging occurs. In addition, a 1000-year cedar strategy is in development. This strategy will ensure that there are large, monumental cedars available in perpetuity for Haida Nation citizens to utilise for pole or canoe carving, weaving or house building projects. The CHN has also established new protected areas and designed effectiveness monitoring programmes, collecting data to support decision-making and research.

While the CHN has participated in many IAS-related projects, collaborating with provincial and federal governments, it is now working to develop a broader vision and targets concerning IAS on Haida Gwaii. This involves setting priorities and assessing current-day challenges. For example, the invasive Sitka black-tailed deer has become a significant food source for the Haida community and its hides, hooves and antlers are now incorporated into ceremonies. Therefore, initiatives need to balance the impacts of IAS on culturally important species while also considering the value these species have in the present-day culture. Generally, CHN-led IAS initiatives will focus on species that impact cultural activities, with a goal of managing IAS on Haida Gwaii in order to create healthy ecosystems for future generations.

HAIDA PLANNING PRINCIPLES

The CHN applies several basic principles to all planning initiatives, including invasive species management. These principles are:

Yahguudang – *Respect*

Respect for each other and all living things is rooted in our culture. We take only what we need, we give thanks, and we acknowledge those who behave accordingly.

'Laa guu ga kanhllns – *Responsibility*

We accept the responsibility passed on by our ancestors to manage and care for our sea and land. We will ensure that our heritage is passed onto future generations.

Gina 'waadluxan gud ad kwaagid – *Interconnectedness*

Everything depends on everything else. The principle of interconnectedness is fundamental to integrated planning and management. This comprehensive approach considers the relationships between species and habitats and accounts for short-term, long-term and cumulative effects of human activities on the environment. Interrelationships are accounted for across spatial and temporal scales and across agencies and jurisdictions.

Giid tlljuus – *Balance*

The world is as sharp as the edge of a knife. Balance is needed in our interactions with the natural world. If we aren't careful in everything we do, we can easily reach a point of no return. Our practices and those of others must be sustainable.

Gina k'aadang.nga gii uu til k'anguudang – *Seeking wise counsel*

Our elders teach us about traditional ways and how to work in harmony. Like the forests, the roots of our people are intertwined. Together we consider new ideas and information in keeping with our culture, values and laws.

Isda ad dii gii isda – *Giving and receiving*

Reciprocity is a respected practice in our culture, essential in our interactions with each other and the natural world. We continually give thanks to the natural world for the gifts that we receive.

CONCLUSION

The ecological impacts of IAS eradications are well studied and documented by the ecological research community. Less-often considered is the importance of eradications to cultural integrity and the continuity of indigenous cultures such as the Haida Nation. The Gwaii Haanas experience demonstrates how partnerships with indigenous governments can broaden the scope of, and support for, IAS projects and make them culturally as well as ecologically meaningful.

ACKNOWLEDGEMENTS

The authors would like to say haaw'a (thank you) to the islanders and international research community members that have initiated and maintained the focus on biosecurity, invasive species research and restoration on Haida Gwaii. This includes but is not limited to Chris Gill of Coastal Conservation, Jean-Louis Martin and others from the RGIS group, the concerned and involved citizens of Haida Gwaii and staff of Gwaii Haanas and the Council of the Haida Nation.

[2]Pacific Cooperative Studies Unit/Coordinating Group on Alien Pest Species, University of Hawai'i at Mānoa, 3190 Maile Way, Honolulu HI 96822, USA.

Abstract From the arrival of Polynesians before 1200 AD until Western contact in 1778, Hawaiian land use and resource distribution were centred on the "ahupua'a" system of watershed-based management areas that made their inhabitants nearly self-sufficient. Those units were grouped into larger regions, each called a "moku," led by lower chiefs who were in turn governed by the high chief or king of each island. While societal and environmental taboo or "kapu" were enforced from above, day to day neighbourhood cooperation served to protect resources, produce food, and sustain up to one million people before Western contact. Following the arrival of Europeans, land and resource management, and governance based on native Hawaiian core beliefs, were replaced by a centralised Western market economy. Modern land ownership, agency mandates and legal jurisdictions provide artificial walls that keep people from moving, but do not constrain invasive species, nor are they effective for managing public trust resources such as water or native species. Over time government and conservation organisations have come to view decentralised cooperation as a key to protecting the 50% of Hawaiian terrestrial, native habitat that persists. Current cooperative efforts serve to protect watersheds via watershed partnerships, and to detect and address invasive species through invasive species committees on each island. These and other projects are facilitated by the University of Hawaii's Pacific Cooperative Studies Unit, which plays a unique role in coordinating the use of private and government grant dollars to hire and manage 460 conservation staff in cooperative conservation projects state-wide.

Keywords: ahupua'a, invasive species, cooperative, watershed partnerships, invasive species committees

INTRODUCTION

The state of Hawai'i comprises eight large islands, seven of them inhabited. The island of O'ahu, home to nearly one million of the state's 1.4 million residents, is the seat of the central state government (<http://files.hawaii.gov/dbedt/economic/databook/db2016/db2016.pdf>). Each of the islands has different land use and economic histories. While most islands have a few major land owners, almost all the islands are currently mosaics of federal, state, county, and private properties, making it difficult to mount effective responses to invasive alien species (IAS), as these recognise neither property boundaries nor jurisdictions, or to manage public trust resources such as native species, habitats, and water resources (Ikuma, et al., 2002; Rago & Sugano, 2015). This paper presents case studies that explore how Hawai'i has responded to conservation challenges through cooperative efforts by both institutions and individuals. The list is illustrative, not exhaustive.

Natural history and the Hawaiian period

Hawai'i is one of the most isolated archipelagos on the planet. From still-forming Hawai'i Island, the archipelago progresses in age through the main islands, to the islets and atolls of Papahānaumokuākea National Monument, and the submerged Emperor Seamounts, representing 70 million years of passage over a tectonic hot spot (Heliker, 1989). Before the arrival of humans, new species became established every 175,000–15,000,000 years (Ziegler, 2002). Isolation and subsequent adaptation to a wide variety of ecological zones and habitats over millions of years produced a stunning biodiversity vulnerable to outside perturbations (Carlquist, 1974; Duffy & Vargas, 2017).

Polynesians settled in Hawai'i by 1200 AD (Kirch, 2011; Wilmshurst, et al., 2011). Initial populations were small and the first Hawaiians subsisted as hunter-gathers with limited agriculture. Even these initial actions had a massive effect on biodiversity in a terrestrial ecosystem that had not known mammalian predators. With increasing human populations and the extinction of terrestrial protein sources such as flightless birds and land crabs, agriculture became more important, requiring communal investment in infrastructure such as fish ponds and irrigation systems (Kirch, 1985; Paulay & Starmer, 2011). Land was often divided into mountain-to-sea pie-shaped wedges (*ahupua'a)* with larger units called *moku* on each island. Although trading occurred, ahupua'a tended to be internally balanced systems (Andrade, 2008). *Ahupua'a* were administered by *konohiki*, resource managers appointed by the *ali'i* (rulers) of large districts or entire islands (Gonschor & Beamer, 2014). There was also a division between the realm of man (*wao kanaka*), the agricultural and community areas, and the realm of gods (*wao akua*), the upper forests where entry was granted only to specially trained individuals following strict protocols. While tenure of the *ali'i* was subject to the political winds of fortune, the residents (*maka'ainana*) of the *ahupua'a* were permanent. Together with the *konohiki*, they made decisions about use of local resources ranging from montane forests and irrigated uplands down to coastal ponds and inshore waters and these decisions were regulated by social/religious strictures (*kapu)* (Mueller-Dombois, 2007).

The arrival of humans greatly increased the rate of species' arrivals, either deliberately for food or other economic or cultural advantages, or as accidentals, incidental to travel and commerce. The first settlers traveling east from Polynesia brought about 30 plant species and several animals, including Polynesian pigs (*Sus scrofa*) and Pacific rats (*Rattus exulans*), some perhaps as stowaways.

Despite the capacity of Hawaiian society to mobilise large numbers of people at the island or moku level to engage in major community efforts such as building *heiau* (temples) and fishponds (Kirch, 1985), we have no direct information on how pre-contact Hawaiians reacted to the impacts of invasive species. For example, archaeological evidence suggests that Pacific rats caused major changes in lowland ecosystems by eating tremendous amounts of seeds, damaging or killing plants, and preying on ground-

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 497–502. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

nesting birds and other species (Athens, 2009). Kepelino (1932: 86) reported oral traditions that rats were a major problem for sweet potato (*Ipomoea batatas*) crops in the lowlands. The *ali'i* organised rat hunting contests, suggesting opportunity, if not necessity (Athens, 2009; Handy & Handy, 1972).

Post-European arrival

The arrival of Captain Cook in 1778 led to rapid changes, including the introduction of diseases such as smallpox to which Hawaiians had little resistance, and the introduction of Western ideals and religion that muted Hawaiian language, culture, and beliefs (Busnell, 1993). Just seventy years later, the Great Mahele (land division) of 1848 placed two-thirds of the crown lands in private hands, the majority non-Hawaiian, as most Hawaiians could not conceive of a world where they needed to claim rights to the land they had always lived on. This alienation of land further weakened the traditional societal structure and the *kapu* restrictions that controlled use of natural resources (Chinen, 1958; LaCroix & Roumasset, 1990).

Land ownership and political power became concentrated in the hands of the "Big Five" corporations which were primarily involved in an export economy centred on sugar production (Dorrance & Morgan, 2000). These shifts eventually led to the overthrow of the Monarchy (Kame'eleihiwa, 1992) and the resulting "plantation system" came to dominate Hawaii's social, political and economic systems with a top-down political structure centred on the island of O'ahu.

Extensive deforestation occurred as lands were converted to cane fields and streams were diverted for irrigation. The drive to export goods also led to further impacts on forests, with harvesting of sandalwood (*Santalum paniculatum*) and *pulu*, the fibre from native tree ferns (*Cibotium menziesii*), in the *wao akua* areas previously regarded as sacred and off-limits (Cuddihy & Stone, 1990). Land devoted to sugar production peaked in the 1940s and economically viable production ceased by 2015 (Dorrance & Morgan, 2000). The end of sugar as a crop left large portions of lower-elevation landscapes fallow or being converted into housing tracts and tourist developments on the coasts. Sugar has been replaced by tourism and the military as drivers of the economy, but the state retains its O'ahu-centric political orientation left over from plantation days (Kalapa, 1992).

Polynesian pigs were initially barnyard animals, but after 1778 they mixed with introduced European strains and soon found their way into upper-elevation forests. Captains Cook and Vancouver left cows (*Bos taurus*), sheep (*Ovis aries*) and goats (*Capra hircus*) as gifts for Hawaiians (Tomich, 1986). Cows were placed under royal protection by King Kamehameha after their introduction in 1794. Protection lasted until 1830 by which point the population had greatly expanded and caused significant deforestation (Tomich, 1986). Cats (*Felis catus*) were brought to the islands both as novelties and to curb rodent populations (Duffy & Capece, 2012). With the rise of the sugar plantations, species such as cane toads (*Rhinella marina*), mongoose (*Urva auropunctata*) and parasitic wasps were introduced to reduce rats and insects that feed on the cane. While their effectiveness is debatable, their negative consequences are not (Doty, 1945; Peck, et al., 2008). Accidental introductions included black and Norway rats (*R. rattus* and *R. norvegicus*) (Tomich, 1986), and mosquitoes (Culicidae) that were stowaways on ships. Earthworms (Lumbricidae) and ants (Formicidae) were absent from pre-contact Hawai'i, but probably arrived in soil and plants, as did numerous other invertebrates with largely undocumented but likely enormous impacts (Gillespie & Reimer, 1993).

More than 100 plant species arrived in the 60 years following Cook's arrival (Nagata, 1985). More recently Loope & Kraus (2009) reported that, during 1995–2003, 89 species per year became established. To date, over 10,000 plant species have been introduced for cultivation in the islands (Imada, et al., 2005). Birds and mammals were introduced for hunting and for human entertainment (Walker, 1967; Long, 1971). Accidental introduction and deliberate smuggling of herptiles have been a problem, with some becoming invasive (McKeown, 1996; Kraus & Cravalho, 2001; Kraus, 2009). Aquatic species have arrived as deliberate introductions for fisheries, through the aquaculture/pet/aquarium trade, in ballast water and as biofouling (Eldredge & Smith, 2001; Brasher, et al., 2006; Carlton & Eldredge, 2009). Finally, pathogens have been a continuing problem for both humans and the rest of the biota since European contact (e.g. Wilbar, 1947; Warner, 1968; Bushnell, 1993).

Responding to alien invasive species

The Kingdom of Hawai'i enacted the first biosecurity measure for the islands, banning the import of coffee beans to prevent alien disease from affecting the islands' own crops (Holt, 1996). Later, import of sugar cane and other grasses was restricted because they might bring in new diseases and pests of the dominant agricultural crop (Territory of Hawai'i, 1941). By 1975, deliberate introductions of organisms had to be approved by the Department of Agriculture. This rule remains in place; however, the vast majority of plants and plant parts are still not effectively restricted from entry (Loope & Kraus, 2009).

King Kalākaua (Kalākaua 1876) began a programme of fencing to exclude feral ungulates from watersheds to protect the water supply. By the turn of the century and the fall of the monarchy, the territorial legislature recognised the continued impact on watershed forests by feral animals and the unregulated harvest of forest products. This led to a massive re-planting of fast-growing non-native trees with the hope that this would sustain watershed function. However, several of the trees became invasive (<https://www.nature.org/media/hawaii/the-last-stand-hawaiian-forest.pdf>; Cox, 1992; Woodcock, 2003; Kaiser, 2014).

During the territorial period and following statehood, legislation created several state governmental agencies to address alien invasive species (AIS) and to protect or manage natural resources. With various name changes over time, the Department of Health dealt with disease vectors such as rats and mosquitoes, while the Department of Land and Natural Resources dealt with establishing forest reserves, managing aquatic and hunting resources, and reducing the impact of invasive species on state-owned watersheds and native ecosystems. The Department of Agriculture dealt with invasive species of importance to agriculture, and the importation of agricultural goods and species. No agency was or is responsible for a holistic assessment or response to the continued arrival of additional invasive species (Rago & Sugano, 2015).

In the decades since these laws were created, there have been major changes in Hawaii's economic drivers, agricultural crops, frequency and quantities of imports, and the rise of air cargo (2.72%/year from 1990 to 2016: DBEDT, 2017), with a resulting increase in magnitude of risk from invasive species. Unfortunately changes to the laws and policies that reduce or address invasive species risks or impacts have been piecemeal and insufficient, with gaps within or between agency mandates (Miller & Holt, 1992; Ikuma, et al., 2002; Loope & Kraus, 2009; Rago & Sugano, 2015).

At the federal level, the National Park Service and the National Wildlife Refuge System, both under the Department of Interior, have broad mandates to manage invasive species and protect natural resources and habitats within their holdings, but their authority and actions historically have been confined within their property boundaries. The Department of Defense (DOD), another large landowner, did not focus effort or attention on mitigating impacts on the natural environment or protecting natural resources unless they interfered with military activities, as did a dengue outbreak during World War II when martial law allowed the agency to ignore property rights to deal with the outbreak (Wilbar, 1947). More recently, DOD has become more active and pre-emptive, in part because of federal laws such as the U.S. Endangered Species Act of 1973 (ESA) and the National Environmental Policy Act of 1969 (NEPA), where actions that may have an impact on Federally listed endangered species and non-compliance might restrict the military mission.

For prevention of new alien invasive species, among other mandates, the Department of Homeland Security Customs and Border Protection is responsible for regulating the importation of goods and conveyances from foreign sources into the U.S., while the U.S. Department of Agriculture focuses on foreign and domestic agricultural imports that may carry pests and diseases. The U.S. Department of Interior (U.S. Fish and Wildlife Service) uses the Lacey Act and ESA to reduce the risk of invasive species being imported into Hawaii in specific circumstances (e.g. the Injurious Wildlife Provisions of the Lacey Act).

With the rise of rapid world trade, Hawaii's borders have become increasingly permeable to invasive species (Loope & Kraus, 2009). Responses to such species are difficult, as potentially invasive species are rarely discovered on a single property where the landowner has the knowledge, skills, interest, and funding to address the species before it spreads. Landowners can also be hesitant to allow government officials onto their properties to search for or control invasive alien species, so government often fails to detect invasive alien species before they spread (Kraus & Duffy, 2010). Action against a new invasive alien species largely depends on its location and whether the species is perceived as falling within the mandate of a particular agency. Further, the bureaucratic process for the addition of new species to official lists mandating control does not keep up with the pace of arrivals (Penniman, et al., 2011). Finally, cooperation between state, federal and county authorities has at times been limited and intermittent (Warren, 2006). In consequence in the last two decades, cooperative, often informal approaches have increasingly supplemented top-down formal efforts. We present four such cooperative models that range from the intergovernmental, to agreements between landowners, to groups open to anyone sharing a common objective.

Pacific Cooperative Studies Unit (PCSU)

One of the earliest natural resource management organisations in Hawaii to extend beyond top-down management was the Cooperative National Parks Studies Unit (CPSU), which formed in 1973 through an agreement between the National Park Service (NPS) and the University of Hawaii. CPSU initially provided collaborative research and technical support for Hawai'i Volcanoes and Haleakala National Parks. Following the passage of three key federal laws: the National Environmental Policy Act, the Endangered Species Act, and the General Authorities Act of 1970 (<https://www.nps.gov/parkhistory/hisnps/NPSHistory/timeline_annotated.htm>), NPS lacked the internal capacity to conduct the research necessary to respond to these mandates. It also lacked a mandate to protect national parks before threats actually reached them, making parks legal but not ecologically sustainable islands. Following initial surveys documenting the native flora and fauna and threats to these species, including from non-native species, UH scientists built a small test ungulate exclosure, which produced rapid recovery of native plants. NPS engaged the CPSU to build more fences, removing ungulates, and monitoring the subsequent recovery. Based in part on this work, fencing as a management tool was adopted by NPS, other federal and state agencies, and non-profit organisations. In response to increasing recognition of threats to Hawaii's biodiversity and perceived gaps caused by narrow agency mandates and jurisdictions, CPSU morphed into what is now the Pacific Cooperative Studies Unit (PCSU) working with a range of state and federal agencies, as well as non-profits and private companies and individuals. PCSU provides research, resource management and outreach expertise via collaborative projects, while also increasing employment opportunities in conservation. Over the last 20 years it has grown from 150 employees to more than 450 (Fig. 1), mentoring and staffing a range of organisations dealing with invasive and endangered species (see below).

Coordinating Group on Alien Pest Species (CGAPS)

A second key development was the formation of the Honolulu-based interagency Coordinating Group on Alien Pest Species (CGAPS) in 1995. In 1992, The Nature Conservancy of Hawaii (TNCH) and the Natural Resources Defence Council published a report on Hawaii's biosecurity measures and the gaps that would likely lead to the arrival and establishment of major new pests such as brown tree snakes (*Boiga irregularis*) and red fire ants (*Solenopsis invicta*) (Miller & Holt, 1992). The report concluded that, although there were funding and policy gaps, the most serious problem was a lack of interagency, and sometimes intra-agency, communication and cooperation, and that many such gaps could be addressed through a coordinated effort (Miller & Holt, 1992; Holt, 1996). These reports, and other events, led to the crafting of the Hawaii Alien Species Action Plan in 1993–94 with the help of more than 80 agency and NGO leaders under a steering committee that morphed into CGAPS (Nakatani & Wilson, 1995).

Today, CGAPS continues to facilitate interagency and NGO communication and cooperation through quarterly meetings, and its steering committee plans and conducts collaborative projects to catalyse action on invasive species. CGAPS was originally administered by the Hawaii Department of Agriculture with staff time contributed by TNCH and agencies, but it now has a rotating chair structure, and staff and logistics supported by PCSU.

One of its recent projects was the crafting of a Plant Health Emergency Response Plan, which laid out how the US Department of Agriculture and Hawai'i Department of Agriculture could engage other federal, state and county

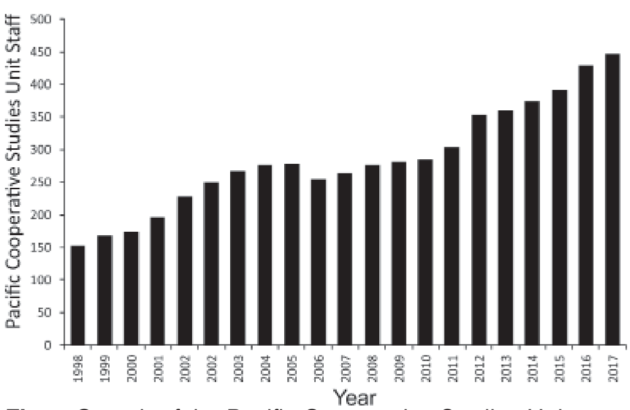

Fig. 1 Growth of the Pacific Cooperative Studies Unit.

agencies, and non-governmental organisations if a serious plant pest were to arrive, requiring a response beyond what the two federal agencies could provide (Loope & Shluker Ryon, 2013). To test the plan, CGAPS conducted a discussion-based "tabletop" exercise in November 2013, using the then-fictitious discovery of the coconut rhinoceros beetle (*Oryctes rhinoceros*, CRB). The tabletop discussion included more than 40 participants and resulted in a report that outlined legal and procedural questions that arose (Coordinating Group on Alien Species, 2013). Coincidentally, a month later, in December 2013, CRB were detected in a trap at Joint Base Pearl Harbor-Hickam, triggering the first use of the Plant Health Emergency Response Plan. Although eradication has yet to be achieved, the emergency response has been successful in many ways, from the initial staffing of the response co-led by the two responsible agencies, and supplemented by multiple federal, state, and non-government partners, to the containment of the beetles to West O‘ahu.

Invasive Species Committees

Invasive Species Committees (ISCs) are voluntary partnerships on each island that address incipient (new) invasive plants and animals on an island-wide basis. The five invasive species committees (Kaua‘i Invasive Species Committee, O‘ahu Invasive Species Committee, Maui Invasive Species Committee, Moloka‘i Invasive Species Committee, and Big Island Invasive Species Committee), represent perhaps the best collaborative efforts in the islands. Their steering committees are essentially self-recruited, made up of interested private individuals and groups as well as representatives of county, state and federal agencies. Together, each island's steering committee provides strategic direction to a paid staff and field crew for island-wide work on early detection and control or eradication of high-risk invasive species. A critical function of ISCs is to obtain right of entry to private lands through education and negotiation. The logistic, fiscal and staffing aspects of each ISC are handled by the Pacific Cooperative Studies Unit.

The first committee sprang from a pioneer effort on Maui Island. A melastome tree (*Miconia calvescens)* had been identified on Tahiti as a major threat to intact native forests (Meyer, 1996). Biologists returning from a visit to Tahiti recognised that the species occurred on Maui and might represent a similar local threat to Hawai‘i (Gagné, et al., 1992). This led to the formation of an *ad hoc* Melastome Action Committee in 1991 to address the problem on Maui (Conant, et al., 1997; Medeiros, et al., 1997). The effort subsequently expanded to Big Island (Tavares, 1998). In recognition that there might be additional IAS threats (Miller & Holt, 1992), the MAC expanded to other species, and in 1997 the Maui Invasive Species Committee was formed, soon followed by O‘ahu, Kaua‘i, Big Island and Moloka‘i committees (Martin, 2003).

The ISCs focus on early detection and rapid response leading to eradication of incipient invasive species, and they also conduct outreach and education to help the public reduce the impacts of established species. All species are chosen for their local, not state, importance, based on evaluation criteria that include risk to an island's economy or ecology, and feasibility of control or eradication (Penniman, et al., 2011). The number of staff in each ISC varies, but generally each has a field team, an outreach specialist, a GIS/data specialist, and an overall manager who is responsible for government relations, obtaining funding, and working with its steering committee and PCSU (Krauss & Duffy, 2010). Since formation, the ISC managers have worked together to develop standard methods, coordinate funding and reports, and even share field crews when advantageous. During the 2008 recession, they redistributed funding to keep all the ISCs staffed and active. Being local to each island, these committees enjoy strong county and legislative support, but funding remains a persistent problem as new invasive species continue to arrive while many of the old ones persist. As of 2010, 27 populations of emerging invasives had been removed by the ISCs, but efforts for others are likely to be drawn out because of reinvasions, persistent seed-banks, or the continued discovery of isolated individuals (Kraus & Duffy, 2010; Penniman, et al., 2011). In addition, the ISCs have worked with the Hawaii Ant Lab (another project of PCSU) and HDOA to survey for and control incipient populations of species such as little fire ants (*Wasmannia auropunctata*) and coqui frogs (*Eleutherodactylus coqui*) on islands where they are not yet established. These early detection and rapid response functions have resulted in dozens of local eradications of these pests before they could establish populations.

Watershed Partnerships

Isolated oceanic islands like the Hawaiian archipelago have limited freshwater supplies. Native forests in Hawai‘i retain water better than do island forests dominated by introduced species (Giambelluca, et al., 2009; Kagawa, et al., 2009; Cavaleri, et al., 2014), so protection of watersheds is a prudent investment toward the persistence of human populations in the islands, as well as for the maintenance of the archipelago's unique biota.

Maui has been the incubator of a number of innovations in Hawaii and so it is not surprising that the first joint effort to manage and improve watersheds across ownerships, the East Maui Watershed Partnership (EMWP), was established in 1991 through the efforts of The Nature Conservancy of Hawai‘i and the state Department of Land and Natural Resources (Loope & Reeser, 2001). There are now ten watershed partnerships or associations on five islands, covering 2.2 million acres and involving 75 land-owning partners, ranging from state and federal agencies to NGOs to private companies and individuals (<http://hawp.org/partnerships/>) (Fig. 2). These partners may have differing objectives in land management so watershed partnerships focus on those they hold in common, rather than imposing the agendas of a minority of partners (cf. Ostrom, 1990).

Like CGAPS and the ISCs, most of the watershed partnerships are informal, with the landowners and agencies functioning as steering committees to determine objectives, and with a manager and staff to address the objectives. PCSU also provides the structure and administrative capacity for most of these partnerships.

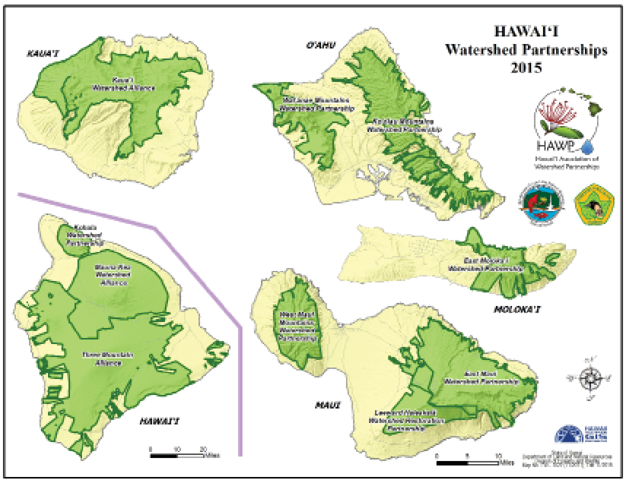

Fig. 2 Extent of watershed partnerships in the Hawaiian archipelago in 2015 (<http://hawp.org/wp-content/uploads/2011/12/WP_2015.png>).

The main task of the partnerships is the long-term protection of forests in watershed recharge areas, by removing alien plants and animals directly or through the installation and upkeep of hundreds of miles of protective fencing to exclude ungulates from sensitive areas. Watershed partnerships can do this at the landscape level without the constraints of political or property boundaries. Indirectly, by protecting native habitat across wide areas, the watershed partnerships have also become critical for the conservation of endangered species. Working with the ISCs, the partnerships are also key to locating and dispatching newly arrived potentially invasive species.

DISCUSSION

Before contact with Western culture and during the monarchy, environmental rules in Hawai'i were mandated at the island or *moku* level. The introduction of Western concepts such as private property and land ownership, coupled with the abolition of the *kapu* system and transition of the monarchs to Christianity, resulted in major changes in the management of natural resources. Major increases in resource extraction and land clearance were permitted and abetted by the republic and territorial governments controlled by the sugar companies. After statehood, strong federal laws dealing with pollution and wetlands functioned through command and control enforcement. Most recently there has been a recognition that such top-down approaches are less effective for non-point problems such as pollution, habitat destruction and managing endangered and invasive species outside government lands (Lubell, et al., 2002). Wider involvement is needed to ensure buy-in by "stake holders" who must be part of solutions (John, 1994). Some of these more participatory approaches are mandated by U.S. law, such as interagency consultation over endangered species, habitat conservation plans for endangered species, and public comments on federal government actions under the National Environmental Policy Act. Within government, *ad hoc* cooperation between agency partners through entities such as CGAPS and PCSU has often proven more nimble than statutory constructs. Outside formal government, limited-access partnerships of landowners such as watersheds partnerships and invasive species committees open to all have proven highly responsive to local conditions.

Overall, partnerships can yield multiple advantages. They can help bring together resources such as outside expertise (e.g. CPSU/PCSU) or undertake landscape-scale management by pooling resources and reducing artificial boundaries (WPs and ISCs), or they can see "the big picture" with collaborators working together to identify and address issues (CGAPS).

Partnerships are not automatic panaceas. Partnerships require flexibility and trust, and a recognition that they may not be appropriate for every problem. Partnerships also require a roughly equal distribution of power and resources. If one partner is dominant, then the partnership becomes merely an advisory group or rubber stamp. Partnerships require a working consensus on approaches. Islands have a limited spectrum of economic activity compared to the mainland so people are more likely to share a common perspective and recognition of the value of the local indigenous environment than may occur at the continental scale. However, even in Hawai'i, issues such as air-dropped rodent control agents, genetically-modified organisms, and biocontrol may remain too controversial for partnership approaches. Feral cat management on the islands of Oahu and Kauai is a particularly contentious issue, but there is hope for an emerging consensus. Twenty years ago, fencing was similarly controversial but it has now become an accepted approach to land protection.

In terms of logistics, partnerships can falter without a lead person and staff whose jobs are to move the partnership's goals forward. Partnerships appear to be less effective when they are burdened with managing such staff, as administrative concerns divert time and energy away from the "big picture" and away from consensus building around common objectives (Lubell et al., 2002). In Hawai'i, the Pacific Cooperative Studies Unit has frequently supplied the stable logistics and organisational underpinning for such partnerships, providing professional staffing, and the ability to handle financial, legal and regulatory requirements. This appears to provide a flexibility not always present in government agencies where funding can vary from year to year and priorities change from one political administration to the next.

Although partnerships and cooperative efforts can be powerful tools for conservation and we can generate general rules about what works and what doesn't, all such efforts are local, dependent on the local economy, local politics and the local environment. It is important that we better document what has worked and what hasn't for Hawaii, both for other areas that might wish to explore the use of cooperation in conservation, and as anthropogenic climate change brings new challenges to islands.

ACKNOWLEDGEMENTS

Among many others, we thank J. Canfield, B. Harry, A. Holt, L. Loope, T. Penniman, and C. Smith for discussions over the years on the challenges and opportunities of collaborative efforts in Hawaii. The views expressed here are our own and do not necessarily represent those of any institution or agency. We dedicate this paper to Lloyd Loope who was seer, savant and sensei to our community.

Invasive species management in Mauritius: from the reactive to the proactive – the National Invasive Species Management Strategy and its implementation

J.R. Mauremootoo[1], S. Pandoo[2], V. Bachraz[3], I. Buldawoo[4] and N.C. Cole[5,6]

[1]InSpiral Pathways, Bristol, UK. <john@inspiralpathways.com>. [2]UNDP, Port Louis Mauritius. [5]Durrell Wildlife Conservation Trust, Jersey. [6]Mauritian Wildlife Foundation, Vacoas, Mauritius.

Abstract This account provides the context behind the need to implement an integrated, cross-sectoral approach to Invasive Alien Species (IAS) management in the Republic of Mauritius (RoM). The challenge of increased travel, tourism and transport is enumerated and the history of IAS entry, establishment and spread in the RoM before and since the formulation of the National Invasive Alien Species Strategy and Action Plan for the Republic of Mauritius (NIASSAP) (2010-2019) is reviewed to judge the effectiveness of biosecurity measures at the national and sub-national level. New incursions appear to have increased since 2010. Examples include, the papaya mealybug (*Paracoccus marginatus*; 2013), the Oriental fruit fly (*Bactrocera dorsalis*), a species that had previously been eradicated from the island (2013 and 2015) and foot and mouth disease (FMD) (*Aphthae epizooticae*; 2016). There have been some effective responses. A biological control agent was released against the papaya mealybug and fruit production has recovered, FMD has been eradicated and a campaign for eradication of *B. dorsalis* is underway. However, management approaches remain reactive and sectorally-driven with little cross-fertilisation of ideas and approaches. Biological control, for example, has been very actively pursued in the agricultural sector but has not been officially undertaken for environmental weeds since 1982. The documented incursions represent biosecurity failures that the NIASSAP was designed to address but it has yet to be systematically implemented. The growing impact of new biological invaders on all sectors of the Mauritian economy has stimulated a revival of interest in biosecurity at the governmental level and in 2016 the Government submitted a US$17M UNDP/GEF project: *Mainstreaming IAS Prevention, Control and Management*, which will provide the incremental cost to review, update and effectively initiate the implementation of the NIASSAP.

Keywords: early detection and rapid response, mainstreaming, management, NISSAP, pathways, prevention, Republic of Mauritius, risk analysis

INTRODUCTION

The expanding IAS threat in the Republic of Mauritius and the adoption of the NIASSAP

The Republic of Mauritius (RoM) comprises the main island of Mauritius and Rodrigues, about 560 km to the east of Mauritius, their associated islets, and the outer islands of Agalega, Tromelin, Cargados Carajos (St Brandon) and the Chagos Archipelago. Mauritius and Rodrigues form part of the Mascarene Islands chain located in the Western Indian Ocean. The Mascarenes belong to one of the 25 internationally recognised biodiversity 'hotspots' (Myers, et al., 2000). Tropical climate, diverse topography and over a million of years of isolation have resulted in the evolution of a diverse biota with a high degree of endemism. Invasive alien species (IAS) constitute a major threat to the remaining biodiversity in the RoM (Florens, 2013; Virah-Sawmy, et al., 2009; Cheke & Hume, 2008). IAS also have serious economic and health impacts, especially if the definition of IAS is broadened to include agricultural pests and zoonotic diseases. This broad conception of IAS was used when developing the country's National Invasive Species Strategy and Action Plan 2010–2019 (NIASSAP) (RoM, 2010), officially adopted by Cabinet in 2010. The NIASSAP is based on the premise that the problems of biological invasions are cross-sectoral in nature, so there is a need for a harmonised approach to biosecurity that cuts across traditional sectoral boundaries. Making use of the 'biosecurity umbrella' will help to ensure that all activities relating to species introductions and spread are based upon a coordinated and science-based approach that is underpinned by the assessment and management of risk. This paper describes some of the RoM's IAS invasion trends, its expanding and diversifying IAS pathways, and examples of IAS management successes and challenges ('the reactive') as a backdrop to the development of the NIASSAP ('the proactive'), its implementation to date and future prospects.

A brief history of alien species establishment in Mauritius

Vertebrate establishment

Human actions resulted in the introduction of vertebrates to Mauritius even before the first documented landing on the island, by the Dutch in 1598 (Cheke, 1987). Black rats (*Rattus rattus*) probably established themselves on Mauritius via shipwrecks and may have been responsible for the extinction of many endemic animal species even before colonisation. Between the first Dutch landing and settlement in 1638 two major animal invaders, the Javanese macaque (*Macaca fascicularis*) and the feral pig (*Sus scrofa*) became established in Mauritius. During the Dutch period (1638–1710), major introductions included Javan deer (*Cervus javanicus*) and cats (*Felis catus*) which became feral.

During French rule (1721–1810), introductions with significant negative economic and environmental effects included the brown rat (*Rattus norvegicus*), the Asian house shrew (*Suncus murinus*) and the tenrec (*Tenrec ecaudatus*).

The steady rate of vertebrate introductions continued under the British (1810–1968) with introductions including the Indian wolf snake (*Lycodon capucinus*), the red-whiskered bulbul (*Pycnonotus jocosus*), African landsnails (*Achatina* spp.) and the small Indian mongoose (*Urva auropunctata*).

Significant vertebrate deliberate and accidental introductions since independence include the Madagascar giant day gecko (*Phelsuma grandis*), the gold-dust day

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 503–509. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

gecko (*Phelsuma laticauda*) and the red-eared slider (*Trachemys scripta elegans*). All of these introductions are believed to be due to the pet trade. It would appear that the numbers of vertebrates establishing in the wild in Mauritius is showing no signs of a levelling off (Fig. 1).

Also of concern is the spread of vertebrates and all other taxa between the islands and islets that make up the Republic of Mauritius. Rodrigues Island, the outer islands and Mauritian and Rodriguan islets harbour only a sub-set of the invasive vertebrates found on Mauritius Island. This has conservation implications. For example: carnivorous mammals have never established on Round Island thus saving several endemic reptile species from extinction (Bullock, 1986); Flat Island was home to 80% of the world's population of Bojer's skink (*Gongylomorphus bojerii*) until 2010 when shrews were accidentally introduced (possibly in building materials) from the Mauritian mainland causing their local extinction (Cole & Payne, 2015); and Rodrigues does not have Javanese macaques which, if introduced, would further threaten their already fragile native biodiversity. These examples illustrate the importance of effective inter-island pathway biosecurity.

Plant establishment

Since colonisation, more than 1,600 plant species have been introduced to Mauritius. Many of these introductions have been desirable and others have been essential as Mauritius only has one native plant species, the hurricane palm (*Dictyosperma album*) that has so far been exploited on a commercial scale. Heeroo (2000) assembled all introduced plants records from the Mauritius Herbarium between 1888 and 2000 and found that 804 of the 1,619 species were classified as 'weedy species', 141 being 'agricultural weeds' and 674 being 'naturalised weeds' (Fig. 2). It should be noted that there can be a turnover of weedy species so, assuming that the records are comprehensive, the cumulative number listed is likely to be higher than the actual numbers of weedy species in the field. Herbarium records can only approximate the rate at which species establish themselves as they are heavily dependent on collection effort but it would appear that new naturalisations levelled off between the 1980s and 2000. Data from 2000 onwards need to be consolidated to clarify recent trends.

Of the naturalised species, about 30 currently dominate the country's natural vegetation in terms of numbers of individuals and biomass. Some of the principal invasive woody and shrubby plants in Mauritius and Rodrigues include *Psidium cattleianum* (Chinese guava) which constitutes the vast majority of the biomass in much of Mauritius' humid forest (Florens, et al., 2016), *Ravenala madagascariensis* (ravenale) which forms monotypic stands in similar climatic zones (Baret, et al., 2013), *Hiptage benghalensis* (liane cerf) a woody climber which is increasing in abundance in less humid forests (C. Griffiths pers. comm. 2015) and *Syzigium jambos* (jamrosa) which dominates many riverine landscapes in Mauritius and is one of the most widespread plant invaders in Rodrigues.

Entry establishment and spread of additional species can exacerbate an already bad situation. For example, species belonging to the genus *Prosopis*, a known invasive group (Richardson, 1998) have been planted for erosion control on dry mountain slopes and a proposal for the plantation of up to 3,200 ha of *Arundo donax* (giant reed) is being considered despite its known invasiveness (Csurhes, 2009).

Insect plant pest establishment

Williams & Ganeshan (2001) documented the acceleration in insect pest establishment in Mauritius from the 1970s. Data from the Entomology Division of the Ministry of Agro Industry and Food Security (MAIFS) indicates that this rate has continued, averaging about one new pest record per year (Fig. 3). Recent insect pest introductions include the papaya mealybug (*Paracoccus marginatus*), detected in 2013, and the yellow sugar cane aphid (*Sipha flava*), detected in 2015. These newly established pests represent a well-documented burden on the country's agricultural sector which has become extremely reliant on the use of synthetic pesticides with all their concomitant drawbacks (Abeeluck, et al., 2009). The impacts of newly-established pests on native biodiversity have not been studied.

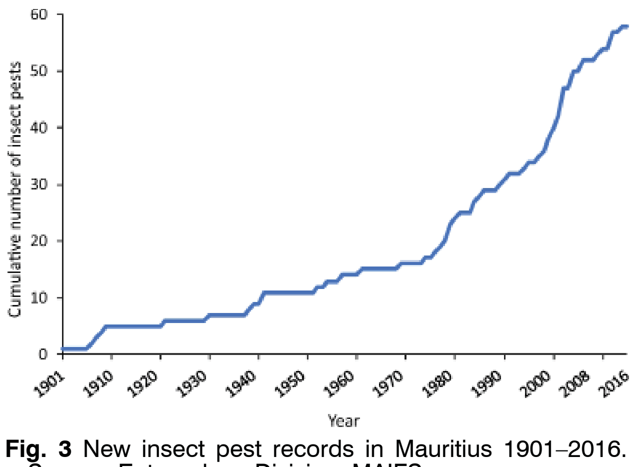

Fig. 3 New insect pest records in Mauritius 1901–2016. Source: Entomology Division, MAIFS.

An example of a repeated insect pest incursion is that of the oriental fruit fly (*Bactrocera dorsalis*): Native to Asia, *B. dorsalis* is one of the world's most destructive pests of fruit with over 300 host species. *Bactrocera dorsalis* is now found in at least 65 countries and continues to spread via infested fruit, either as cargo or carried illegally by airline passengers (CABI, 2017). It was first detected in Mauritius in 1996 and, following an eradication campaign involving bait spraying, male annihilation, fruit collection and destruction, Mauritius was declared free of *B. dorsalis* in 1998 (Seewooruthun, et al., 2000). A further incursion was detected in 2013 and eradicated using similar methods in 2014. The pest was discovered once again in 2015 but at many more locations that previously, so eradication using established methods was not possible. The population is currently being contained and suppressed while an irradiation facility for the breeding of sterile males is being constructed. The first release is scheduled for February 2018 to treat an area of 400 km^2 with the release of 15 million males per week for at least eight months. In the medium term, this programme will be expanded into eradication campaigns for the eight other fruit fly species present in Mauritius (P. Sookar pers. comm. 2017). These planned eradications are being accompanied by increased pest screening of all imported fruit and vegetables.

Disease establishment

A number of zoonotic diseases have been introduced into Mauritius in recent years. The country experienced a major outbreak of chikungunya, a debilitating mosquito-borne virus, in 2006 (Ramchurn, et al., 2008), it's first ever outbreaks of African swine fever in 2007 (Lubisi, et al., 2009) and in 2016 the first foot and mouth disease outbreak in 100 years (Hamuth-Lauloo, et al., 2016). All three diseases are no longer present in the RoM but the outbreaks had major social, political, economic and environmental impacts.

IAS pathways are expanding and diversifying

The major IAS pathways for Mauritius are international shipping and air travel but there is also a risk posed by the unknown numbers of pleasure crafts that land informally on the Mauritian mainland, Rodrigues and their associated islets and are therefore unregulated.

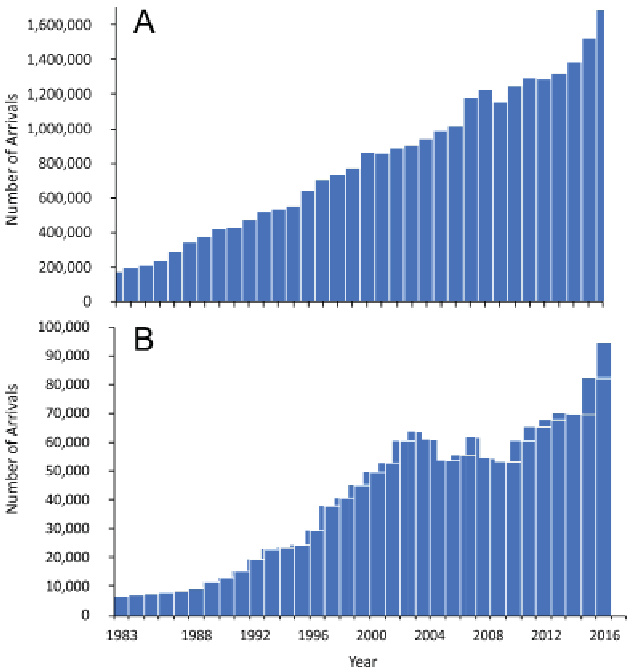

Fig. 4 Passenger arrivals in (A) Mauritius Island and (B) Rodrigues Island 1983–2016 (prior to 1994 figures exclude cruise travellers). Source: Statistics Mauritius (2017).

The volume and diversity of traffic along air and sea pathways into and within the RoM has increased substantially over the past decades. Passenger arrivals into Mauritius Island have increased nearly tenfold from 177,665 in 1983 to 1,684,835 in 2016 (Fig. 4a). Of these arrivals, 409,608 were returning Mauritian residents. Arrivals into Rodrigues over the same period have increased more than fourteenfold from 6,556 to 94,270 (Fig. 4b). Most flights to Rodrigues come from Mauritius Island with an additional scheduled service from Réunion. In June 2017, Air Mauritius, the country's national carrier, was running scheduled services to 24 destinations in 15 countries.

Despite the large increase in absolute numbers, the proportion of travellers from different regions of the world has been relatively consistent (Fig. 5). However, it is highly likely that the diversity of passenger origins has increased substantially although this is not possible to conclude definitively as comprehensive data on passenger's original port of embarkation is only available from 2013. According to Statistics Mauritius (2017), passengers began their journey in at least 110 countries or territories in 2016. Air travel to and through Mauritius is likely to further increase through the continued growth of the tourism industry and the efforts Mauritius is making to position itself as an air travel hub for the fast-growing Africa-Asia market. More and more people coming from more and more biogeographic zones has biosecurity implications for a variety of frontline agencies – currently the airport entry point is staffed by representatives of the the Mauritius Revenue Authority (Customs Department), the Ministry of Agro Industry and Food Security (Plant Protection Office) and Ministry of Health and Quality of Life.

Imports into Mauritius by weight have increased nearly seven-fold from 905,398 tonnes in 1974 to 6,007,056 tonnes in 2016 (Fig. 6). At the same time the number of countries exporting to Mauritius has increased from 33 to 61. However, in contrast to the continued growth in tonnage, the increase in numbers of exporting countries levelled off from 2000 (Fig. 7). The relative importance of exporting countries by monetary value of their exports to Mauritius has changed with two trends being particularly evident: the growth in exports from Asia (from 37–53%) and decline in exports from Europe (from 40–25%) (Fig. 8). These changes have implications for biosecurity including the increased risk that comes with greater volumes of movement, increases in the numbers of source locations and an increase in sources from the warmer parts of the world. However, the precise nature of the risks involved

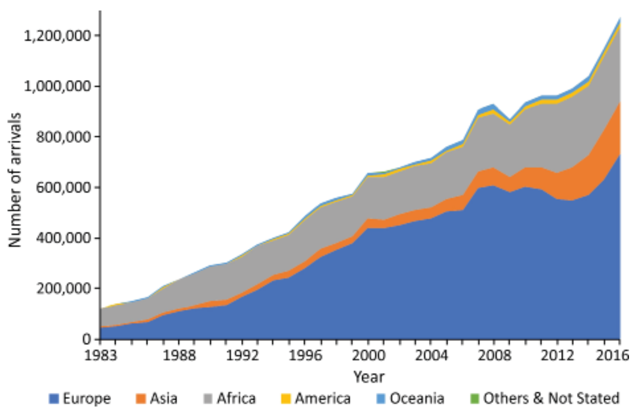

Fig. 5 Foreign passenger arrivals per region of residence. Source: Statistics Mauritius (2017).

cannot be ascertained from aggregate figures. For example, goods such as high value electronics and processed grains, which can be relatively 'clean', pose lower risks than 'dirtier' imports such as semi-processed and unprocessed food and timber, and used machinery which can harbour a wide range of invasive species.

Nearly all official shipping to Rodrigues comes from Mauritius Island, which simplifies pathway analysis. However, pleasure boats and artisanal fishing boats also operate between Mauritius and Rodrigues islands and their offshore islets. Precise numbers of local and international visitors to islets have not been recorded but are known to be in the hundreds of thousands per year. Biosecurity practices are adopted for organised tours of islet nature reserves such as Ile aux Aigrettes and for conservation missions to Round Island and Gunner's Quoin but similar protocols have yet to be formally adopted by private tour operators, pleasure craft owners or fishers.

IAS MANAGEMENT SUCCESSES AND CHALLENGES

Prevention: keeping white grubs out of Mauritius

The white grub (*Hoplochelus marginalis*), a beetle indigenous to Madagascar, was accidently introduced to Réunion, 150 km to the west of Mauritius, in 1973 in potted ornamental plants and became a threat to Réunion's sugar industry in the 1980s (Jeuffrault, et al., 2004). Sugar cane is Mauritius' principal crop and the generalist white grub also affects other crops and wild grasses. Collaboration between Mauritius and Réunion has prevented the white grub from reaching Mauritius and includes the following measures: reduction in the population densities of white grubs in Réunion by the use of the fungal pathogen *Beauveria brongnartii*; sustained public awareness campaigns; changes in flight and boat departure times in summer when the beetle actively flies around dusk and is attracted to light; regular inspections and spraying around the Mauritius port and airport areas. This systematic approach reflects sugar cane's economic importance and the priority given to agriculture.

Early detection and rapid response: stopping redbacks in their tracks

The redback spider (*Latrodectus hasseltii*) is a venomous Australian spider, responsible for far more bites requiring antivenom than any other creature in Australia. It was found on Gunner's Quoin, an islet of key conservation importance, 8 km from the north coast of Mauritius in 2008 by scientists carrying out conservation activities (N. Cole, pers. obs.). The individual spider and three egg cocoons were found, the spider was collected to confirm identification and the cocoons destroyed, although two had previously hatched. Systematic searches were conducted and subsequently three more spiders and additional egg cocoons were detected and destroyed. Since 2010, there have not been any new detections despite intensive surveys every four to six months. It is not known how the redback was introduced but it is suspected that it could have been a stowaway on private yachts from Australia that are known to travel in the region. Since 2010, 15 invasion events by 10 invertebrate and vertebrate species have been detected on six islets surrounding Mauritius. The periodic presence of biologists on these islets has in most cases permitted rapid response resulting in seven of these invasion events being prevented from establishing or subsequently eradicated with another two eradication efforts ongoing. Increased use of the islets for tourism and leisure activities have been identified as the most significant IAS pathway. Effective biosecurity systems do not exist for most islets with the exception being Round Island which is managed for strict conservation purpose, is difficult to access, and is permanently staffed by conservationists.

Eradication: elimination of foot and mouth disease from Mauritius and Rodrigues

The following is a summary of the detailed account given by Hamuth-Lauloo, et al. (2016). From 7–27 July 2016, 62 cases of cattle illness had been reported in Rodrigues. On 31 July, a team from Mauritius observed Foot and Mouth (FMD) symptoms in cattle and pigs. This was confirmed by blood tests on 1 August. In the meantime, two consignments of livestock had been exported to Mauritius Island. The presence of FMD was confirmed in Mauritius on 5 August. The most probable source of FMD was frozen buffalo meat imported from India via Mauritius. The response comprised of stamping out, movement control, disinfection, quarantine, surveillance, destruction of animal products, official disposal of carcasses, by-products and waste, zoning and vaccination and no FMD cases have been detected from both Rodrigues and Mauritius since December 2016. Inspection of export facilities in India could have prevented the outbreak, more rapid diagnosis and better inter-island quarantine could have reduced its severity and spread and a contingency plan would have resulted in a more coordinated response than was the case.

Management: the use of biological control within an IPM approach in the agricultural sector

As outlined, there has been an increased rate of insect pest introduction to Mauritius since the 1970s. This has been one of the reasons for the growing use of pesticides in Mauritian agriculture. However, at the same time, the country, notably through the sugar sector, which barely uses insecticides, has made grounds in integrated pest management (IPM), advocating a package of measures designed to reduce the prophylactic use of pesticides. One of the main planks of this approach has been the use of biological control. This has been reflected in the consistent use of biological control agents (parasitoids, pathogens, and biopesticides) in recent decades. A major recent success was the introduction of the parasitoid *Acerophagus papayae* in 2013 to control the papaya mealybug.

The sectoral nature of IAS management – the case of biological control

Approaches developed in one sector are not necessarily adopted and adapted to other sectors. An example of this is biological control which is actively pursued in agriculture but not in the conservation sector. The priority given to biological control in agriculture, using protocols based on International Sanitary and Phytosanitary Measures (ISPMs), reflects the sector's economic importance and the clear direction offered to the plant protection sector through the International Plant Protection Convention (IPPC), to which the country has been a signatory since 1971. There has been no deliberate introduction of a biocontrol agent against an invasive plant that threatens native biodiversity since 1982, despite the fact that biocontrol of environmental weeds in Mauritius has a very successful history with a full/partial success rate of 80% (Fowler, et al., 2000). Ironically, two recent examples of possible biosecurity failures are likely to have had positive impacts on biodiversity in the RoM. Firstly, there is the movement of *Teleonemia scrupulosa* (lantana lace-bug), a biological control agent for *Lantana camara* (vieille fille) already present in Mauritius, to Rodrigues which has hugely reduced the vigour of *L. camara* in areas of conservation importance and on rangeland in Rodrigues. Secondly, the spread of the biocontrol agent *Cibdela janthina* (mouche bleu) from Réunion to Mauritius, which may have arrived in 2015 (Florens, et al., 2017), has the potential to substantially reduce the vigour of *Rubus alceifolius* (giant bramble) a major invasive plant in Mauritian forests. *C. janthina* could have conceivably dispersed naturally from Réunion but the chances of the *L. camara* agent dispersing naturally from Mauritius to Rodrigues are very low. Whatever the case, biosecurity systems need to be tightened but responsible biological control for invasive plants must to be part of an integrated approach to invasive plant management.

THE DEVELOPMENT OF A NATIONAL INVASIVE ALIEN SPECIES STRATEGY AND ACTION PLAN

Following its accession to the Convention on Biological Diversity in 1992, the Mauritian conservation community was very actively engaged in the Global Invasive Species Programme (GISP) which operated between 1997 and 2011 to encourage the adoption of measures in line with CBD Article 8h: "Each Contracting Party shall, as far as possible and as appropriate prevent the introduction of, control or eradicate those alien species which threaten ecosystems, habitats or species" (UN, 1992). Towards this end, MAIFS established the National Invasive Alien Species Committee (NIASC) in August 2003. One of the priorities for the NIASC, which comprises representatives from the agriculture, biodiversity conservation, health, environment and education sectors as well as the private sector, was the production of a National Invasive Alien Species Strategy and Action Plan (NIASSAP) for the Republic of Mauritius (RoM, 2010). Funding was secured for its development from 2008 and the NIASSAP was approved by cabinet in 2010. The NIASSAP presents a vision in which the negative impacts of IAS on the economy, environment and society of the RoM are avoided, eliminated or minimised. The strategy was based on the assumptions that an effective biosecurity system is built upon a risk analysis framework and that its success depends upon effective collaboration between all those concerned with invasion pathways.

The Strategy comprises ten interlinked elements: five hierarchical "Management Elements" and five "Cross-Cutting Elements". The management elements are those "on the ground actions" that directly address the Strategy's vision. The cross-cutting elements are enabling actions.

The NIASSAP Management Elements, with their accompanying goal or goals are listed in order of priority based on the maxim that "prevention is better than cure":

1. Prevention – to minimise the number of unintended and intended IAS introductions to the RoM;
2. Early detection and rapid response – to minimise the number of IAS that go on to have harmful consequences once they are introduced to the RoM;
3. Eradication – an agreed framework for eradication priorities in place, eradications undertaken as necessary and results disseminated;
4. Control and management – to contain the distribution and abundance of IAS in the RoM to a long-term acceptable level; and
5. Restoration – to undertake ecosystem restoration where necessary in the RoM to achieve long-term ecosystem goals.

The Cross-Cutting Elements, again listed with their goal or goals, are:

6. Legal, policy and institutional frameworks – to have a coordinated policy and management framework that minimise the risk of IAS;
7. Capacity building and education – to make available appropriately skilled personnel to implement all aspects of IAS management in the country;
8. Information management and research – (i) To have a clear understanding of the impacts of IAS that have become established in the RoM; (ii) to have ready access to critical information that will support IAS management programmes and (iii) to provide a strong scientific basis for decision-making and resource allocation;
9. Public awareness and engagement – all stakeholders in the RoM should have a high level of awareness of IAS risks and the benefits of IAS prevention and management;
10. International cooperation – (i) the RoM should have access to the necessary information, technical and financial support and other resources it needs to effectively meet its international obligations; (ii) Mauritian IAS experiences and lessons learnt are effectively disseminated to help IAS initiatives regionally and internationally and (iii) the RoM is not a source of IAS for other countries

Partial implementation of the NIASSAP (2010–2017)

The NIASSAP has yet to be systematically implemented. Major reasons for this were the fact that lead agencies were not designated to carry out each action and timelines, milestones and estimates of resources required were not agreed upon. The National IAS Committee only met sporadically between 2010 and 2015 and was only made statutory in 2015 under the Native Terrestrial Biodiversity and National Parks Act (2015).

However, actions in line with the NIASSAP have been undertaken in Mauritius since 2010, some of which have been outlined above, but they were not implemented because of the NIASSAP.

The prospects for effective implementation of the NIASSAP received a boost with a broadly costed and timetabled provision for its implementation under the National Biodiversity Strategy and Action Plan (NBSAP) 2017–2025 as the National contribution to Aichi Target 9: “By 2025, the NIASSAP is revised and fully implemented through adequate financial and human resources commensurate to the existing challenges, and the impacts caused by IAS are minimised” (RoM, 2017). Linked to the above, from 2015–2018, has been the development of a UNDP/GEF VI Project to mainstream IAS prevention, control and management (US$20.89M project: US$3.89M from Global Environment Facility and US$17M from National co-financing).

Next steps: mainstreaming IAS prevention, control and management

The objective of the ‘IAS Mainstreaming Project’ is to safeguard globally significant biodiversity in vulnerable ecosystems through the prevention, control and management of IAS in the RoM. This will be achieved through four outcomes which are summarised below together with key outputs and activities that contribute to intended outcomes:

1. By 2024, the RoM has a gender sensitive policy, regulatory and institutional framework and capacity to manage IAS effectively:
   - The NIASSAP is reviewed and revised, with progress assessed, gaps identified and activities fully costed with precise timelines for implementation for both terrestrial and marine IAS;
   - Existing legislation is strengthened for more effective control and management of IAS;
   - A cross-sectoral policy coordination framework is established for the incorporation of IAS issues into the legal and policy framework of all relevant agencies;
   - A technical secretariat for IAS is established;
   - Capacity is strengthened in key agencies and organisations;
   - Financial sustainability of the apex agency and IAS operations are secured through the development and application of new market-based and fiscal mechanisms and incentives to support IAS management.
2. By 2024, the government effectively prevents and manages IAS threats based on risks:
   - National and inter-island biosecurity priorities and resource needs, including baselines are established;
   - A comprehensive risk assessment system is in place and being used in the Republic of Mauritius, to (1) assess the risks that new species proposed for importation to the RoM or moved between its islands may become invasive (border control), and (2) assess the risks associated with species already present in the RoM but which may not yet have become invasive there;
   - Species identified by formal risk assessment as having high invasiveness potential in the Republic of Mauritius are refused permission for importation or for translocation between its islands;
   - Procedures for controlling the unregulated (illegal) importation of species to the Republic of Mauritius or between its islands are improved (effective quarantine system with sanctions for deliberate infractions);
   - Species present in the Republic of Mauritius, with high invasive potential but still present only in limited areas, are prioritised for management and, where feasible, eradication by means of a formal risk assessment process, including, as far as possible, their declaration as “harmful”, “prohibited”, or similar;
   - Pilot biodiversity conservation and ecological restoration operations developed on key islets and in Rodrigues;
   - Equipment and infrastructure updated to help ensure that priority biosecurity measures are effectively implemented.
3. By 2024, planning, management and decision-making by all relevant stakeholders are informed by knowledge management and learning:
   - Review and survey of the status of IAS pathways, IAS distributions, the cross-sectoral economic, environmental and cultural impact of IAS and the successes and lessons learnt from past and ongoing IAS prevention, early detection and rapid response, eradication, control and mitigation and restoration;
   - Up-to-date lists of terrestrial and marine invasive species of all taxa present in the Republic of Mauritius are completed and publicly available, and a system for their regular updating is in place and is being used;
   - Pathways of introduction of new species into Mauritius and between the islands of the Republic of Mauritius are identified, their relative importance is quantified, and they are prioritised for management action to reduce the rate of arrival of new species;
   - A national IAS information system is developed and operationalised to monitor and inform risk-based management of species, pathways and ecosystems based on agreed protocols;
   - A national IAS gateway is developed to provide rapid access and dissemination of information to enhance deployment of coordinated actions between institutional partners on IAS management;
   - A national IAS communications and awareness strategy and action plan is developed and implemented;
   - IAS tools and manuals are developed to complement training courses and for use in day to day IAS management operations, and guidelines are developed to embed IAS issues into key sectors whose activities have IAS implications.

Project risks include increased liberalisation of movement and trade, the continuation of a fragmented sector by sector and case by case approach, lack of support for strengthened biosecurity measures at different levels, and economic and political pressure being used to circumvent decision-making based on a transparent risk analysis process. It is clear, therefore, that the NIASSAP represents an ambitious and costly undertaking, but the costs of not systematising IAS prevention and management (business as usual) are likely to be considerably higher.

ACKNOWLEDGEMENTS

Thanks to staff of the Ministry of Agro-Industry and Food Security (National Parks and Conservation Service, Forestry Service, Plant Quarantine Service and Entomology Division) and the Mauritian Wildlife Foundation for helping to provide information for this paper and for their contributions towards putting invasive species on the national radar. Thanks to the reviewers for their valuable comments on an earlier draft of this paper. A special thanks to all the dedicated staff from the concerned agencies who undertake the daily activities to minimise invasive species impacts in the Republic of Mauritius.

Islander perceptions of invasive alien species: the role of socio-economy and culture in small isolated islands of French Polynesia (South Pacific)

J.-Y. Meyer[1] *and M. Fourdrigniez*[2]

[1]*Délégation à la Recherche, Government of French Polynesia, B.P. 20981, 98713 Papeete, Tahiti, French Polynesia. <jean-yves.meyer@recherche.gov.pf>.* [2]*Groupement Espèces Envahissantes, Bioconsulting, B.P. 50902, 98716 Pirae, Tahiti, French Polynesia.*

Abstract Islands, often celebrated as natural laboratories for evolution and ecology, also provide unique experimental grounds for societal studies. Although biological invasions are widely recognised as one of the main causes of biodiversity erosion and a driver of global change, the human perception of invasive species may vary at regional and local levels, especially in societies with different levels of socio-economic development and cultures. This study was conducted in French Polynesia (South Pacific), a territory formed by 120 tropical and subtropical oceanic islands (76 being inhabited) divided into five archipelagos (Austral, Marquesas, Society, Tuamotu, and Gambier Is), comprising both highly populated and urbanised islands (such as Tahiti in the Society Is) and less populated and very small islands, sometimes very isolated (without airstrips) and where traditional life style and strong dependence on natural resources still persist. During an eight-month education and prevention campaign targeting alien plant and animal species legally declared invasive in French Polynesia, public meetings were organised on 19 small islands for a total of 2,045 consulted people in 41 different villages. Negative, positive and neutral comments made by participants on some invasive species present in their islands were recorded. Our results show that their perceived status differs from one archipelago to another, or even among islands in the same archipelago, with more positive comments (i.e. species benefits) on more isolated islands. Perception of invasiveness varied according to societal and cultural values (e.g. utilitarian or aesthetic), and often depends on the species' date of introduction ("indigenisation" of old introduced plants and animals). These surveys can provide useful baseline information on the degree to which local island communities are likely to support invasive species management, to get involved in prevention, surveillance and control efforts, and to avoid potential conflicts of interest between different stakeholders in small but sometimes complex insular societies.

Keywords: conflicts, indigenisation, invasiveness, isolation, prevention, social dimension, values

INTRODUCTION

The human or social dimension is increasingly recognised as a crucial issue for the effective management of invasive alien plants and animals (McNeely, 2000; Marshall, et al., 2011; Estévez, et al., 2014). Indeed, many control, eradication or prevention programs have been delayed or even failed because of differing public attitudes and feelings towards the targeted invasive species. The various stakeholders (such as foresters, pastoralists, horticulturists, pet shop managers, conservationists and environmentalists) may have different or opposite views of species status (e.g. "noxious/harmful" versus "useful/beneficial" species) and strong opposition by some influential groups of people or even single individuals may occur. Control or eradication programs of animals such as feral cats (*Felis catus*), feral deer (*Cervus* spp.), pigs (*Sus scrofa*), or grey squirrels (*Sciurus carolinensis*) (see references in McNeely, 2000; Estévez, et al., 2014), and of plants such as gorse (*Ulex europaeus*) in New Zealand (Hill, 1989) or strawberry guava (*Psidium cattleianum*) in the Hawaiian islands (Veitch & Clout, 2000; Warner & Kinslow, 2013) and La Réunion (Mascarene Is, Indian Ocean) are well-documented examples of social conflicts of interests, often associated with "controversies" reported in public and media opinions.

Thus, studying human perceptions and attitudes towards invasive species is often useful and sometimes an important prerequisite before starting often costly and long-term management programmes. Many recent studies have been conducted in "western" and/or well-developed regions/countries, such as Europe, Canada and USA (Bremner & Park, 2007; Garcia-Llorente, et al., 2008; Selge, et al., 2011; Fischer, et al., 2014), and New Zealand (Fraser, 2001; Russell, 2014), using questionnaires or interviews addressed to different stakeholders among different socio-professional categories. A few other studies have been conducted in developing countries where invasive species may sometimes constitute a natural resource rather than a nuisance (e.g. the potential use of water hyacinth (*Eichhornia crassipes*) as biofuel in south-east Asia, Bhattacharya & Kumar, 2010). The case of "true" island countries and territories (excluding large continental islands such as Australia, Madagascar, or Great Britain) is even less studied, although they are highly vulnerable to the impacts of invasive alien species, with many cases of native species' extinction and extirpation and stronger conservation challenges. Moreover, islands, often celebrated as natural laboratories for evolution and ecology, may also provide unique experimental grounds for societal and cultural studies, as they also harbour a high cultural diversity and different levels of socio-economic development. In this study conducted in the small tropical oceanic islands of French Polynesia (South Pacific), we tested the two following hypotheses:

Does human perception of invasive species vary with island isolation, human population and socio-economic development?

What is the influence of cultural (traditional) values on public attitudes toward introduced species in small remote islands?

MATERIAL AND METHODS

This study was conducted in French Polynesia, a European Overseas Country and Territory (OCT) located in the South Pacific, formed by about 120 small tropical oceanic islands (76 being inhabited by a total of ca. 276,000 inhabitants in 2017) divided into five archipelagos (Austral, Marquesas, Society, Tuamotu, and Gambier Is), and dispersed over a marine area as wide as Europe (Fig. 1).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 510–516. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

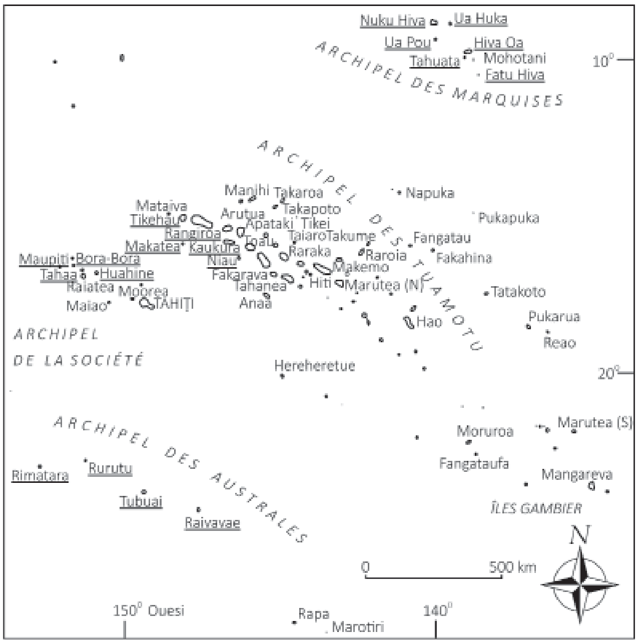

Fig. 1 French Polynesia and its 120 tropical oceanic islands located in the South Pacific. The names of the 19 surveyed small islands are underlined.

This OCT comprises both highly populated and urbanised islands (such as Tahiti, the largest with a land area of 1,045 km² and over 183,000 inhabitants) and very small isolated islands (sometimes without airstrips such as Tahaa in the Society, Fatu Iva and Tahuata in the Marquesas, Makatea in the Tuamotu, Rapa in the Austral Is with an area of only 40 km² and 515 inhabitants), which are less populated and developed, where traditional lifestyles and strong dependence on natural marine and terrestrial resources still persist. As an example, coconut plantations for copra and coconut oil production remain the main source of income in the Leeward Islands (Society), the Tuamotu atolls and the Marquesas high volcanic islands (IEOM, 2017). The island isolation or "remoteness" (distance from the most urbanised and populated island of Tahiti in km) and the number of regular flights per week departing from Tahiti or "connectivity" were used as proxies for the socio-economic development of each surveyed island.

Environmental matters and issues fall to the authorities of the French Polynesian Government, (i.e. they are different from French laws and regulation texts), with a "Code de l'Environnement de la Polynésie Française" voted by the Assembly of French Polynesia in 2003, including a chapter specifically dedicated to invasive alien species. A total of 46 species including 35 plants and 11 animals have been legally declared "a threat to biodiversity" in French Polynesia (Table 1) because of their significant negative impacts on the endemic fauna and flora. New introduction, culture or propagation, as well as inter- and intra-island transportation, of these species is banned in all islands of French Polynesia and control or eradication programmes have been set up. Their presence on each inhabited island was compiled based on literature, plant and animal databases and local expertise (Fourdrigniez, et al., 2014).

During a communication, education, prevention and capacity building campaign conducted (by the second author M.F.) between May and December 2014 (about eight months), public meetings were organised on 19 small islands (< 400 km² and 10,000 inhabitants) within 41 different villages. A total of about 2,045 people were consulted (Table 3). These meetings were held at the city halls ("mairie" in French) or community houses during the morning or the evening, and were attended mainly by adults (for a total of 1,781) and some schoolchildren.

An oral PowerPoint presentation listing and describing the 46 legally declared invasive species (38 of which were present in the surveyed small islands) was delivered, without providing details on their ecological and socio-economical impacts. Two main following questions were asked to the participants:(1) do you know or have you seen these species in your island? (2) do you consider them invasive (i.e. abundant and/or spreading) in your island, and where (i.e. which locations)?

Although no direct question was asked about species perceptions and associated values, comments were given by participants related to the negative impacts of species on biodiversity and other sectors (e.g. agriculture, health), and also their positive impacts (past and current benefits), which were systematically recorded.

RESULTS

Effects of island isolation, human population and socio-economic development

The total number of legally declared invasive alien species known to be present in each surveyed island (according to Fourdrigniez, et al., 2014) in the four archipelagos of the Leeward (Society), Austral, Marquesas and Tuamotu Is does not decrease with island remoteness (Fig. 2), comprising 44 of the 46 invasive alien species (Table 3). Invasive species diversity also does not increase with island size (Table 3) although the two largest remote islands of Hiva Oa and Nuku Hiva in the Marquesas (> 300 km² of land area) have a high proportion of species (between 50–56% of the total), probably related to their higher habitat diversity (ranging from coastal vegetation and littoral forest to dry-mesic forests, valleys and slopes rainforests, and montane cloudforests and summit ridges up to 1,200 m elevation, Lorence, et al., 2016) compared to the other surveyed islands. There is a relatively weak correlation between invasive species and the number of inhabitants (R^2=0.48, P-value < 0.01, Fig. 3a), which becomes stronger with the number of regular flights departing from Tahiti per week (R^2=0.53, P-value < 0.05, Fig. 3b), i.e. with human and goods transportation connection and frequency. This "connectivity" between Tahiti and the other French Polynesian islands constitutes a very good proxy for the socio-economic development of isolated islands. If the Tuamotu atolls are removed from the analysis, the correlation coefficient is significantly higher (R^2=0.72). Indeed, the atolls and raised atolls have fewer invasive species mainly because of their small terrestrial areas, their calcareous substrate and strong insolation

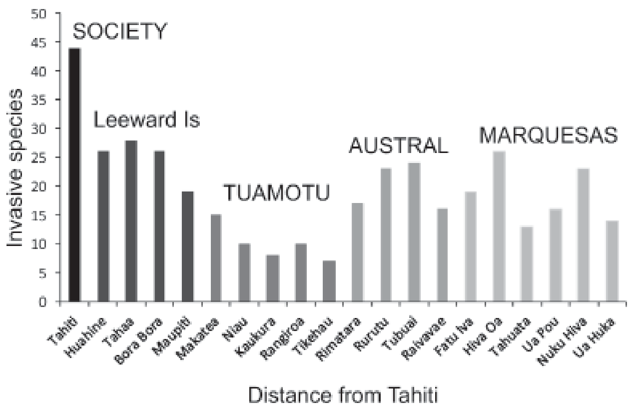

Fig. 2 Relationship between the number of invasive alien species on Tahiti and the 19 surveyed small islands according to distance from Tahiti: Leeward Is (Society Is) >170–310 km from Tahiti; Tuamotu Is >220–350 km; Austral Is >500–700 km; Marquesas Is >1,000–1,500 km (Spearman test, P-value = 0.000995).

Table 1 List of the 46 invasive alien species legally declared a "threat to biodiversity in French Polynesia" (according to the French Polynesia "Code de l'Environnement") and their presence in Tahiti and the other 19 surveyed small islands (Fourdrigniez, et al., 2014).

which constitute demanding ecological conditions for both introduced animals and plants. The Austral high volcanic islands have a cooler climate due to their southern geographical location (mean annual temperature between 18°C for Rapa Iti and 20°C for the other islands) which may also prevent the establishment and invasion of some "truly" tropical species. If the Austral islands are removed from the analysis, the correlation coefficient is slightly higher (R^2=0.57).

Perceptions of invasive species in different archipelagoos and islands

The total number of negative, positive and neutral comments (50) recorded by participants for each species was analysed for all the 19 surveyed islands. Comments were reported only for 15 of the 38 species occuring in the islands, most of them were positive (Fig. 5). More comments were made in the isolated islands of the Austral Is (> 500–700 km from Tahiti) and the Marquesas Is (> 1,000–1,500 km) with lower socio-economic development but where people seem to show a stronger interest in the use of available natural resources (Fig. 4), compared to the Leeward Is in the Society Is. Comments in the Tuamotu Is were the lowest and the number of reported invasive species is also the smallest (between 7 and 15 species, i.e. 15–33% of the total). It is noteworthy that all comments made on invasive species were positive in the Tuamotu atolls (Fig. 4), meaning they are more considered as "useful" for people than "noxious/harmful". In all surveyed islands and archipelagos, positive comments exceeded negative ones, but this rather surprising result might be biased as

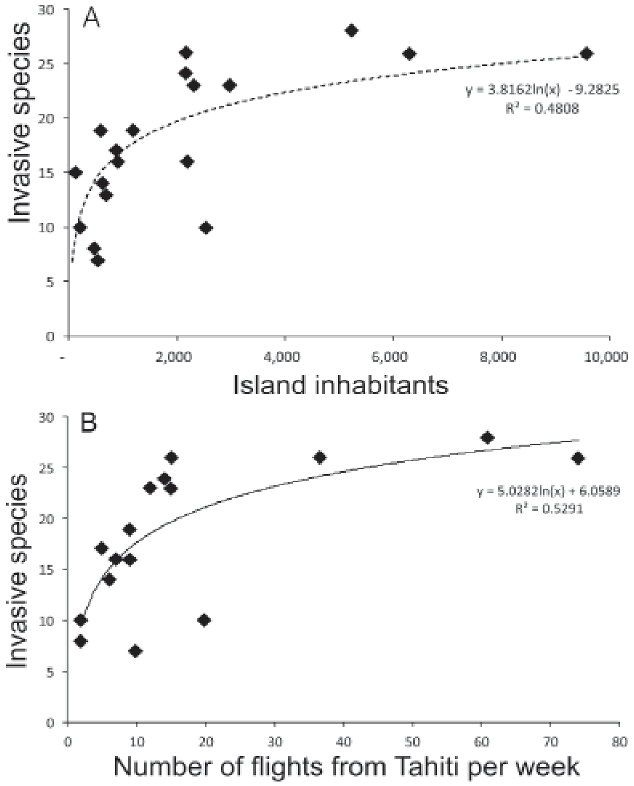

Fig. 3 A. Relationship between the number of invasive alien species and the number of inhabitants (2012 population census) in the 19 surveyed islands (Spearman test, P-value = 0.001407). B. Relationship between the number of invasive alien species and the plane transportation frequency (number of flights per week from Tahiti) in the 16 surveyed islands with a domestic airport.

most people agreeing with the invasiveness status did not make specific negative comments (e.g. for the three species of rats – *Rattus* spp.). To avoid this bias towards positive comments, future studies should explicitly ask participants for their inputs on the ecological and socio-economical impacts of the targeted invasive species.

One animal species, the common myna (*Acridotheres tristis*), has received only positive comments. This bird, first introduced to Tahiti in the early 1900s (Meyer, 2003) is indeed considered as a useful animal because it eats introduced wasps and ticks especially in the Leeward Islands of the Society archipelago (e.g. in Huahine), whereas it is subjected to an active control programme in Tahiti to protect the threatened endemic flycatcher *Pomarea nigra* (Monarchidae) (Blanvillain, et al., 2003). For vascular plants, the 29 invasive species were not considered as "noxious/harmful" in all the surveyed islands where they are present. There were many positive comments for ornamental plants or fruiting trees, especially in the most remote islands of the Austral and the Marquesas (Table 4).

It is interesting to note that the perceived status of invasive alien species differs from one archipelago to another, but also among islands in the same archipelago, such as the climbing liana *Passiflora maliformis* in the Austral Is because of its edible fruits or the large tree *Falcataria moluccana* in the Marquesas as a timber tree (Table 4). Both species are currently being controlled in areas of high conservation values in Tahiti.

DISCUSSION

Island invasibility, species invasiveness and socio-economic development

Perception of invasiveness is complex because of diverse mental representations by different key interest groups and socio-economic contexts (Garcia-Llorente, et al., 2008). An understanding of human dimensions is necessary to avoid potential social conflicts in invasive species management (Estévez, et al., 2014; Russell, 2014).

Our results conducted on small islands of French Polynesia show that the number of invasive alien species is not decreasing with island remoteness (i.e. distance from Tahiti) and island size, but is more correlated with human development (e.g. the number of inhabitants and the frequency of transportation connection with Tahiti) and habitat diversity, as documented in other islands elsewhere (Kueffer, et al., 2010). The island of Tahiti can be considered as a "transportation hub" in the South Pacific, with an international airport opened in 1960 and direct flight connections to Rarotonga (Cook Is), Australia, New Zealand, New Caledonia, California and Hawaii (USA), Chile and Japan; and a major trade port in 1962 with goods imported from Europe, North and South America and South-east Asia. The increasing development of commercial trade during the past decades (from 330,000 tons in 1989 to 980,000 tons in 2015, ISPF, 2016) was associated with a dramatic increase of accidental plant and animal introductions. Invasive insects such as fruit flies (*Bactrocera* spp., Tephrididae), the glassy-winged sharpshooter (*Homalodisca vitripennis,* Cicadellidae) and the little fire ant (*Wasmannia auropunctata,* Formicidae), first introduced to Tahiti between the 1970s and the 1990s (Meyer, 2003), have subsequently spread to many other

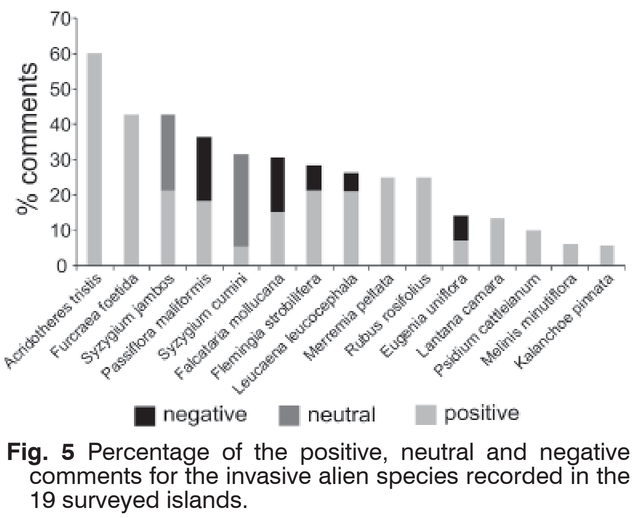

Fig. 5 Percentage of the positive, neutral and negative comments for the invasive alien species recorded in the 19 surveyed islands.

Table 4 Examples of positive and negative comments for some invasive alien plants introduced by Europeans in the surveyed islands with their date of first introduction or record in Tahiti, French Polynesia (Baas Becking, 1950; Jacquier, 1960).

Scientific name	Positive comment(s)	Island(s)	Negative comment(s)	Island(s)	Date of first introduction or record
Eugenia uniflora	Edible fruits, wood used for fish tools	Rimatara, Tubuai	Alters feral goat meat	Fatu Iva	1848
Falcataria (syn. *Albizia*) *moluccana*	Honeybee-forage plant, wood used for boats	Fatu Iva, Raivavae	Dries out rivers	Rurutu	1936
Flemingia strobilifera	Flower used in necklaces	Nuku Hiva, Ua Huka, Rimatara	Spreads in gardens	Tahuata	1937
Furcraea foetida	Formerly used for ropes & traditionnal dance skirts	Rimatara, Rurutu, Tubuai	-	-	?
Lantana camara	Ornamental garden plant	Nuku Hiva, Ua Huka	-	-	1853
Leucaena leucocephala	Forage for cattle, improves soil erosion control	Nuku Hiva Ua Huka	-	-	1845
Passiflora maliformis	Edible fruits used for jams	Rimatara	Suppresses orange and coffee trees	Fatu Iva, Tubuai	?
Syzygium cumini	Edible fruits	Tikehau, Makatea	-	-	1880
Syzygium jambos	Edible fruits	Tubuai			1890

French Polynesian islands through inter-island boat and/or plane transportation.

The perceived status of the 46 legally declared invasive species, a small subset of the total number of invasive species in French Polynesia (e.g. with more than 80 plants considered as invasive, Fourdrigniez & Meyer, 2008), differs from one archipelago to another, or even among islands in the same archipelago. They are more positively considered in the most isolated islands with lower socio-economic development and/or where natural resources are extremely limited, e.g. in atolls where invasive woody plants are used as tools or for wood construction, such as *Leucaena leucocephala*. This is very similar to the different attitudes of urban *versus* rural residents to pest species management in western developed countries or in Australia and New Zealand in the Pacific region (Fraser, 2001; Johnston & Marks, 1997). When abundant, invasive alien species are often seen as potential natural resources by islanders whereas when they are less common or rare, people agreed to eradicate introduced species. Species prioritisation that includes socio-economic values may thus contribute to a better efficiency in control or eradication by gaining support of local communities in remote islands.

Importance of cultural values

Human perceptions and attitudes vary with time, places, societies, economic conditions and culture (Dalla Bernardina, 2010; Fitzgerald, et al., 2007). The importance of cultural (traditional or ancestral) values of introduced species in the Pacific islands is well illustrated by animal species that were introduced by the first humans during their migration and colonisation, and became invasive with time, with sometimes dramatic impacts on the native biodiversity. Feral pigs (*Sus scrofa*) are still a source of dispute between conservationists and native Hawaiians who hunt them as in the past (Van Driesche & Simberloff, 2016), and Pacific rats (*Rattus exulans*) are considered a treasure brought to New Zealand by their Maori ancestors, thus may be worshipped and of high significance (Haami, 1994; Veitch & Clout, 2000). Some plants introduced by the first Polynesians for ritual, aesthetic or utilitarian values (Whistler, 2009) have also spread into native lowland forests in French Polynesia and Hawaii, including the candlenut tree (*Aleurites moluccana,* Euphorbiaceae) and the bamboo (*Schizostachyum glaucifolium,* Poaceae) where they are considered as either invasive (Smith, 1985) or part of the Polynesian social heritage (Larrue, et al., 2010).

Our survey indicates that the date of species introduction in the islands of French Polynesia, more particularly in Tahiti (Baas Becking, 1950; Jacquier, 1960), seems to be an important factor explaining attitudinal differences, as old introduced species seem to be more widely accepted or positively considered by people, because of their long co-existence (more than one century). This is the case of the small tree *Leucaena leucocephala* and the shrub *Lantana camara* which were introduced by Europeans in French Polynesia in 1845 as a fodder plant and 1853 as an ornamental garden plant respectively, and often still considered as beneficial species (Table 4). This phenomenon is sometimes, but incorrectly, called “indigenisation”, as these naturalised species (“naturalisation” is defined as an ecological proces where the alien plant species establishes and becomes incorporated within the natural flora, Richardson, et al., 2000) are not becoming indigenous or native but part of the human culture or natural heritage. It should be refered to as “heritagisation” (“patrimonialisation” in French) which describes a socio-cultural, legal or political process where an area, a good or a species is transformed into an object of the natural, cultural or religious heritage with conservation or restoration value.

One of the crucial challenges in invasive species management is the active involvement, engagement and support of local communities (Hart & Larson, 2014), as well as resolving or at least avoiding potential conflicts of interest between different stakeholders. The small Pacific islands, including French Polynesia, provide an excellent ground for testing new methodologies and initiatives in complex insular societies. Based on the results of this survey, we propose that an “invasive species perception index" should be included in feasibility studies to manage biological invasions in isolated inhabited islands.

A first step to integrate the local socio-economic and cultural dimensions of invasive species in the islands of French Polynesia was the creation of a network during and following this survey (called "Te Rau Mata Arai" in Tahitian, literally the "numerous watchful eyes"). Its aims are the prevention, detection, surveillance and control of invasive alien species by identifiying local, key people in each island (a total of 36 on the 19 surveyed islands) including local government and city council representatives, members of nature protection groups, small entrepreneurs, and other civil society actors.

ACKOWLEDGEMENTS

We are grateful to all the participants of the survey conducted in the 19 small islands of French Polynesia in 2014, the city councils ("mairies") and the local representatives of the Service du Développement Rural (Department of Agriculture of the Government of French Polynesia) for organising the public meetings. We also thank the Délégation à la Recherche and the Direction de l'Environnement (Government of French Polynesia) for the moral and funding support, Charles Chimera (Hawaii-Pacific Weed Risk Assessment, Hawaii, USA) for revising the English, Robin Pouteau (Institut Agronomique néo-Calédonien, Nouméa, New Caledonia) for performing the statistical tests, and two anonymous reviewers for their constructive comments that helped to improve the manuscript.

Abstract Island restoration is expanding as a tool for enhancing conservation outcomes. The ability of conservation managers to eradicate multiple invasive species over increasingly complex or large areas is steadily improving, but progress inevitably presents new challenges. There is always a larger, even more complex operation ahead, and islands with human populations present their own suite of problems and opportunities. The majority of the large and/or complex island restoration projects to-date have been carried out with a high level of government commitment including funding support (e.g. New Zealand, Australia, USA). However, there is increasing interest in applying this methodology to islands in jurisdictions where there is less central government support. This can be further complicated by regulatory systems and implementation logistics. Non-governmental organisations are now taking lead roles in many projects to restore islands worldwide, working collaboratively to share the financial, logistical and regulatory challenges and share in the outcomes. If we are to succeed in truly "turning the tide" on invasive species it will be necessary for governmental and non-governmental organisations to partner even more effectively in order to expand the capacity for such conservation actions worldwide. Choosing the right partners, clarifying shared values, programme goals, responsibilities and definitions of success is needed for NGOs, governments and other partners to work effectively and make the progress that is necessary to continue achieving good conservation outcomes in the future.

Keywords: collaboration, eradication, organisational structure, planning, project management

INTRODUCTION

"Cross sector partnerships ... are far from commonplace. True partnerships are the stuff of legends. Think of the Fellowship of the Ring..." Tennyson (2011).

The eradication of invasive vertebrates, especially rodents, as a key component of island restoration has an extensive history spanning more than 50 years (e.g. Towns & Broome, 2003; Howald, et al., 2007; Towns, et al., 2013; Russell & Broome, 2016). Techniques for carrying out this work have developed over this time, and eradication projects are now often highly complex and specialised operations using equipment and people from all over the world.

Until the last fifteen years, the agencies with the resources to undertake the largest projects were generally government conservation agencies (GCAs) in developed countries such as New Zealand, Australia, the USA and Canada. Projects included the consultation of stakeholders, but early operations were often led and managed by single organisations on government land (Towns & Broome, 2003).

As the case for carrying out island restoration projects has become more established (Courchamp, et al., 2003; Bellingham, et al., 2010; Jones, et al., 2016), new organisations, especially non-governmental organisations (NGOs) and for-profit enterprises (FPEs) have become increasingly involved in island restoration. There are now several NGOs and initiatives worldwide that are entirely dedicated to the restoration of islands through the removal of invasive species (e.g. Island Conservation (USA); Grupo de Ecología y Conservación de Islas (Mexico); Predator Free New Zealand (New Zealand)), and this work is gaining in prominence within the wider conservation NGO community (e.g. recent work by the Royal Society for the Protection of Birds (UK) and the South Georgia Heritage Trust). In addition, new commitments to carry out this work have been made by international organisations and through international agencies, e.g. the International Union for the Conservation of Nature (IUCN)'s Honolulu Challenge (IUCN, 2016), BirdLife International's Invasive Species Programme (BirdLife International, 2017).

The increasing challenge of partnerships

In order to continue to obtain the conservation benefits available from the eradication of invasive species on islands, projects will need to be carried out in even more complex conditions. In light of current technology and experience, we could describe a project where area is less than 10,000 ha; there is a single owner; country jurisdiction is clear; and a single funding source is available as "simple". In some countries all, or the majority of these projects have now been tackled, or the need for them has not arisen (Howald, et al., 2007; Dawson, et al., 2015; Parkes, et al., 2017; Stanbury, et al., 2017). In less developed countries where conservation funding is much scarcer, the idea of national governments supporting island restoration projects is often not well established and finding funds for any project of this sort is difficult. In many countries, islands without human habitation or regular use are extremely uncommon.

Islands with significant human populations, complex and challenging topography, and/or located in extremely remote parts of the world are thus becoming a higher priority (Oppel, et al., 2011, Dawson, et al., 2015; Parkes, et al., 2017; Stanbury, et al., 2017). For example, the Royal Society for the Protection of Birds (RSPB) is currently developing a project to restore Gough Island (Tristan da Cunha) through the eradication of house mice (*Mus musculus*).

The island is extremely remote and is located in a UK Overseas Territory with a small human population and insufficient financial resources to support the operation. The project partnership will include no fewer than six project partners from at least three countries, including government agencies, NGOs, and the local community.

The DIISE (2017) records 25 rodent eradication attempts that have been made on islands greater than one square kilometre in area since 2010. Of these, the majority (15 of the 25) were not undertaken solely by government agencies, and even where operations were government-led, some sort of partnership was needed (e.g. between State and Federal government agencies).

Howald, et al. (2011) explored the advantages and challenges of different organisational structures conducting island restoration projects. The authors found that there were clear advantages and disadvantages attached to GCAs, NGOs and FPEs in conducting eradication campaigns, but concluded that the potential advantages of collaboration were often greater than the challenges. In this paper, we consider local community groups separately from NGOs as another type of organisation which is increasingly proposing and supporting new island restoration projects. As well as type, the size and culture of organisations also has significant importance and impacts on internal bureaucracy, speed of decision-making and level of tolerance for risk.

Whilst it is apparent that partnerships provide opportunities to capitalise on the strengths and compensate for the weaknesses of different types of organisations, partnerships can be complicated to establish and maintain. The same people who have significant strengths and experience in designing and implementing island eradication projects do not always have a similar level of experience or expertise in developing or maintaining organisational partnerships, especially when organisations' cultural aspects can be highly variable. Staff turnover can be an issue, as partnerships are effectively formed between individuals as well as organisations, and some organisations have higher turnover than others. It is important for the organisations that are planning and managing eradication projects to recognise the importance of consistency of staffing in these projects, and endeavour to provide this, as well as supporting training in partnership-working for technical staff wherever possible.

This paper assesses some of the factors that may be influential in making partnerships work. There is no way to carry out a scientific analysis of how to create a strong partnership that will lead to a successful project outcome: partnerships (like marriages) are not a scientific construct. However, the authors of this paper have been involved in a wide range of projects with partners from government, NGOs, and local communities. From our combined experience, the main elements needed, in our opinion, are presented, along with some of the common pitfalls. Sharing our experiences may enable other project managers to analyse their own potential partnerships, and hopefully use these principles to enhance the likelihood of project success.

What partnerships are, and when they should be established

According to Wilcox (1998) a partnership is an agreement between two or more individuals or groups to work together to achieve common aims. Sterne, et al. (2009) identified nineteen characteristics of partnerships, including mutual trust and respect, clearly identified roles and responsibilities, transparency of decision-making, and a process for adjudicating disputes. The Nature Conservancy (2017) suggests there are six stages to most partnerships, and Tennyson (2011) defines twelve stages. The main points are:

- Prepare: define the need for partners.
- Select: choose the best partner(s) to work with.
- Negotiate: create agreement to inspire action and reduce the potential for conflict.
- Manage: implement joint work.
- Measure: monitor and evaluate the partnership.
- Conclude: adapt, improve or conclude the partnership.

During the first stage, it is important for project managers to consider carefully whether forming a partnership is the best choice in their individual situation. Reasons to establish a project partnership include the desire to increase capacity amongst other organisations and stakeholders; the need to access a new decision-making authority or constituents; the opportunity to share costs; and the ability to make projects more sustainable and resilient. One method of comparing these potential benefits with the potential costs would be a SWOT (Strengths, Weaknesses, Opportunities, Threats) analysis.

It is advisable to establish partnerships early in the project planning process, if indeed it is considered that a partnership would be beneficial. The Nature Conservancy (TNC) recommends a partner scoping exercise at the start of planning any conservation project (The Nature Conservancy, 2017). However, this step is not currently included in resources specific to island restoration, such as the Pacific Invasives Initiative (PII) Resource Kit (Pacific Invasives Initiative, 2011). In particular, there appear to be significant benefits from involving community partners, including landowners, at the initial stages of project planning (Varnham, 2011; McClelland, et al., 2011), not least because their local knowledge can add value to planning and their drive to succeed can assist in motivating the rest of the partnership.

Potential partners could be identified in a stakeholder analysis which may be carried out as part of the feasibility study for an operation, e.g. step 2.1 of the PII Resource Kit (Pacific Invasives Initiative, 2011), or through a scoping exercise (The Nature Conservancy, 2017; Flora and Fauna International, 2009). However, it is likely that if external funds are to be sought for an eradication, partners may need to be identified even sooner than this. As part of considering the composition of a partnership, it can be useful to consider the implications of excluding a particular organisation or group and how this could affect the outcome and the other partners. For example, excluding local people from a partnership could lead to mistrust from funders and external agencies as well as the community themselves, or even prevent the project from going ahead.

Often, there may be little or no choice about who to work with, for example it is often necessary to work with a local government agency, or the island owner. In some cases, they could be reluctant partners at first, but may become more engaged when they see the benefits of the relationship. This engagement could take a long time to achieve, and in some cases may never be possible. In other cases, partners may be willing, but there may be high costs connected to their involvement. Thinking ahead about the costs and benefits will help in considering whether a partnership is appropriate, and in minimising the costs and maximising the benefits (Flora and Fauna International, 2009).

The level of intensity of partnership that is desired should also be considered. Some partnerships are short-term, and relatively informal relationships, whereas others may develop into strategic long-term, organisation-wide relationships. It is also possible for any partnership to break down before its objectives have been achieved. A plan for how to deal with such a break should be included in the partnership agreement or memorandum of understanding (see discussion below).

Key elements of strong partnerships

Although there is a diverse range of organisations involved in island restoration work worldwide, the elements required for partnerships are the same. It has been suggested that the key principles of equity, transparency, and mutual benefit should apply to most partnerships (Tennyson, 2011). These principles provide a foundation on which the partnership can operate. In order to build this foundation, those forming new partnerships should consider the following in particular: good communication; clearly defined roles; appropriate leadership, staffing and personalities; clear, shared vision and expectations; and clarity over funding and resource issues (Wilson, 2005; Tennyson, 2011; Ozarski, 2015).

One basic tool that most partnerships use is a written partnership agreement (also referred to in some cases as a memorandum of understanding or memorandum of partnership). Partnership agreements can vary widely in their level of detail depending on the complexity and aims of the partnership and the degree of formality but should, at a bare minimum, define the boundaries of the partnership. Partnership agreements should cover the areas set out below and may include others, depending on the specific needs of the project.

As previously noted, one of the main characteristics of partnerships is that the partners are working towards a common aim. Where a group or individual has an interest in delivery of an island restoration project but is not as committed to the same goal as others, a partnership should not be formed – this could lead to confusion and frustration. The project team should seek to maintain a good relationship with such stakeholders but should not force an inappropriate partnership.

Good communication

When partnerships do not work, poor communication is often blamed. Effective communication is essential to move projects forward, especially in partnerships where partners may have different motivations and expectations. Setting out a shared communication strategy is recommended within partnerships. General principles of communication for partnerships (after The Nature Conservancy, 2017) include:

- be timely in communication;
- brainstorm new issues;
- be consultative, not dictatorial;
- be flexible;
- document agreements and plans, and revisit, adjust and adapt as the situation changes;
- a policy of "no surprises".

In addition to these principles, it is important to respect cultural and organisational differences and challenges when communicating. Communication methods should be adapted to suit each partner organisation's strengths and weaknesses, e.g. emailing high resolution newsletters to communities with limited internet access is not effective communication.

Partnerships may be formed for many reasons. These may include the development of fundraising support, advocacy, avoiding bureaucracy, the need for landowner and resident buy-in and support, resource sharing, research, provision of expertise, and to enable different organisations to gain project experience, perhaps building towards their own projects in the future. All of these reasons are legitimate; however, it is important that all partners are clear about their own and other partners' motivation, and the scope of each partner's involvement. It is only ongoing communication that will enable this clarity. At times, some partners may also need to operate transparently outside the scope of a partnership, for example, government agencies which may also have a regulatory role. If the scope of each partnership has been clearly established and communication is clear, this should be possible.

It is important to include positives in communication. Even though project planning and implementation is challenging, project teams benefit from celebrating successes, recognising achievements, and saying "thanks". It is important to ensure dispersed partners are all able to take part in celebrations and reflect on the achievements and progress being made.

It is also important to consider the way in which a project will communicate itself externally. Publicity and "branding" can often be stumbling blocks in partnerships, and many projects have developed their own brands, independent of the partner organisations (e.g. the Isles of Scilly Seabird Recovery Project). Early decisions on shared messages and how to acknowledge partners and supporters can help to avoid issues later on.

Clearly defined roles and responsibilities

It is extremely important that the partners in any island restoration project understand their respective roles and what is expected of them. The roles and responsibilities of different organisations will vary over the course of the project and it is important that all partners understand how their roles and those of other partners will change over time. This is particularly important in the planning and post-operational phases of the project where roles may be less obvious.

Communities, local and non-local NGOs, and local and non-local government agencies may all have a role. In federal systems, it may also be necessary to involve different levels of government (e.g. the Macquarie Island pest eradication project involved both the Tasmanian State Government and the Australian Federal Government, or in the UK Overseas Territories where local and UK governments may play a role). In the Macquarie Island pest eradication project, the funding agreement between the Tasmanian and Australian Federal governments outlined that funding was joint, but that implementation was a Tasmanian government responsibility. Based on that agreement there was no confusion over operational roles. Without such clarity, multiple partners and stakeholders may perceive themselves to have decision-making authority leading to confusion and potentially to operational difficulties.

In order to minimise this sort of confusion, most projects develop some sort of partnership agreement or Memorandum of Understanding. This may be legally binding in some partnerships. However, even if roles are clearly set out in writing, it should not be assumed that all project partner staff who are participating in meetings or in project teams are aware of these roles, and they may need to be reiterated and revisited many times. Templates for developing project partnership agreements are available from Flora and Fauna International (2009), The Nature Conservancy (2017) and in the Partnering toolbook (Tennyson, 2011). None of these are specific to island restoration projects, and it would be useful if practitioners could develop and share resources in this area in the future.

Sometimes the project plan can be effective as a partnership agreement. All projects should have a clear plan which clearly describes the agreed roles and responsibilities of all partners. A good reason to have a partnership agreement is when a partnership is likely to go beyond the scope of a single project.

It is also important to set out the roles and responsibilities for the various advisory and steering groups that will be developed within most partnership projects, each of which may involve a subset of the project partners. Terms of reference for these groups have been developed by many projects but, as with partnership agreements, they are not yet generally shared. Developing such a resource would be of great use to future projects, and this could be hosted on websites such as those of the Pacific Invasives Initiative (section now in development) or the Great Britain Non-native Species Secretariat.

Leadership, staffing and personalities

As with any endeavour, the people involved are a major factor that will lead to the work being enjoyable and effective, and the success of any island eradication project will largely depend on the skills, dedication, and attitude of the team involved. If a project is being carried out by a single agency, then that agency can recruit a team made up of the most suitable/experienced people available and although there may be some personality issues during the project implementation period, it should be possible to manage these as part of normal business practices.

However, when working in partnership, there can be pressure to include representatives from different organisations in teams despite substantial differences in experience and culture. In addition, the representatives of the partner organisations who should meet regularly to discuss project planning and implementation may have differing views and experiences. If one organisation/individual has been leading/driving the project for some time prior to implementation, they may have particularly strong opinions on how things should be done, and this could lead to clashes with others.

Personality clashes and power struggles can derail an operation, and lead to breakdowns in organisational relationships if left unaddressed. Whilst large organisations may have the capacity to replace staff that are causing difficulties within a partnership, smaller organisations may not have this ability. Individuals who may be skilled at motivating others and providing leadership within a project may not always be best suited to developing and maintaining complex project partnerships and vice versa.

Most partnerships require more management time than anticipated. If a particularly wide partnership is necessary, it may be necessary to bring in new staff whose job is primarily to service the partnership in terms of communications and logistics. Organisations that are planning large projects with complex partnerships should consider recruiting personnel who have skills and experience in this area and can complement the technical skills of the operational management team.

If possible, organisations partnering in island restoration projects should aim to involve more than one staff member in each project so that there is a chance to review decisions and assess how the partnership is developing, and to assist continuity in case of staff turnover. If problems arise, each partner organisation should have a clear understanding of how they can raise concerns and address them at an early enough stage to avoid a complete breakdown of the partnership and potentially of the whole project.

Clear, shared expectations

As discussed above, organisations may enter into partnerships for a variety of reasons and with a variety of expected benefits. Additionally, motivations for wanting to be involved may be very different, even if the ultimate goal is shared. At the start of the partnership relationship, organisations should work to establish their shared goals and vision for the work to be undertaken. They should develop a project plan or agree the process that will be used to develop this. They should set out guidelines for decision-making and what will happen in the event of disagreements. It is also helpful to agree on a formal grievance process before a dispute emerges.

One area where there seems to be particular potential for a mis-match of expectations is in relation to pre-eradication preparation. It is important to make clear plans regarding who will make an island "ready" for eradication, e.g. track cutting, removal of waste, informing residents, leading on any research, etc., as well as who will fund this work. Sometimes preparation can take a long time, and it can be difficult maintaining enthusiasm and energy throughout this phase.

There must also be clear expectations about how the partnership will move on, in the event of either success or failure of the planned eradication operation. Partners should be clear on: who will assume responsibility for reviewing the project, and for a repeat attempt if necessary; how failure will be communicated and who will lead on this and whether the partnership will be expected to remain in place until a repeat operation is planned and concluded. It is good practice to build in a review point for partnerships at a key milestone (e.g. once an eradication operation is completed) to assess how well the partnership has progressed, whether all partners have met their commitments, etc. The outputs of this process could inform the organisations if they are considering extending the partnership to cover further projects.

Project plans for eradication projects often conclude two years after on-island operations cease, or when the island is declared officially 'pest-free'. However, in many situations, site managers or residents will need to remain engaged with projects in the longer-term, for monitoring, biosecurity, or to begin more intensive restoration efforts such as the reintroduction of threatened species. Partners should make their plans clear as soon as they can, as if some partners plan to withdraw from working on the island post-eradication, it may be necessary to introduce new partners to assist in post-project site management. In particular, it is extremely important to be clear about who will be responsible for maintaining monitoring and biosecurity arrangements after the eradication project is complete, and who will respond in the event of a pest incursion (either of the pest that was eradicated, or something entirely new).

Clarity over funding and resource issues

It is good practice for partners to share information on their planned contribution to a project, including cash and non-cash (in-kind) contributions. Some contributions may be invisible to those partners who are not directly involved. For example, a partner who is taking the lead on drafting legal contracts may be spending time and money on expensive services, but another partner may be completely unaware of this activity. Project budgets should ideally take account of in-kind contributions of time from all project partners, as well as cash contributions from donors. A clear project plan (as discussed above), and a designated project manager are important to ensure all partners know what contribution they are expected to make. Clear governance of a partnership is also important so that the project manager is given clear accountability and responsibility for deliverables and is not told to do different things by different partners.

Joint fundraising can be a problematic and difficult area for many partnerships. Partnerships should aim to develop a collaborative fundraising agenda with mutually agreed messaging. There should be clarity over which partners have responsibility for donor cultivation and management, and how donors will be managed after the project has concluded to avoid perceptions of "donor poaching" (The Nature Conservancy, 2017).

Partners need to be clear on what financial disbursement or opportunities they expect from the project. For example, if local communities wish for project supplies to be purchased from local outlets, this should be flagged early so that any increased costs associated with this can be dealt with. If government agencies expect to charge fees to the project (or conversely will waive standard fees) these expectations should be raised and addressed early on to avoid budgetary shocks.

CONCLUSIONS

The days of single agencies implementing island restoration projects may be waning, as islands with human populations, mixed tenure, complex legal status and multiple stakeholders are now high on international priority lists for future operations (Oppel, et al., 2011; Dawson, et al., 2015; Stanbury, et al., 2017). Operational managers and organisations committing to carry out these operations in future need to be aware of the skills and the level of time needed to maintain partnerships, and the potential pitfalls. Recent experiences have served to illustrate that partnerships can deliver immense gains for conservation – without them, we would not have seen recent operations on Vahanga, Antipodes, Palmyra, Desecheo and the Isles of Scilly (as just a few examples).

Lessons from particular partnerships for island restoration projects may be captured in grey literature such as project review documents, but there is little openly accessible material available about best practice in this area. It would be very helpful to future project managers if review documents and templates for partnership agreements could be shared openly with others. Websites such as those for the Pacific Invasives Initiative or the Great Britain Non-Native Species Secretariat could usefully host this sort of information.

Although working in partnerships can be very challenging at times, it is apparent that island restoration will only continue to deliver benefits worldwide if its practitioners are able to work together and draw in new organisations. By considering the elements of partnerships early in the process, we hope that more operations will be “matches made in heaven” and a shotgun will seldom need to be drawn from the figurative cupboard.

ACKNOWLEDGEMENTS

We would like to acknowledge the organisers of the Island Invasives Conference 2017 for including this paper in the conference programme. Thanks to the audience at the conference, and those who took the time to comment on the presentation. Two anonymous reviewers made comments on the paper which improved it substantially. Finally, thanks to all in the island eradications community for your interest in developing and improving the way we work in future partnerships.

Abstract Lord Howe Island (LHI) is a World Heritage listed volcanic remnant island, 600 km from mainland Australia. Home to many threatened endemic species, and an important nesting site for many migratory seabirds, LHI is also home to an established community of 350 people. The island economy relies heavily on tourism, based around the World Heritage landscapes, and terrestrial and marine biodiversity. The impact of rats and mice on the world heritage values of the island are well documented. A feasibility study in 2001 considered the eradication of both rats and mice on the Lord Howe Island Group (LHIG) in a single operation as feasible and achievable. Since then, numerous studies and community consultations have been undertaken; and the methodology, risks and benefits of an eradication effort have been carefully considered and evaluated. The project has long been topical in the community, with both ardent support and opposition. Though funding for the project was secured in 2012, implementation of the project has had repeated delays, and consequently, additional consultation efforts, studies and assessments have been required to address lingering community concerns. This paper describes a wide range of techniques that were used in an effort to gain community support and acceptance of the project, and ultimately, to enable its implementation. The paper also outlines those aspects of the social process that have led to greater support and those which led to less support and, in some cases, opposition. Within these lessons learnt, the paper presents some insights around how communities engage with and respond to scientific information and pest control (including perceived influence on livelihoods, conservation, health and the legacy to be left for future generations). These insights are explained in the context of psychological processes such as emotional responses (fear/trust) and personal values (economic, environmental, social). Given that the eradication of invasive predators on larger inhabited islands is the next logical step for island conservation, projects such as the LHI Rodent Eradication Project are of particular value as real life hard-earned lessons. We hope that these findings can help facilitate future successful island eradication programmes that work with the community.

Keywords: community, economic, engagement, human health, inhabited, tourism

INTRODUCTION

Purpose

The purpose of this paper is to present a case study of eradication planning on an inhabited island, illustrating the importance of social impact considerations and presenting some guiding principles and lessons learnt.

The island

Lord Howe Island (LHI) is located 570 km east of Australia (Fig. 1). It covers 1,455 ha, is 12 km long, and 1.0–2.8 km wide. The LHIG was listed as a World Heritage Area in 1982 and is located within the Lord Howe Island Marine Park (NSW).

LHI is part of the State of New South Wales and is administered by the Lord Howe Island Board (LHIB), which comprises four locally elected islanders and three ministerially appointed mainland members. The LHIB (and its administrative arm) are directly responsible for the care, control and management of the island's natural values and the affairs and trade of the island and carry out all local government functions on behalf of approximately 350 island residents.

The settlement area covers about 15% of the island (400 ha) and is used predominantly for residential, pastoral/agricultural and commercial purposes. Tourism is the most significant industry and major source of income on the island and is heavily focused around the world heritage values of both the marine and terrestrial environments (Lord Howe Island Tourism Association, 2015).

Current impacts of rodents on LHI

Ecological impacts

The devastating ecological impacts of introduced rodents on offshore islands around the world are well documented (Groombridge, 1992; Towns, et al., 2006; Jones, et al., 2008). Similar impacts on LHI have been observed since the arrival of mice (*Mus musculus*) in approximately the 1860s and ship rats (*Rattus rattus*) via a shipwreck in 1918. The Lord Howe Island Biodiversity Management Plan (DECC, 2007a) summarises the immediate and ongoing impact the introduction of rodents has had on flora and fauna species on LHI, including extinction of several species of birds, plants and invertebrates.

Socio-economic impacts

From the perspective of the human population, rats and mice are major domestic pests. They infest residences, destroy foodstuffs and vegetable gardens; and contaminate homes with excrement. They are also a known health risk to humans as they harbour and transmit diseases and parasites such leptospirosis and rat lungworm disease (Shiels, et al., 2014).

From an economic perspective, rats cause considerable economic loss to the island's kentia palm industry, with predation of seed as high as 30% (Parkes, et al., 2004) severely reducing seed production (Pickard, 1983; Billing, 1999; further detail in Wilkinson & Priddell, 2011).

Tourism, the LHIG's main industry, is based on the islands' unique biodiversity and World Heritage values. These values are significantly threatened by rodents (IUCN, 2017) therefore reducing the visitor experience offered by the island.

History of rodent control on LHI

Islanders and the LHIB have been involved in the control of rodents (rats and mice) on Lord Howe Island since about

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 522–530. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

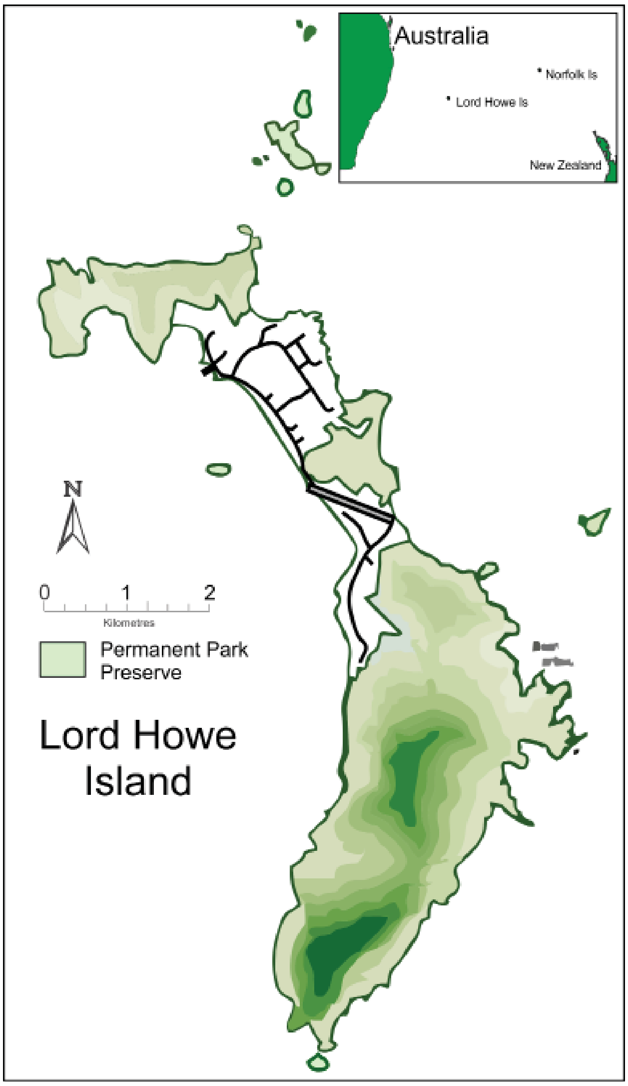

Fig. 1 Lord Howe Island showing the Permanent Park Preserve, airstrip and roads.

1920, highlighting both the long-recognised impacts of rodents and difficulty in achieving meaningful outcomes through ongoing control on the island (Saunders & Brown 2001). Previous control methods included a bounty on rat tails, hunting with dogs and shooting, introduction of owls and the use of various poisons including barium chloride, diphacinone, warfarin and brodifacoum (ibid). Control baiting on the island has undergone several reviews over time with Billing (1999) the most recent, resulting in a current pulse baiting schedule delivering over 4.5 tonnes a year of Ratex (coumatetralyl) and Roban (difenacoum) over approximately 10% of the island. While the use of brodifacoum has been discontinued by the LHIB in the lead up to the eradication, many Island residents continue to use brodifacoum-based rodenticides such as Talon™ and Tomcat™ to control rats and mice around their properties and inside dwellings. The above is intended to highlight the long-term and extensive use of rodenticides on the island, which could be avoided through a one off eradication, but also to highlight that the use of poison on the island is not new and residents are quite familiar with it.

The project

The LHIB is proposing to undertake the Lord Howe Island Rodent Eradication Project (LHI REP) to eradicate introduced rodents from LHI. A secondary outcome would be eradication of the masked owl (*Tyto novaehollandiae),* which was deliberately introduced to LHI in the 1920s and 1930s to control rats. The species now also preys on on many island birds (Milledge, 2010).

The one-off eradication proposes to distribute a cereal-based bait pellet (Pestoff 20R) containing the toxicant brodifacoum across the LHIG via dispersal from helicopters to the uninhabited parts of the island, and by a combination of hand broadcasting and the placement of bait in bait stations in the settlement area (for more information, see LHIB, 2016). Post eradication, rodent prevention and surveillance monitoring would be ongoing to prevent reinvasion and would need a high level of community vigilance.

The LHIB received significant funding (AUS$9.5M) in 2012 for planning and implementation of the REP from the Federal Government's former Caring for Our Country programme (now National Landcare program) AU$4,500,000 and the NSW Environment Trust AU$4,542,442.

PROJECT DEVELOPMENT AND EARLY CONSULTATION

During the turn of the century, successes in island eradications undertaken primarily in New Zealand (summarised in Russell & Broome (2016)) were gaining international attention. At the same time there was growing recognition by government in Australia (state and federal) of the impacts of rodents on LHI (summarised in NSW Scientific Committee, 2000; TSSC, 2006 and DECC, 2007a).

In 2001, a LHIB staff member and a community member attended an international eradication conference and subsequently submitted a proposal to the LHIB seeking support for research into feasibility of eradicating rodents on LHI. This led to commissioning of a feasibility study (Saunders & Brown, 2001) jointly funded by the LHIB and WWF. Saunders and Brown concluded that eradication on LHI was feasible using a combination of aerial broadcast, hand broadcast and bait stations with a brodifacoum based product. Based on some initial consultation undertaken with community on the island during the study, it was considered that the socio-political environment on LHI was conducive to supporting a possible eradication. The study identified potential ecological and social risks and gaps that needed to be further explored and recommended key next steps including:

- a cost benefit analysis
- additional field trials on rodent densities, bait uptake and non-target species impacts
- that a process be established to allow the community to be kept informed and be able to influence decisions
- establishment of a Taskforce to drive implementation
- the feasibility report be made available to the community and briefing sessions provided.

Following the feasibility study, a Rodent Eradication Taskforce was established by the LHIB through an "expression of interest" process in the community, meeting initially in 2002.

Receipt of a donation (ca. AUD$34,000) from the Foundation for National Parks and Wildlife allowed commissioning of a Cost Benefit Analysis (Parkes, et al., 2004). The study looked at additional feasibility, risks and benefits of eradication on LHI and again confirmed that eradication was feasible and highly beneficial, provided risks could be appropriately managed and funding and approvals obtained. The analysis identified social constraints suggesting that people may oppose any proposed eradication attempt at two levels: some may not see the need to attempt it, while others may disagree with the methods required. A process to involve the LHI community in considering options and an active process to seek agreement for baiting on properties and in houses was recommended in the study, but not detailed.

For several more years the LHIB sought funding to deliver facilitated community engagement and on island trials prior to implementation of the REP. Further funding (ca. AUD$ 200,000) was secured in 2008 from the Australian Government Caring for our Country Program to continue planning and trials, community consultation and engagement of a project manager. Consultation in 2008 included several rounds of public hall meetings including:

- specific sessions for livestock, poultry and dog owners
- for residents on the fringe of the settlement area where special consideration are required
- follow up sessions to address concerns previously raised.

A theme emerged that the meetings quickly disintegrated as some community members become vocal and dominating, particularly those opposed. Over several meetings, this led to a reduction in numbers of attendees. It was also unfortunately stated by a scientist at one of the public hall meetings at the time that “the eradication would not go ahead unless there was 100% support”. This created an undeliverable promise still haunting the project today.

Ad-hoc consultation also occurred through development of fact sheets, individual meetings and through briefing papers and updates at Board meeting open sessions.

Based on recommendation in Saunders & Brown (2001) and Parkes, et al. (2004), additional studies were also conducted on the LHI currawong (Carlile & Priddel, 2006) and non-toxic field trials (DECC, 2007b) that examined rodent and non-target species uptake of the bait pellets, bait breakdown in the environment and spread of the bait using helicopter.

In July 2009, locally elected Board members went door to door surveying residents on their views and concerns regarding the REP based on set questions. In total 125 residents were interviewed and detailed responses showed that there was sufficient community support to proceed. The survey results were used together with results of field trials to develop the Draft LHI Rodent Eradication Plan (LHIB, 2009) which then underwent external peer review. The Draft Plan was peer reviewed by the Island Eradication Advisory Group (IEAG) of the New Zealand Department of Conservation; the Invasive Species Specialist Group of the Species Survival Commission of the World Conservation Union; the Worldwide Fund for Nature (WWF), Australia; Birds Australia; Landcare Research, New Zealand; CSIRO and Professor Tim Flannery. All peer reviews of the Plan were supportive.

Public comment on the Draft Plan was sought in November 2009. Of the 83 submissions received, 39 submissions opposed the Plan, 33 supported it, four gave in-principle support, while one submission was undecided. All 39 submissions opposing the Plan were from LHI residents, organisations acting on their behalf, or had strong links with LHI community members. Of the 37 submissions supporting the proposal, 11 originated from LHI, and four came directly from scientists or scientific groups with experience in rodent eradication. All four submissions giving in-principle support originated from LHI as did the single undecided submission. It should be noted that 84 submissions is considered a very high level of response on LHI.

The most frequently raised issue (25 submissions) was concern about non-target impacts during the proposed eradication operation. Other dominant issues included concerns about possible impacts on the health of the community, the tourism industry and the marine environment, as well as the need for improved consultation. The most commonly mentioned issue supporting the Draft Plan was that eradication would deliver clear environmental benefits to LHI (13 submissions) (see Table 1).

The submissions provided a valuable snapshot of opinion, setting the direction for future studies and consultation for the project once additional funding could be secured. A submission analysis report was prepared but unfortunately due to not being able to secure funding for consultation, was not released to the community until 2013. A revised Draft Plan was also prepared addressing submissions but was never released, for reasons unknown.

One study that was progressed immediately was a Human Health Risk Assessment (HHRA) undertaken by a toxicology consultant Toxikos (2010). The HHRA considered all potential pathways related to direct and indirect contact with the poison from the REP (e.g. ingestion, inhalation, skin contact, ingestion of contaminated water and food) and found there to be no significant risk associated with any pathway with the proposed mitigation in place. The HHRA was presented to community and helped to satisfy some community concerns. However, although the LHIB undertook a competitive tender process to select the consultant Toxikos, some members of the community criticised the independence of the study and therefore disregarded the results. Subsequent third-party reviews of Toxikos’ HRRA by New South Wales Health, South Australian Health and Pacific Environment Pty Ltd (outlined in LHIB, 2016) did little to change the perception of some community members.

From 2010 to 2012 the LHIB continued to seek staged funding for progression of the REP. In May of 2012 it was recognised by the Board, that despite information provided to date it was clear that community concerns remained, and further work was required to address these. To enhance community awareness of the benefits that eradication would deliver for the environment, tourism and public health, it was recommended that a professional facilitator be engaged to consult with the LHI community. It was also recommended that a Community Liaison Group (CLG) was created. In June 2012 the project manager at the time resigned.

In July 2012, the LHIB received funding of AU$9.5M to implement the REP in full from the New South Wales Government’s Environment Trust and the Australian Government’s Caring for Our Country programme. The project was divided into three stages:

- Stage 1 – to complete all planning and preparations for the eradication operation
- Stage 2 – to implement the baiting strategy including captive management and post baiting monitoring
- Stage 3 – to monitor the environmental outcomes of the baiting operation.

Again, unfortunately, receipt of the full funding at once led to some perception in the community that the REP was a *fait accompli* and no longer open for community discussion.

In late 2012, a selection process for engaging a community consultation facilitator was undertaken. This included involvement of Board members and 13 community panel members to choose an applicant that would be able to "connect" with islanders. Two shortlisted consultants travelled to the island and were interviewed individually by the 13-member community panel. Consultants 'Make Stuff Happen' were selected and contracted to establish the CLG and, together with the CLG, to develop a draft Communication and Community Engagement Strategy. The CLG (12 members from 17 nominations) held their first meeting on Friday 8 February 2013. Terms of reference were to:

- Review REP information so it is clear, correct and relevant
- Identify ways to communicate with the community about implementing the REP
- Discuss issues and concerns about the REP

Additional meetings were held in March, April and June 2013, facilitated by the consultants. These meetings, whilst unpicking community issues also brought to light that community support: opposition was approximately 50:50. A Community Engagement Report and Plan (Make Stuff Happen, 2013) was developed recommending:

- Providing sufficient resources to restore trust and information flow
- Maintaining the momentum of the CLG and relationship with the LHIB
- Creating a compelling case by focussing on key drivers of change
- Providing content information at different levels
- Providing a variety of options for *how* information is received focusing on small scale approaches
- Demonstrating respect for community concerns and local knowledge.

Further detail can be found in the report (Make Stuff Happen, 2013).

As a recommendation of the report was to try and build support, the consultant facilitated an "open house" bringing experts relevant to the eradication to LHI in Aug 2013. This included a toxicologist, a medical doctor who has worked on eradications (Macquarie and South Georgia), an animal husbandry expert and project staff. Experts were available separately at small tables where community members could sit and ask questions of them over two days. This was held in the neutral ground of the museum and was attended by about 65 residents. Some individuals, however were known to actively boycott the event.

Additional activities in 2013 included:

- Meeting with Tourism Association to discuss risk analysis
- Targeted discussions with specific businesses related to tourism issues
- Key messages refined and communicated through a variety of means.

Following the open house, 'Make Stuff Happen' provided additional recommendations and proposed a Stage 2 engagement strategy to the LHIB. However, given the value of the contract, it had to be retendered on the open market.

Table 1 Key issues raised in submissions to the 2009 Draft Rodent Eradication Plan.

Issue	Number of submissions	% of submissions
Non-target impacts	25	30.1
Human health concerns	18	21.7
More consultation required	18	21.7
Tourism impacts	16	19.3
Marine impacts	14	16.9
Economic impacts	13	15.7
Eradication will deliver environmental benefits	13	15.7
Proposed eradication too risky	10	12.0
Children's health concerns	9	10.8
Threat posed by negative media associated with eradication	9	10.8
Question rodent impacts	8	9.6
Feasibility – it won't work!	8	9.6
Captive management issues	7	8.4
High cost of operation	7	8.4
Use of divers to remove bait	7	8.4
Rodents have significant impacts	7	8.4
Don't support aerial baiting	6	7.2
Peer review process flawed	6	7.2
Quarantine efficacy – new protocols to prevent reinvasion	6	7.2
Expand current control programme	5	6.0
The eradication is an experiment	5	6.0
Need to work with community to gain support	5	6.0
Distrust of Board	5	6.0

In recognition of the differing views within the community putting successful implementation at risk, the LHIB decided in early 2014 to put the proposed eradication on hold, and to go back to the community and to discuss the available options. The Board made the decision to divide the project into two separate but linked stages.

Stage One: community engagement and consultation which would go back to basics and ask what the community wants in relation to the eradication of rodents so that they can make an informed decision on the future of the project. This included the consequences of not doing the eradication. At the completion of that process an assessment was to be made of the level of support to gauge whether it is sufficient to progress to Stage Two.

Stage Two: operational implementation, which would commence in June 2015, but would only take place if there was sufficient community support for the project following the consultation process.

The tender process to select a consultant for the additional community engagement was undertaken with the assistance of the Department of Premier and Cabinet in early 2014 with Elton Consulting selected. Between July 2014 and February 2015, Elton Consulting undertook a series of community consultation visits to Lord Howe Island. They spoke on a one-on-one basis, through personal visits or open sessions at the public hall, to many island residents, (on a number of occasions) concerning the issue of rodent control and potential eradication on the island. They implemented an incremental approach to consultation to unpack the complexity of the community response to the previous rodent eradication process, and to identify what it would take for the community to actively engage in the evaluation of alternatives and options, with the aim of obtaining community support or endorsement of one of the options.

A Community Working Group (CWG) was established, based on residents who indicated a willingness to participate, along with an open call for nomination / involvement, put out through a newsletter to community residents. In working towards a solution, the CWG identified many issues (particularly regarding human health, potential impacts to business and tourism and potential impact to the environment) and considered a range of options. The option to "do nothing" was generally not considered as an alternative, as there was broad agreement that rats and mice are a problem, and that Lord Howe Island would be better off with no rodents.

Two scenarios were therefore further investigated and discussed:

1. Ongoing control through the existing baiting program, and the potential to expand this.
2. An eradication programme as previously proposed or modified where possible to address island residents' concerns.

The CWG agreed to develop and implement a community survey to test community support for these scenarios, whilst recognising that many of the community concerns with the proposed eradication could be addressed during the Planning and Approvals Phase. The CWG also agreed that an additional independent HHRA was needed and should be progressed.

In May of 2015, an options paper (Elton Consulting, 2015a), providing detailed explanation of options and answers to key questions, was disseminated to all people registered on the electoral roll for Lord Howe Island, together with an anonymous survey (Elton Consulting, 2015b) to allow the community to choose between:

Option 1 – Retain and expand the current management programme

Option 2 – moving to the planning and approvals stage of an eradication programme.

The survey also asked for level of agreement on whether the rodent problem needed to be addressed and ranking of areas concerns for both options.

A total of 212 respondents (71% of the 299 people on the electoral roll) participated in the survey. 208 survey responses were received before the closing time. A consensus was reached that the rodent problem on Lord Howe Island needs to be addressed with the majority of respondents (91%) agreeing (38%) or strongly agreeing (53%). A marginal majority 52 of the respondents expressed a preference for Option 2, while 48% of respondents expressed a preference for Option 1.

In line with the agreed Process for Resolution (Fig. 2), the LHIB responded to the majority view and on 19 May 2015 made the decision to proceed to the Planning and Approvals Phase (Option 2).

PROGRESSING TO IMPLEMENTATION

Since 2015, the project team focussed jointly on progressing the necessary approvals and operational planning; and continuing to increase community support for and/or acceptance of the REP, recognising that some people who may not support the REP would however accept it. The latter is critical to ensuring that baiting can be conducted on every property on the island. Residual community issues and how we are attempting to resolve them are detailed below.

Human health

Safety of people has always been a priority for the LHIB and the community when considering the LHI REP. Given the criticism of the independence of the original HHRA described previously, the community suggested that a further additional study be undertaken.

The NSW Office of the Chief Scientist and Engineer (OCSE) was identified by the community / CWG as an agency with a high level of independence and credibility and was subsequently requested to oversee an additional

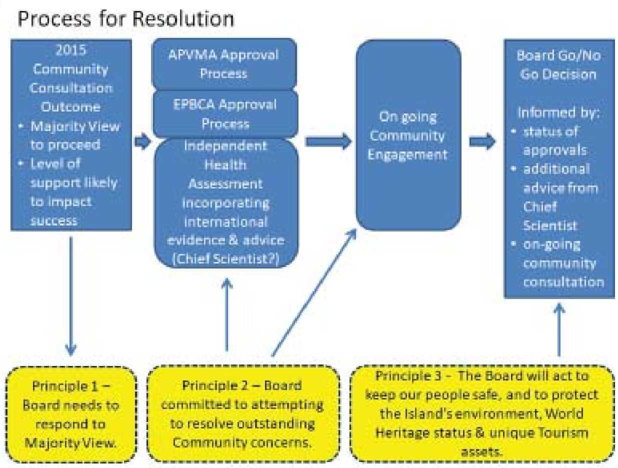

Fig. 2 The agreed process for resolution.

independent HHRA for the project in line with the agreed Process for Resolution (Fig. 2). The OCSE was requested by the NSW Minister for the Environment to convene an Expert Panel in 2016 to:

- Provide advice to the Board on processes for commissioning the HHRA including identification of suitable experts and scope of the request for proposal. (The CWG endorsed the Scope.)
- Review proposals to undertake the HHRA and select a preferred candidate; review project plans and methodologies, and review draft and final reports of the HHRA as required. (Proposed membership of the panel was endorsed by the CWG.)
- Provide advice to the Minister for the Environment on the HHRA.
- Respond to media enquires as they relate to the Terms of Reference for the Expert Panel.

The Expert Panel (with the assistance of two nominated CWG members) selected Ramboll Environ Pty Ltd. to undertake the HHRA. This work, overseen by the OCSE, concluded that estimates of exposure from all potential sources associated with the REP are below those likely to result in adverse health effects for residents and visitors. (Ramboll Environ, 2017).

The outcomes from this additional HHRA and expert panel review concur with the results of previous HHRA undertaken by Toxikos Pty Ltd (2010), which found that, with the proposed mitigation in place, the REP would be safe for the community and visitors. Whilst the outcome was the same as the previous study, it should be noted the process undertaken by the OCSE to select Ramboll was very different to how Toxikos were originally selected, giving the report substantially more credibility within the community.

Economics, tourism and livelihoods

Ongoing concern from some elements of the community regarding potential impacts to tourism (specifically reduction in visitors) before, during or post eradication led the LHIB to commission an economic evaluation of the project in 2016. Community input was sought for the development of the scope of the evaluation and a prominent local business owner was included on the tender selection panel.

A study by Gillespie & Bennett (2017) looked at the costs and benefits (market and non-market services) of not proceeding with the REP compared to the costs and benefits of proceeding (i.e. a Cost-Benefit Analysis) as well as the distribution of said costs and benefits. Though all costs and benefits were considered, particular focus was placed on the potential impacts or benefits to biodiversity (non-market services) and tourism (market service) as the major contributors. This is based on the fact that a key motivation for visiting LHI is to experience the natural, undeveloped and unspoilt surroundings (Lord Howe Island Tourism Association, 2015), some of which are under threat from rodents.

Using choice modelling undertaken for other relevant studies, Gillespie & Bennett (2017) applied the benefit transfer technique to provide an economic value estimate for the biodiversity value of protecting species from extinction. Considering the economic importance of tourism to LHI, tourism impacts or benefits were modelled using supply and demand data in peak and off-peak tourist periods, before, during and after the REP. The study showed that accommodation providers on the island would be the biggest beneficiaries during the REP as the workforce required for the project would more than offset any temporary reduction in tourism. It also showed that tour and accommodation providers would be the major beneficiaries of increased tourism after the eradication. The REP was demonstrated to have a Benefit to Cost ratio of 17:1, resulting in an estimated net social benefit of AU$142M, with AU$58M of that returning directly to LHI residents. Hence, the REP was justified on economic efficiency grounds.

Overall, the cost-benefit analysis was considered an important tool for the REP in overcoming some residents' concerns about tourism and the economy. Others, however, will not be convinced until they actually see the visitors on island during or after the REP.

The eradication method

There has been considerable debate in the community about the method proposed for the eradication and, in particular, the aerial distribution delivery method.

A range of alternatives for eradicating rodents were considered for LHI including alternative techniques and mortality agents. Many were considered to have fatal flaws and were unsuitable for use for eradication on LHI because: a) the technique was not suited to the terrain or size of the island, b) it did not ensure that all individuals would be killed or c) was too experimental. However, early in the project these flaws in alternative methods were not well communicated with the community. The only method identified as capable of removing every rat and mouse on LHI was aerial distribution, in conjunction with minimal hand broadcast and bait stations where required (i.e. the settlement area), of highly palatable bait containing an effective toxicant.

To overcome concerns in the community relating to the method, the project team has recently taken the community through the process of looking at all the options and ruling out options with fatal flaws and therefore not suitable for deployment on LHI (see Table 2). In addition, the project team have undertaken one on one property management plans with all residents to agree the particular baiting method to be used on their property considering their concerns. These two tools have led to a greater understanding in the community of the methods proposed and why other methods were unsuitable.

Environmental and non-target impacts

Some members of the community have been concerned about environmental and non-target impacts. We have used a combination of methods to help allay concerns including:

- Undertaking monitoring on the island to provide evidence of rodent damage to a range of species on LHI and communicated those results back to the community regularly. We have found that a single photo of a rat taking a seabird chick or egg at a local nesting ground to be much more powerful than scientific reports of images of rodent damage locally or images from other locations around the world.
- Conducting a range of studies on the island to determine locally at-risk species and those not at risk (detail in Wilkinson & Priddell, 2011) and repeatedly communicating the results to community.
- Engaging world experts in captive management to manage the captive management programmes on LHI for the two high risk species and conducted trials on-island to show the community how the species can be managed without harm (Taronga Conservation Society, 2014).

Table 2 Assessment of eradication options.

Eradication technique	Suitable for eradication	Feasible for eradication on LHI	Justification
Disease	No	No	No suitable pathogen yet developed that could eliminate all individuals.
Trapping	Yes	No	May be feasible for eradication on small islands, however may cause individuals to become trap shy. Size and inaccessible terrain of LHI makes this option unfeasible.
Biological	No	No	Currently experimental. Likely to fail to completely eradicate the target species.
Fertility Control	No	No	No suitable fertility control yet developed that could eliminate all individuals.
Toxicant – bait station / hand broadcast only	Yes	No	May be feasible for eradication on small islands. Size and inaccessible terrain of LHI makes this option unfeasible.
Toxicant – aerial broadcast only	Yes	No	Highly successful on uninhabited islands. Socially unacceptable on LHI. Problematic with the number and nature of buildings.
Toxicant – combination of aerial and hand broadcast / bait stations	Yes	Yes	Allows for bait to be made readily available to all individual rodents. Brodifacoum in the form of Pestoff 20R has been selected as the preferred toxicant on LHI considering proven success, efficacy and non-target impacts.

- Talking to the community about the differences (particularly in species) between LHI and other islands where non-target impacts have been observed. This included talking through differences in ecology and feeding behaviour leading to different risk profiles.
- Being open and up front with people about our expectations of non-target impacts, how we have formed those expectations and how those impacts compare to current impacts from rodents.
- Conveying the thoroughness, scientific rigour, and independence behind the environmental assessments undertaken by the various regulatory agencies that have assessment and approval roles on the project.
- Highlighting recovery of species and ecosystems from eradications around the world, through sharing recovery stories, science and media on other eradications.
- Developing appropriate mitigation plans for domestic animals and livestock at an individual level.

Lack of trust

Lack of trust of new people, new technologies, and the LHIB in general, was perhaps the most difficult issue to address. It manifests as suspicion of non-island experts and scientific reports, unwillingness to accept change, spreading of misinformation and criticism of LHIB decisions and communications. It stems partially from a sense of resentment by islanders of Government control of the island. It also stems partially from a history of poor communication and follow through by the LHIB on many issues unrelated directly to the REP. Trust is essential to being able to communicate all aspects of the REP, including new information risk, benefits, mitigation and for people to feel comfortable expressing their true concerns. Trust is not easily given and has to be earnt over a long time through listening, demonstrating genuine interest in all aspects of the community (not just those related to rodent eradication), doing what you say you will and following through on commitments.

The most important mechanism we have found to build trust is to have our core project staff living on the island and living in the community for as long as possible. Our Project Manager and Assistant Project Manager have both been resident on LHI for at least two years. Wherever possible we engaged locals in the project including in communications roles, in advocacy, in adding local knowledge, in brainstorming and in any other aspect where they are willing and able.

CURRENT STATUS

The Planning and Approval phase was completed in 2017. At the Sept 2017 Board meeting, the LHIB made the final decision to proceed with the eradication based on the technical, social and financial feasibility of the project as per the agreed process for resolution that was an outcome of ongoing community consultation in 2015 including:

- the status of approvals
- level of community support
- recommendations from an additional independent HHRA.

In March 2018, a decision was made to delay implementation of the REP until winter 2019 due to not having received one of the permits (previously received and surrendered due to a technical administrative flaw).

LESSONS LEARNT

Planning a rodent eradication project on an inhabited island over a long period of time has given us many chances to reflect on what has worked well and what hasn't and to adapt our strategies over time.

Least effective tools

On reflection, the tools we have found least effective were:

- Having a predetermined solution (eradication by the methods proposed) with little opportunity for genuine community input and influence on the decision-making process at the start. This has left some members of the community disenfranchised.
- Flooding the community with more and more technical, scientific information. While science plays a critical role in providing information and answers, it needs to be provided in a way that key concepts and results can be easily understood, are relatable and align with people's values. Many scientific reports are too technical and too detailed for many people to understand, easily, or relate to. More information is not always better.
- Public Town Hall meetings. We have found that these have generally been dominated by a select minority of people (either supporters or opposition), which leaves many people unheard or losing interest.
- Scientists and ecologists are not always the best at community engagement. Often pure science does not address the emotional issues particularly when they concern people's children or livelihoods.
- Mainland consultants and experts. We have found generally (although not always) poor engagement outcomes where we have flown specialists from the mainland to help with various technical aspects. Often the consultants are there for very short timeframes and may not return. As a result, the required depth of understanding of community issues is often overlooked and, consequently, there is little opportunity to build rapport and trust. While we recognise that subject matter and consultation experts are required, they may be best deployed behind the scenes providing the right advice to the core project team.
- Presenting information from other sites – each community considers their island to be different from all others.

Most effective tools

We have found the most effective tools for communicating with our community to be:

- Having key members of the project team based on the island for as long as possible before implementation. This gives the community the opportunity to get to know the team and start to build trust. An open-door policy allows people to come to the project team at any time to discuss any concerns they have with the project. Being based on LHI also allowed the team to understand the broader issues that face the community and to interact with the community outside of work.
- One-on-one consultation with every resident, repeatedly and as many times as necessary on their properties. This has allowed us to identify individual concerns (and underlying motivations) and work with residents to address them. Working through with residents about exactly how they would like baiting undertaken on their properties considering their concerns (i.e. vegetable gardens, pets, children, etc.) has been critical for getting people comfortable with the project.
- The economic evaluation was an important piece of work as it converted biodiversity values (negative outcomes without eradication and positive outcomes with eradication) into economic (tourism) terms that our community could relate to in a meaningful way (livelihoods) and understand key concepts and implications.
- Independence and credibility of the OCSE in undertaking the HHRA.
- Engaging locals on as many aspects of the project as possible where skills allowed.
- Being patient, passionate, resilient and willing to go the extra mile to succeed. These personality traits of individuals in the core project team are essential to gaining trust in the community.

DISCUSSION

The LHI REP has been a long time in planning and community consultation. Implementation of the project was likely drawn out most due to the fact that early planning and consultation was not done as effectively as it could have been. Additionally, funding was received in full which could have sent the message to the community that the project was a *fait accompli*. This did not engender the initial community support that was essential and has led to a long road to recovery. Though many of the tools from the emerging Strategic Environmental Assessment/ Social Impact Assessment toolbox (Russell, *et al*, 2018) were eventually employed on the project, these were often reactive, not integrated and used too late in the process.

The project would have likely encountered much less community resistance if these tools were used much earlier and in an integrated and methodological fashion. It is likely that the plan that was taken to community was too far developed down a particular path and was therefore considered not open to community input. This meant that it wouldn't have allowed sufficient opportunity for the community to adapt the plan to their needs or to feel a sense of ownership of the plan. Although extensive community engagement has since identified issues, and these were addressed, it would have been much more effective if this was done at the start of the planning process. Early community engagement (not information sharing) to gain support needs to be the top-priority for future eradications.

ACKNOWLEDGEMENTS

The LHI REP is funded by the Australian Government's National Landcare programme and the New South Wales Environmental Trust. This paper provides an update to a previous paper published by Wilkinson & Priddell (2011) and builds on a paper by Hutton, et al. (2016) at the Island Arks 2016 conference.

Thanks to previous and current staff involved in the project. This paper has been prepared with the benefit of hindsight and is by no means criticism of those previously involved.

Abstract The Baja California Pacific Islands, Mexico, are globally important breeding sites for 22 seabird species and subspecies. In the past, several populations were extirpated or reduced due to invasive mammals, human disturbance, and contaminants. Over the past two decades, we have removed invasive predators and, for the last decade, we have been implementing a Seabird Restoration Programme on eight groups of islands: Coronado, Todos Santos, San Martín, San Jerónimo, San Benito, Natividad, San Roque, and Asunción. This programme includes monitoring; social attraction techniques; removal of invasive vegetation; reducing human disturbance; and an environmental learning and biosecurity programme. Here, we summarise historical extirpations and recolonisations during the last two decades of restoration actions, and we update the status of breeding species after more than a decade. To date, from 27 historically extirpated populations, 80% have returned since the first eradication in 1995. Social attraction techniques were key in recolonisations of Cassin's auklet (*Ptychoramphus aleuticus*), royal tern (*Thalasseus maximus*), and elegant tern (*T. elegans*). A total of 19 species breed on these islands, four more species than a decade ago, including 12 new records. The most abundant seabirds, black-vented shearwater (*Puffinus opisthomelas*), Cassin's auklet, western gull (*Larus occidentalis*), and Brandt's cormorant (*Phalacrocorax penicillatus*), have shown a remarkable population increase. Current threats include the potential reintroduction of invasive mammals, guano mining, recreational activities, pollution, and commercial fisheries. To maintain these conservation gains in the long-term it is necessary to continue implementing restoration actions and reinforcing protection on these important natural protected areas.

Keywords: conservation, invasive mammal eradications, population status, seabird recovery, social attraction techniques, threats

INTRODUCTION

Mexican islands and their surrounding waters are key breeding and foraging sites for one-third of all seabird species worldwide, placing Mexico as the third most diverse country and the second in terms of endemism (Croxall, et al., 2012). In particular, the Baja California Pacific Islands (Fig. 1), influenced by the productive waters of the California Current System, support more than a million breeding pairs of 22 seabird species and subspecies (Wolf, et al., 2006). Unfortunately, on these islands at least 18 seabird populations were extirpated, several more diminished from their former abundances, and the Guadalupe storm-petrel (*Oceanodroma macrodactyla*) is presumed extinct due to the presence of invasive mammals, human disturbance, and contaminants that affected their breeding grounds during the last two centuries (Everett & Anderson, 1991; McChesney & Tershy, 1998; Wolf, et al., 2006).

Over the past two decades, we have removed 60 populations of invasive mammals from 39 islands in Mexico, in collaboration with government agencies, academic institutions, fishing cooperatives and a donor network (Aguirre-Muñoz, et al., 2011, 2016, 2018). In the Baja California Pacific, 12 islands smaller than 1,000 ha are now free of invasive predators; 24 populations of cats (*Felis catus*), goats (*Capra hircus*), rabbits (*Oryctolagus cuniculus*), donkeys (*Equus asinus*), dogs (*Canis lupus familiaris*), ship rats (*Rattus rattus*), and deer mice (*Peromyscus eremicus cedrosensis*) were eradicated between 1995–2004 and 2013 (Aguirre-Muñoz, et al., 2011, 2016). Only a small population of house mice (*Mus musculus*) remains on Coronado Sur Island, and white-tailed antelope squirrels (*Ammospermophilus leucurus*) on Natividad Island (Aguirre-Muñoz, et al., 2016).

Seabird surveys, carried out on some of these islands a few years after the eradications, recorded a low number of natural recolonisations (Palacios pers. comm., 2003, Wolf, et al., 2006, Whitworth pers. comm., 2007). In order to attract birds back and improve recolonisation rates, we initiated, in 2008, a Seabird Restoration Programme that includes monitoring, implementing social attraction techniques used successfully elsewhere (Jones & Kress 2012), removal of introduced vegetation for habitat enhancement, and an environmental learning and biosecurity programme with local communities (Aguirre-Muñoz, et al., 2011, 2016). Over the last decade, we have recorded several positive

Fig. 1 The Baja California Pacific islands where seabird restoration actions have been done.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 531–538. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

outcomes after the implementation of these restoration actions that have not been documented yet. Moreover, the last comprehensive compilation of the status of seabird breeding populations on these islands was made more than 10 years ago and needs to be updated (Wolf, et al., 2006).

Here, we summarise historical seabird extirpations for each island and subsequent recolonisations after the implementation of restoration actions during the last two decades and update the status of all breeding species on eight islands groups: Coronado, Todos Santos, San Martín, San Jerónimo, San Benito, Natividad, San Roque, and Asunción.

METHODS

We used historical records of breeding seabirds from published and grey literature to determine the number of extirpated populations and compare the status of seabird populations after the implementation of restoration actions (invasive mammal eradication, social attraction techniques). Current information derives from our own seabird censuses and estimations conducted in 2008–2017 on San Roque and Asunción islands, in 2013–2017 on Coronado, Todos Santos, San Martín, San Jerónimo, and Natividad, and in 2016–2017 on San Benito islands. For surface-nesting species, we surveyed active nests from land-based vantage points, complemented with boat counts and searches around the islands, every 15 days during the whole breeding season. All colonies were mapped and divided into sub-colony sites to increase count accuracy. For burrow-nesting species, we conducted a continuous exhaustive and intensive search of active nests in all potential breeding sites. On islands with accessible nesting sites, we conducted a census all around and across the whole island and checked nest content using a hand-lamp or a borescope. For those species with high nest density such as western gull (*Larus occidentalis*) on Todos Santos Islands, Cassin's auklet (*Ptychoramphus aleuticus*) on San Jerónimo Island, and black-vented shearwater (*Puffinus opisthomelas*) on Natividad Island, we estimated nest densities during peak incubation, counting nests within circular and square plots randomly distributed and georeferenced. Burrow occupancy was determined by recording apparently occupied burrows, i.e. with signs of activity such as guano, feathers, clear entrances, and footprints (Walsh, et al., 1995). Population size was calculated through Bayesian statistics using the total number of nests and occupied burrows (McCarthy, 2007). We included in our counts pairs nesting within artificial colonies installed on all the islands (Table 1).

We analysed the number of recolonisations of extirpated colonies by island and seabird group (surface-nesting species and burrow-nesting species). A recolonisation rate was not possible to estimate as post-eradication surveys were not systematic on many islands until we started our monitoring in 2008. We also present a brief account for each currently breeding species, where we include the maximum number of breeding pairs estimated during our own survey period on each island, except for storm-petrels on San Benito Islands.

Table 1 Social attraction techniques implemented on seabird populations on the Baja California islands, Mexico, from 2008 to 2017. Y = Yes, N = No. *Mirrors were used from 2008–2011.

Ashy storm-petrel	Coronado Norte	2017–2017	Artificial burrows, acoustic playbacks	N
	Coronado Sur	2015–2017	Acoustic playbacks	N
	Todos Santos Sur	2016–2017	Artificial burrows, acoustic playbacks	N

Study area

The eight island groups are located on the continental shelf off the west coast of the Baja California Peninsula, Mexico within 66 km of the coast (Fig. 1). Their climate is Mediterranean to desert-like. The northern islands are characterised by subarctic waters throughout the year while a tropical-subtropical domain persists during summer and autumn in the southern islands (Durazo & Baumgartner, 2002; Durazo 2009, 2015). Natividad (736 ha), San Roque (35 ha), and Asunción (41 ha) islands were designated as part of the El Vizcaíno Biosphere Reserve in 1988 (CONANP, 2000) while Coronado (173 ha), Todos Santos (118 ha), San Martín (265 ha), San Jerónimo (48 ha) and San Benito (541 ha) were recently included in the Islas del Pacífico de la Península de Baja California Biosphere Reserve in 2016 (DOF, 2016).

RESULTS AND DISSCUSION

Recovery and status

In total, according to historical records, 27 seabird populations were extirpated from the 12 coastal Baja California Pacific islands where restoration actions were conducted; Todos Santos, San Martín, and San Roque islands were the most affected islands, with between five to six taxa extirpated on each island. In contrast, San Benito Islands have no historical record of any extirpation (Table 2, Fig. 2). Extirpated species included five burrow-nesting species: Leach's storm-petrel (*Oceanodroma leucorhoa*), black storm-petrel (*O. melania*), Scripps's murrelet (*Synthliboramphus scrippsi*), Craveri's murrelet (S. craveri) and Cassin's auklet; and five surface-nesting species: brown pelican (*Pelecanus occidentalis*), double-crested cormorant (*Phalacrocorax auritus*), Brandt's cormorant (*Phalacrocorax penicillatus*), royal tern (*Thalasseus maximus*), and elegant tern (*T. elegans*) (Table 2). Burrow-nesting species lost 15 breeding populations of which 9 colonies corresponded to Cassin's auklet and Scripps's murrelet that were extirpated from almost all their historical breeding sites in Mexico (Table 2, Fig. 3). Similarly, 12 colonies of surface-nesting species were extirpated, with brown pelican and double-crested cormorant being the most impacted species (Fig. 3).

After two decades of restoration actions, in total, 22 colonies of extirpated seabirds have returned to breed to these islands, which represent 80% of all extirpated colonies. San Martín and San Roque islands are the islands that have benefited the most as currently all extirpated species are breeding again on these islands. Likewise, the species with more colonies extirpated are now breeding on almost all their historic sites (Table 2, Fig. 3). Social attraction techniques were key in recolonisations of Cassin's auklet on Natividad Island; and royal tern and elegant tern on San Roque Island (Table 1).

Moreover, we have recorded 12 new colonisations during the last decade that have never been recorded before, five of them on San Jerónimo Island (Table 2). These new records together with recolonisations have increased considerably the number of breeding taxa on many islands in comparison with the last comprehensive compilation (Wolf, et al., 2006). For instance, San Jerónimo Island with only four species recorded last decade now supports 12 breeding species (Fig. 4). Currently, breeding seabirds on these 12 islands comprise 19 species, four more species than the last record (Wolf, et al., 2006).

The most abundant seabird is the black-vented shearwater, which has a total population an order of magnitude higher than all other species, but is restricted to three breeding sites (Natividad, San Benito and Guadalupe islands). Cassin's auklet, western gull, Brandt's cormorant, and double-crested cormorant are relatively abundant and have a wide distribution. In contrast, elegant tern and blue-footed booby (*Sula nebouxii*) only have one pair nesting in one site (Table 2).

Black-vented shearwater (*Puffinus opisthomelas*)

In the past, the breeding population of black-vented shearwater declined on Natividad Island, its main breeding colony worldwide due to predation by feral cats and habitat destruction (Keitt, et al., 2002, 2003). At present, we estimate a population of 110,000–120,000 breeding pairs, which indicates almost a twofold increase in relation to the last estimation two decades ago (Keitt, et al., 2003). The small population on San Benito Islands of around 100 pairs remains almost unchanged since its last record (Wolf, et al., 2006, Table 1).

Leach's storm-petrel (*Oceanodroma leucorhoa*)

Leach's storm-petrel, considered the most abundant species in the region, currently breeds only on Islote Medio in Coronado Islands and on San Benito Islands (Wolf, et al., 2006), however, its population estimate has not been updated yet. In the last century, it was extirpated from Coronado Norte Island by feral cats (Grinnell & Daggett, 1903, van Rossem, 1915), our surveys indicate that the species is possibly extirpated. In 2016, we captured adults with brood patches using mist nets on San Jerónimo Island, thus, we consider this species as a probable breeder but we have not found active nests.

Ashy storm-petrel (*Oceanodroma homochroa*)

The Coronado Islands are considered the southernmost breeding range of the ashy storm-petrel and the only breeding site in Mexico (Ainley, 1995). This species was considered as a probable breeder on Coronado Norte Island (Jehl, 1977) and at present, our surveys indicate the same, although we have not found an active nest. In the last decade, Islote Medio, an islet historically pest-free, was the only confirmed site with a small breeding population (Wolf et al., 2006, Carter, pers. comm. 2006). However, we recently confirmed this species breeding on Todos Santos Islands. In 2014, we found the first active nest on Todos Santos Sur Island, and we corroborated species identification by measuring adults captured using mist-nets at night; broadcasting responses in the nest; and carrying out genetic analyses (GECI unpubl. data). We captured five adults with brood patches on San Martín Island, which indicates that the breeding range of the ashy storm-petrel is probably expanding or is wider that was recorded before (Table 2).

Black storm-petrel (*Oceanodroma melania*)

In the Mexican Pacific, black storm-petrels nest exclusively on Coronado and San Benito islands (Ainley & Everett, 2001). On Coronado Islands, this species is recorded as breeding on Coronado Norte, Coronado Medio, and Islote Medio, and as extirpated on Coronado Sur, with a total estimated population of 100–150 breeding pairs (Grinnell & Daggett, 1903; Osburn, 1909; Sowls, et al., 1980; Ainley & Everett, 2001; Carter, pers. comm. 2006). In 2016, we found 120 breeding pairs breeding on Coronado Norte and Islote Medio, and one nest on Coronado Sur, which indicates this species recolonisation of this island (Table 2). On San Martín Island, we captured adults with fully developed brood patches in 2017, thus, we consider this species as a probable breeder, but we have not found an active nest yet. Its breeding population size on San Benito Islands has not been updated yet since the last estimate in 1999 (Wolf, et al., 2006).

Brown pelican (*Pelecanus occidentalis)*

Currently, the brown pelican breeds on all its historical breeding sites on these islands, except on Todos Santos Norte Island, and 40% of its breeding population is concentrated on Todos Santos Sur Island (Table 2). San Jerónimo Island, previously not recorded as a breeding site (Wolf et al., 2006), recently supports a population of around 300 pairs (Table 2). This species was one of the most affected by organochlorines and human disturbance; colonies of thousands or hundreds of pairs recorded in the last century were dramatically reduced on Coronado (ca. 5,000 pairs; Jehl, 1973, Gress, 1995), and San Benito islands (~1,000 pairs, Everett & Anderson, 1991; Wolf, et al., 2006), and was extirpated on Todos Santos (Everett & Anderson, 1991; Palacios & Mellink, 2000; Palacios, pers. comm. 2003), San Martín (ca. 1000 pairs; Jehl, 1973; Anderson & Keith 1980), and Asunción islands (Anthony, 1925; Wolf, et al., 2006). All colonies, except on Todos Santos Islands, recovered considerably after these threats were mitigated (Palacios & Mellink, 2000; Wolf, et al., 2006; Whitworth, pers. comm. 2007). At present, no declined colony has reached its historical numbers as the species' population size remains in the hundreds of pairs, except on Todos Santos Sur Island that supports a population of more than 1,000 pairs (Table 2).

Blue-footed booby (*Sula nebouxii*)

We recorded one nest of blue-footed booby with two chicks on San Jerónimo Island in September 2016. This record represents the first on the Baja California Pacific islands and the northernmost breeding range for this species that was previously considered on Midriff Islands, in the Gulf of California (Hernández Díaz & Salazar Gómez, 2011).

Double-crested cormorant (*Phalacrocorax auritus*)

During the last century, the double-crested cormorant was extirpated from Todos Santos Norte (Van Denburgh, 1924; Palacios pers. comm. 2002), San Martín (Everett & Anderson, 1991), and San Roque islands (Wolf, et al., 2006). Currently, this species breeds on all 12 islands, except on Todos Santos Norte Island where it remains extirpated (Table 2). In the past, San Martín Island supported the largest colony in North America with hundreds of thousands of pairs (Wright, 1913; Gress, et al., 1973; Carter, et al., 1995); after the main threats were removed, the colony increased from zero to around 600 pairs (Palacios & Mellink, 2000, Palacios, pers. comm. 2003) and, at present, this island sustains the biggest population in the region with about 800 pairs (Table 2).

The breeding colony on the Coronado Islands declined from thousands to hundreds of pairs (Howell, 1917; Gress, et al., 1973, Carter, et al., 1995), and on San Roque Island from thousands to zero pairs (Townsend, 1923; Huey, 1927; Wolf, et al., 2006). We recorded double-crested cormorant recolonisation on San Roque in 2008. These colonies have remained in the hundreds of pairs during the last two decades (Carter, pers. comm. 1996; Palacios, pers. comm. 2003; Whitworth, comm. pers. 2007; Table 2).

The small colony recorded on Natividad in 2000 of around 60 nests (Wolf, et al., 2006), at present, has a sevenfold increment in population size (Table 2). On Todos Santos Sur Island the colony doubled its size and social attraction techniques were successful with a record of eight nests within an artificial colony.

Brandt's cormorant (*Phalacrocorax penicillatus*)

Brandt's cormorant returned to nest at all its historical breeding sites on the Baja California Pacific Islands (Table 2). In the past, it was extirpated from San Martín Island, the main breeding site with several thousand nests (Wright, 1913; Everett & Anderson, 1991; Palacios & Mellink, 2000; Palacios, pers. comm. 2003), and from San Jerónimo

Island (Wolf, 2002). At present, both islands maintain colonies of hundreds of pairs, and the largest colonies with > 3,000 pairs are located on the southernmost islands, Natividad, San Roque, and Asunción that before had low numbers of pairs (Table 2; Wolf, et al. 2006). In total, the breeding population of Brandt's cormorant has increased nine times more than the last decade from around >1,000 pairs to > 10,000 pairs (Table 2; Wolf, et al. 2006).

Pelagic cormorant (*Phalacrocorax pelagicus*)

Coronado and Todos Santos islands are considered the southernmost breeding range for the pelagic cormorant (Hobson, 2013). On these islands, small breeding populations have been previously reported on all four Coronado Islands and Todos Santos Norte Island (Palacios, pers. comm. 2003; Carter, pers. comm. 2006, Whitworth, pers. comm. 2007). During our monitoring in 2013–2017, we have recorded nests on Coronado Sur, Coronado Medio, both Todos Santos islands, and, for the first time, one nest on San Jerónimo Island in 2017, which represents an expansion of its breeding range to the south (Table 2).

Heermann's gull (*Larus heermanni*)

Heermann's gull breeds in small colonies (ca. 50–100 pairs) on San Benito Medio and San Roque islands (Table 2). On San Benito, the colony has increased from nine nests (Jehl, 1976) to more than 100 pairs that has not changed during the last decade (Wolf, et al*.,* 2006, Table 2). On San Roque, previous surveys showed a population of 35–42 pairs (Huey, 1927; Mellink, 2001). In 2008, when we started implementing social attraction techniques, we recorded 23 nests within the artificial colony and also during all subsequent years. The colony has reached its maximum number in 2017 with 42 nests (Table 2).

Western gull (*Larus occidentalis*)

The western gull is a species widely distributed on the Baja California Pacific islands. There are no historical records of extirpated colonies. It breeds on all 12 islands and is one of the most abundant species, with a total population estimate of approximately 20,000 breeding pairs (Table 2). The Todos Santos Islands concentrate around 50% of the current population. Estimates 10 years ago, showed a total population three times smaller than today. This increase has been very remarkable mainly on Todos Santos Sur, but also on Todos Santos Norte, San Martín, and San Jerónimo where colony sizes range from about 1,000 to 8,000 pairs (Table 2).

Caspian tern (*Hydroprogne caspia*)

In 2013, we recorded 15 nests of Caspian tern on San Jerónimo Island, the first record on the Baja California Pacific islands. In 2014, the population increased to 49 pairs and we also recorded nests on San Martín Island (89 pairs). The colony on San Jerónimo decreased to 11 pairs the last year because it was established on a California sea lion (*Zalophus californianus*) resting area. In contrast, the colony on San Martín found suitable habitat on the island and has increased to almost 200 pairs. (Table 2).

Royal tern (*Thalasseus maximus*)

This species was extirpated from San Roque Island and its last breeding record was 90 years ago (Bancroft, 1927; Everett & Anderson, 1991). In 2017, after eight years of the implementation of social attraction techniques, 870 breeding pairs were recorded nesting within the artificial colony installed for elegant tern (Table 2). For the first time, we found 80 nests of royal tern on San Jerónimo Island in 2013 but their numbers decreased rapidly to seven in 2017 (Table 2).

Elegant tern (*Thalasseus elegans*)

In the past, the elegant tern bred on San Roque and Asunción islands (Anthony, 1925) but was extirpated from both islands (Everett & Anderson, 1991). Currently, in 2017, we found one pair nesting on San Roque Island within the colony of royal tern associated with the artificial colony. On Asunción Island, this species remains extirpated.

Scripps's murrelet (*Synthliboramphus scrippsi*)

Scripps's murrelet was presumably extirpated from all historical breeding sites, except Coronado and San Benito islands (Table 2; Jehl & Bond, 1975; Everett & Anderson, 1991; Drost & Lewis, 1995; Wolf et al., 2006). At present, it has returned to breed on all the islands where was extirpated (Table 2). Our nest census on the islands shows lower population sizes from Coronado to San Benito in comparison to nocturnal surveys at-sea conducted a decade ago (Wolf, et al., 2006; Carter, pers. comm. 2015). We considered the last monitoring overestimated the population size. We found four breeding pairs nesting in artificial burrows on Todos Santos Sur Island (Table 1).

Guadalupe murrelet (*Synthliboramphus hypoleucus*)

Guadalupe murrelet breeds on the San Benito islands in a low proportion in comparison with Scripps's murrelet, but we do not have a precise number as identification in the nest is complicated. Colonies extirpated from Natividad, San Roque and Asunción islands mentioned by Wolf, et al. (2006) may have been a misidentification of *Synthliboramphus craveri* (Keitt, 2005, Carter pers. comm. 2015; Whiworth, et al., 2018). We recorded a pair (one individual was Guadalupe and the other Scripps's murrelet) on a trap-camera on San Jerónimo Island but the species' breeding status is not confirmed yet.

Craveri's murrelet (*Synthliboramphus craveri*)

Craveri's murrelet is currently breeding in low numbers on San Benito, Natividad, San Roque, and Asunción islands (Table 2). Whitworth, et al. (2018) previously found breeding evidence on San Martín, San Roque, and Asunción islands in 2007.

Cassin's auklet (*Ptychoramphus aleuticus*)

Cassin's auklet was also extirpated from almost all of its historical breeding sites, except from San Jerónimo and San Benito islands (Table 2). Currently, it is breeding again on all islands but Coronado Norte, an island that supported a population of thousands of breeding pairs (Osborn, 1909) extirpated by cat predation (Jehl, 1977). Extirpated colonies from San Roque and Asunción islands have been growing from about 100 pairs in 2008, when we recorded their recolonisation, to around 2,000 pairs in 2017 (Table 2).

Social attraction systems were key for the colonisation on Coronado Sur and recolonisation on Natividad Island. In 2017, we recorded 20 breeding pairs nesting in artificial burrows on Coronado Sur Island, which represents the first record for this island, and for the archipelago, as the last record was on Islote Medio, a pest-free islet, three decades ago (Everett & Anderson, 1991). After more than a century since the last breeding record (Kaeding, 1905), in 2016, we found five breeding pairs on Natividad Island, including one pair inside an artificial burrow close to a sound system (Table 1). We recorded one nest on Todos Santos Sur in 2014, and currently, more than 40 pairs are nesting on the archipelago, 17 of them in artificial burrows (Tables 1 and 2).

THREATS

Major historic threats to seabird colonies included predation by invasive mammals, habitat modification, and direct disturbance (Everett & Anderson, 1991; Wolf, et al., 2006). Current threats are similar to a decade ago but less extensive: 1) potential reintroduction of invasive mammals; 2) invasive plants that reduce nesting habitat, 3) habitat modification by guano mining, 4) exploitation of eggs, 5) disturbance by human activities including recreation and inadequate waste management; 6) fisheries impacts, and 7) pollution.

All these islands are now free of invasive predators (Aguirre-Muñoz, et al., 2016), however, potential reintroduction is high on all islands due to constant movement from the continent, as temporal and permanent fishermen's camps are established on all of them, except on the Coronado Islands. Natividad Island, inhabited by a fishing community of about 300 people, is the most susceptible to this threat: the reintroduction of a few pets has been recently recorded (CONANP, comm. pers.). The impacts of house mice that remain on Coronado Sur Island and white-tailed antelope squirrels on Natividad Island need to be evaluated.

Invasive plants such as ice-plant (*Mesembryanthemum crystallinum*) are widely distributed on many islands (Rebman et al., 2016), and are displacing native flora and affecting their associated fauna. Brandt's cormorants that nest on clean areas along the coast line, and Cassin's auklets and black-vented shearwaters that breed in subterranean burrows might be the most affected species.

Guano mining caused severe damage on San Jerónimo, San Roque, and Asunción islands during the last century (Everett & Anderson, 1991; Wolf, et al., 2006). At present, this activity continues on San Jerónimo Island at least since 2015 and is causing disturbance and destruction of the Cassin's auklet colony (GECI unplub. data). Human exploitation of western gull eggs persists on San Benito and Natividad islands. However, the impact on these populations is unknown. In 2016, the harvesting of Heermann's gull eggs on the small colony of San Benito Medio Island caused low productivity (GECI unpubl. data).

Recreation activities (surfing, kayaking, and fishing) are a threat on Todos Santos, San Benito Oeste, and Natividad islands. We have recorded tourists and residents walking close to breeding colonies which could cause temporal abandonment of nests and increase gull predation, and also damage to the burrows of nocturnal species. On Natividad Island, a metal fence around the town landfill built in front of the breeding colony in 2014, severely impacted the population. In 2016, the structure was removed by the fishing cooperative, however, inadequate waste management is a serious problem for the black-vented shearwater.

Commercial fishing is one of the most important economic activities along the Mexican Pacific coast (CONAPESCA, 2014). Although no fisheries bycatch impacts have yet been evaluated, information from the Gulf of California, shows that 17 species of seabirds and aquatic birds, mainly brown pelicans and blue-footed boobies, are incidentally caught in nets during fishing operations (Comunidad y Biodiversidad, A.C. pers. comm.). The most abundant seabird species in the region forage on small pelagic fish, thus, probable competition for food with commercial fisheries represents a potential threat that should be studied.

Light pollution in fishermen's camps created an important impact on nocturnal species decades ago (Wolf, et al., 2006) – currently this threat has been mitigated (GECI unpub. data) but still it is necessary to evaluate it on fishing boats around the islands. Current information about pollution-related threats is scarce. Oil spill hazards are a potential threat due to the region being an important transportation route and having fuel reception facilities. However, there is no action plan or personnel trained to manage oiled seabirds, and fauna in general.

Plastic consumption for variety of seabird species is increasing worldwide (Wilcox, et al., 2015). We have found evidence of plastic consumption in black-vented shearwater breeding on Guadalupe Island (GECI unpubl. data), thus, the impact of microplastics on seabirds in the region requires evaluation.

CONSERVATION

Although 65% of all seabirds recorded breeding on the islands are listed in the IUCN Red List of threatened species and are protected in Mexico in the Norma Oficial Mexicana NOM-059-SEMARNAT-2010, it is essential to update the status of several species. The majority of protected natural areas fully protect breeding and foraging areas for coastal species, however, foraging sites of pelagic seabirds are not included as most are located hundreds of kilometres from colonies. To address this issue, we are developing a Marine Important Bird Areas (Marine IBAs) proposal in collaboration with government agencies, national and international NGOs and seabird experts. We are also in the process of publishing an action plan for endemic seabirds that delineates the next actions to improve their conservation status. In the short-term this plan will incorporate all breeding seabirds in Mexico.

Regulations and surveillance enforcement to prevent introduction of invasive species, mitigate disturbance to colonies and impacts of fisheries are primordial. An important step is the National Island Biosecurity Programme, recently initiated on several islands including San Benito Islands, which aims to involve all key stakeholders in the protection of island environments from invasive alien species (Latofski-Robles et al., 2019). Moreover, it is necessary to continue working together with local communities to raise awareness about the threats seabirds are facing.

We consider research priorities to improve management decisions are: 1) to continue monitoring of populations and obtain data on productivity; 2) to obtain accurate population estimates for nocturnal seabirds, especially for storm-petrels; 3) to evaluate the impact of threats such as fisheries interactions and microplastics.

ACKNOWLEDGEMENTS

We thank organisations and agencies that have collaborated for several years in this Programme: SEGOB, SEMARNAT, CONANP, CONABIO, SEMAR, National Audubon Society (Steve W. Kress, Paula Shannon, Susan Schubel), Cornell Lab of Ornithology (Eduardo Íñigo-Elías), CICESE, UABC, Coop. Buzos y Pescadores de la Baja California, Coop. Ensenada, Coop. California de San Ignacio, Coop. Pescadores Nacionales de Abulón, FEDECOOP. This Programme is supported by the Montrose and Luckenbach Trustee Councils, the Alianza WWF-Fundación Carlos Slim, FMCN, the National Fish and Wildlife Foundation, the David and Lucile Packard Foundation, and the Marisla Foundation.

The recovery of seabird populations on Ramsey Island, Pembrokeshire, Wales, following the 1999/2000 rat eradication

E.A. Bell[1], M.D. Bell[2], G. Morgan[3] and L. Morgan[3]

[1]Wildlife Management International Ltd, PO Box 607, Blenheim 7201, New Zealand, <biz@wmil.co.nz>. [2]Wildlife Management International Ltd, PO Box 607, Blenheim 7201, New Zealand. [3]Royal Society for the Protection of Birds, Ramsey Island, c/o Trefeiddan Farm, St David's, Pembrokeshire, SA62 6PY, United Kingdom.

Abstract Ramsey Island, 259 ha, is ca. 1 km off the Pembrokeshire coast, south-west Wales. The eradication of brown rats (*Rattus norvegicus*) was successfully completed in the winter 1999/2000 using a ground-based bait station operation. The pre-eradication survey using tape playback estimated the Manx shearwater (*Puffinus puffinus*) population to be 849 pairs. These surveys were repeated in 2007, 2012 and 2016. Each survey showed the Manx shearwater population had increased, reaching 4,796 pairs in 2016 with birds spreading from previously known breeding locations. European storm petrels (*Hydrobates pelagicus*) were first recorded breeding on Ramsey Island in 2008 with up to 12 pairs in 2016 (a minimum estimate based on accessible survey areas). Other species have also shown improvements to population estimates and range since the rat eradication. This evidence shows that there can be little doubt that the presence of brown rats on Ramsey played a significant role in suppressing breeding numbers and limiting the breeding range of seabirds on the island and the positive results following the successful eradication are now being seen.

Keywords: brown rat, European storm petrel, *Hydrobates pelagicus*, Manx shearwater, *Puffinus puffinus*, *Rattus norvegicus*, survey

INTRODUCTION

Rats are known to have devastating effects on seabird and land bird populations by predation of eggs, chicks and adults which reduces breeding success, recruitment, population size and distribution. They have caused extinctions of birds on numerous islands throughout the world (Moors & Atkinson, 1984, Atkinson, 1985, Towns, et al., 2006; Jones, et al., 2008). Smaller burrowing seabirds are recognised as the species most affected by invasive rats (Jones, et al., 2008; Towns, et al., 2011). The eradication of rats from seabird islands is recognised as one of the most important tools in avian conservation in recent times, with significant long-term restoration benefits such as increased productivity and populations sizes and establishment of new, or return of previously locally extinct, seabird species being achieved (Atkinson, 1985; Moors, et al.,1992; Lock, 2006; Ratcliffe, et al., 2009; Booker & Price, 2010, Bourgeois, et al., 2013; Le Corre, et al., 2015).The protection and enhancement of UK seabird breeding habitat has been recognised as an important conservation priority, including under international conservation agreements (Brooke, et al., 2007; Ratcliffe, et al., 2009; Dawson, et al., 2015; Thomas, et al., 2017). Over 400 islands around the world have been successfully cleared of rats, including twelve in the United Kingdom, with a subsequent increase in bird populations (Thomas & Taylor, 2002; Towns & Broome, 2003; Jones, et al., 2008; Howald, et al., 2007, DIISE, 2015, Thomas, et al., 2017).

A feasibility study of eradicating brown rats (*Rattus norvegicus*) from Ramsey Island was completed in 1998 and led to the ground-based eradication in autumn 1999. Documenting the recovery of bird species on islands that have had invasive mammals removed is becoming increasingly important. RSPB has been monitoring bird populations on Ramsey Island since 1992. Due to difficulty in accessing natural burrows, between 2013 and 2016, RSPB constructed a man-made seabird habitat using artificial burrows with the aim to establish a Manx shearwater (*Puffinus puffinus*) colony that could be used to monitor productivity, recruitment and adult survival. This paper details the changes to the Manx shearwater population on Ramsey Island, including within the man-made habitat, and the subsequent colonisation of the island by European storm petrel (*Hydrobates pelagicus*) following the eradication of brown rats.

STUDY AREA AND METHODS

Study site

Ramsey Island, 259 ha (5°20′W, 51°51′N), is located about 1 km off the Pembrokeshire coast, south-west Wales (Fig. 1). It is a nature reserve owned and managed by the RSPB. Ramsey Island is approximately 3.2 km long and 1.6 km across at its widest point and is surrounded by coastal cliffs which are particularly high and steep on the western side of the island. There is also a number of small islets (including a chain of islets from the southern end) and caves around the coastline. The coastline of the island is made up of exposed rocky shores with a small number of sandy coves. The top of the island is gently rolling and is dominated by two prominent peaks (Carn Ysgubor 101 m and Carn Llundian 136 m). The island supports three main habitats; acid grassland, bracken-dominated grassland and coastal heathland (Doncaster, 1981; Hurford & Evans, 2006; CCW, 2008). The heathland and maritime grassland communities are of conservation importance in Wales (JNCC, 2001; Hurdford & Evans, 2006; CCW, 2008). The rush-pasture fields are grazed by rabbits (*Oryctolgus cuniculus*), ponies (*Equus caballus*) and sheep (*Ovis aries*) as part of the management to support wildlife, particularly choughs (*Pyrrhocorax pyrrhocorax*) (Doncaster, 1981; Long, 2003). The bank vole (*Myodes glareolus*) and common shrew (*Sorex araneus*) are also present on the island.

Fig. 1 Location of Ramsey Island, Wales.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 539–544. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

The island is part of the Pembrokeshire Coast National Park and has a range of designations including as a Site of Special Scientific Interest (SSSI), National Nature Reserve (NNR), Important Bird Area (IBA), Special Protection Area (SPA) and Marine Special Area of Conservation (MSAC) (JNCC, 2001; CCW, 2008; Hayhow, et al., 2016). Ramsey holds important breeding populations of razorbill (*Alca torda*), guillemot (*Uria aalge*), kittiwake (*Rissa tridactyla*), Manx shearwater, chough and wheatear (*Oenanthe oenanthe*) (JNCC, 2001; Johnstone, et al., 2011). Ramsey Island is also an important breeding site for Atlantic grey seals (*Halichoerus grypus*).

The island is popular with visitors who are interested in the seabirds, land birds, flora and history. These visitors travel to the island on small passenger vessels from St David's between April and October. There is a jetty and several buildings on the island, including the warden's home and information shelter.

Manx shearwaters have been recorded on Ramsey Island since the 18th century (Mathew, 1894; Holloway, 2010; Lovegrove, et al., 2010). Historical reports and more recent seabird monitoring on Ramsey recorded declines in Manx shearwaters and other seabirds (Mathew, 1894; Humpridge & Bullock, 1999; Lovegrove, et al., 2010). These declines were attributed in part to the presence of brown rats and predation on eggs and chicks (Humpridge & Bullock, 1999; Lovegrove, et al., 2010).

It is not known when brown rats became established on Ramsey Island; but this was likely to have occurred more than two hundred years ago from an early shipwreck.

Brown rat eradication

The eradication of brown rats was completed as a ground-based operation using rodenticide cereal blocks in protective bait stations to reduce risk to non-target species. A 50 m ×50 m grid was established in autumn 1999. Bait stations were made from 500 mm lengths of corrugated plastic drainage pipe staked into position using wire. A total of 1,260 stations were placed on the main island and offshore stacks. The poisoning operation ran from 11 January 2000 to 10 March 2000. Two 24 g blocks of cereal-based rodenticide bait (Neosorexa™, active ingredient 0.005% difenacoum, manufactured by Sorex Ltd) were placed in each station on the main island and ten blocks on the offshore stack throughout the poisoning programme and replaced as required when eaten by rats, non-target species and/or damaged by weather.

The stations on the main island were checked daily, but stations on the offshore stacks were checked when sea conditions allowed. Bait take was recorded by bait station number and the species believed to have consumed or removed the bait.

From 1 March to 15 March 2000, monitoring stations were established around the island next to and in-between the bait stations. Chew sticks, chocolate blocks and small pieces of candle were used. Sand and mud areas on the island were checked for rat foot prints and burrows and rat runs were checked for fresh activity. All monitoring points were individually numbered and any evidence of activity (i.e. teeth marks or foot prints) was recorded by station number and the species believed to have consumed or marked the monitoring item. Each monitoring site was checked regularly, either separately or together with the poisoning bait station grid. Any rat and non-target species sign found on detection devices was recorded.

Manx shearwater breeding population survey

Earlier surveys on Ramsey Island had shown that Manx shearwaters only occur in a narrow strip around the coast of the island on hills Carn Llundain and Carn Ysgubor (I.D. Bullock, unpublished data; Perkins, et al., 2017). For burrow counting and sampling purposes, Ramsey Island was divided into 42 sub-areas by topographical features. A full count of suitable burrows (i.e. more than 0.7 m in length and not doubling back to the surface) in these 42 sub-areas was completed in 1999, 2007, 2012 and 2016.

Estimation of the numbers of Manx shearwaters on Ramsey Island was based on playback of recorded calls (Brooke, 1978; Smith, et al, 2001; Perkins, et al., 2017). This method relies on the fact that if a male Manx shearwater call is played down a sample of burrows during the incubation period, most incubating males, but no incubating females will respond to that call (Smith, et al., 2001). For a given number of breeding pairs, it is then possible to establish the number of males that respond to recorded calls. From this, using the following formula it is possible to estimate the number of breeding pairs in the burrows on the island.

$$\textit{Breeding pair} = \textit{No. of burrows} \times \frac{\textit{No. Responding}}{\textit{No. Sampled}} \times \frac{1}{\textit{Response Rate}}$$

The response rate for Manx shearwaters was calculated by Bullock in 1999 (0.409) and was based on a study set of 13 burrows (Humpridge & Bullock 1999). Alternative response rates were available from Skomer (0.43, Smith, et al., 2001) and Skokholm (0.505, Brooke, 1978) or the seabird monitoring handbook (0.505, Walsh, et al., 1995). The Ramsey response rate of 0.409 was used in 2007 as it allows direct comparison to the earlier survey on the island. The response rates were recalculated for the 2012 survey (to 0.4625) using methods developed by Murray, et al. (2003), Newton, et al. (2004) and Perrins, et al. (2012). The response rates were recalculated for the 2016 survey (to 0.845) which used dual-sex calls which had been shown to give a more reliable correction factor (Perkins, et al., 2017).

A recording of male Manx shearwater calls was played down 20% of burrows in each sub-area during the main incubation period unless the sub-area contained fewer than 50 burrows up to 2016 and then duetting male and female calls were used for 2016 (Perkins, et al., 2017). In those cases, the recording was played in all burrows. Recordings were played at natural volumes ('normal' Manx shearwater call volumes as heard from the burrows that were set 'by ear' before 2016 and by a decibel reader in 2016) within 30 cm of the burrow entrance for up to 25 seconds. Playback of calls was carried out in the day and responses, or lack thereof, were recorded. Playback was undertaken between the end of May and mid-June at a time when all eggs laid should be being incubated by one adult (Brooke, 1990).

Between 2013 and 2016 nearly 100 artificial nest boxes were established on the island. These burrows are the same design as those developed in New Zealand for fluttering shearwaters (*Puffinus gavia*) by Bell (1995) and recommended for burrow-nesting petrel and shearwater species (Gummer, et al., 2014). These artificial burrows were put in place to provide easily accessible study burrows for tracking studies and to determine productivity and population parameters such as survival and recruitment (Morgan, 2012; Kirk, et al., 2013).

European storm petrel breeding population survey

Surveys of suitable storm petrel habitat (i.e. stone walls, rock tumbles and scree) on Ramsey Island were undertaken using playback in 2008, 2010, 2012 and 2016. A recording of a male European storm petrel was played close to a suspected site and a reply listened for (Ratcliffe, et al., 1998; Gilbert, et al., 1999; Mayhew, et al., 2000). Burrow entrances that had responses were mapped using GPS.

RESULTS

Brown rat eradication

Bait acceptance was good, with rats accounting for 165 kg of bait consumed. As the LD_{50} for a 250-g brown rat is 9 g and the mean (± SE) bait take by rats was 81.6 ± 0.7 g (3.4 ± 0.02 blocks, range 0–30 blocks) the rat population on Ramsey Island was estimated to be between 1,850 and 5,400 rats). The bait take pattern was typical of other rat eradication operations; very high in the immediate five to ten days after original baiting and dropping to a relatively low level 21 days after original baiting. Bait take dropped to zero by day 41 after the original baiting (Fig. 2). The rats were widely distributed across the island, but the density was not even, as shown by the distribution of bait take (Fig. 3). Rats were present in all coastal areas and in highest numbers within the central and northern areas of the island.

Rabbits interfered with the bait stations between days 12 and 26 of the operation, with a number of carcasses being collected. Bait stations were modified by halving the entrance size to prevent access by rabbits and this greatly reduced their interference levels. Carrion crows (*Corvus corone*), ravens (*Corvus corax*) and herring gulls (*Larus argentatus*) also interfered with the stations from day 25 after the birds had learnt to reach into the stations to get access to the bait. Eight crows and three raven carcasses were located but no herring gull deaths were recorded. The bait stations were further modified by extending the length from 500 mm to 750 mm which reduced crow, raven and gull interference to almost nil. Crows were observed working in pairs to remove wires; one pulling the wire out while the other stood on top of the station to hold it in place, to get access to the bait. Access to the bait by the bank voles could not be prevented and 30 dead voles were found. A small captive population was maintained during the eradication as a precaution and was released after the poison had been removed. Voles and vole sign on monitoring tools were recorded throughout the eradication.

Monitoring for rat presence continued for two years after the end of the poisoning operation. No rats or sign were detected. The rat-free status for Ramsey Island was declared in March 2002.

Manx shearwater breeding population survey

The number of Manx shearwater burrows on Ramsey Island totalled 13,800 burrows in 1999, 14,970 burrows in 2007, 12,302 burrows in 2012 and 12,319 in 2016 (Humpridge & Bullock, 1999; Morgan & Morgan, 2008; Morgan & Morgan, 2013; Morgan & Morgan, 2017).

The Manx shearwater breeding population size increased 3-fold and 5-fold, 8 and 17 years after the rat eradication respectively (Table 1).

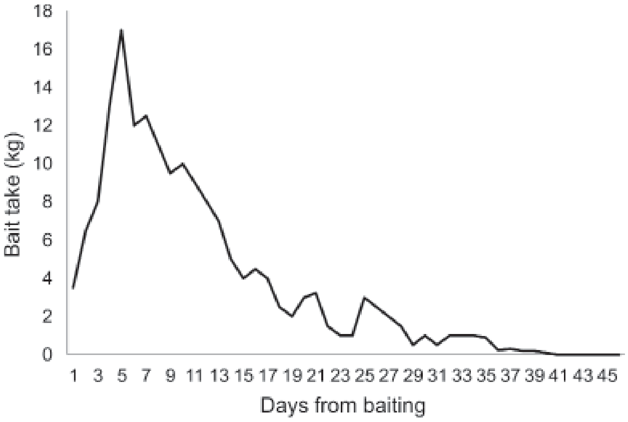

Fig. 2 Bait take by rats during the brown rat (*Rattus norvegicus*) eradication on Ramsey Island, Wales, 1999/2000.

The distribution of Manx shearwaters remained largely unchanged between 1999 and 2007 censuses, but the range spread between the 2007, 2012 and 2016 censuses (Fig. 4). There have also been significant increases in the population within the distribution with new areas recorded in 2007, 2102 and 2016 that previously had no responses recorded in 1999 (Fig. 4).

Burrow density is greatest along the west, north and north-east coasts and on the hills (Fig. 4). Interestingly in a section at the northern end of Ramsey Island there was no response to the recordings despite a high number of suitable burrows available for Manx shearwaters (n = 2,247) in 1999 or 2007. This area showed a low level of response in 2012 and higher in 2016.

A prospecting pair of Manx shearwaters was recorded in one of the artificial burrows in 2015. Two pairs nested successfully in the artificial burrows in 2016 and seven pairs were recorded incubating eggs in April 2017.

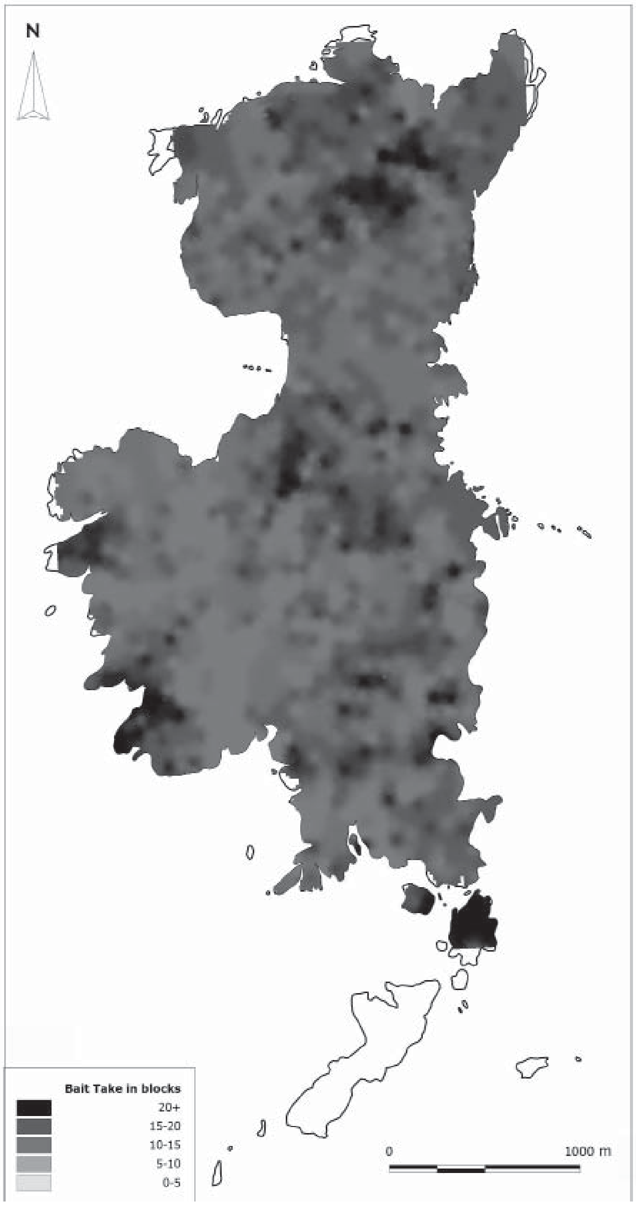

Fig. 3 Distribution of bait take during the brown rat (*Rattus norvegicus*) eradication on Ramsey Island, Wales, 1999/2000.

Table 1 The total number of burrows, response rate used, total number of burrows sampled using playback, total number of responses and total number of breeding pairs of Manx shearwater *Puffinus puffinus* on Ramsey Island between 1999 and 2016.

Year	Total number of burrows	Response rate used	Total number sampled using playback	Total number of responses	Total number of breeding pairs
1999	13,800	0.409	2,760	74	905
2007	14,970	0.409	3,190	208	2,387
2012	12,302	0.4625	2,788	402	3,835
2016	12,319	0.845	2,860	941	4,796

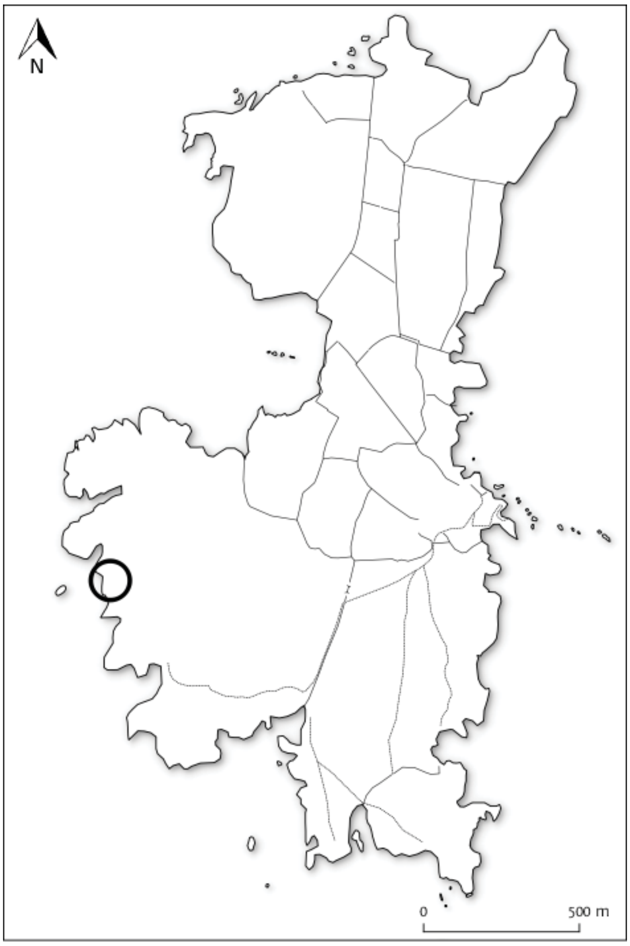

Fig. 5 Location of European storm petrel breeding sites (in black circle) on Ramsey Island, Wales, 2016.

European storm petrel breeding population survey

The first storm petrel breeding burrows were detected in 2008 (4 pairs). By 2016, the numbers had increased to 12 breeding burrows (Table 2).

DISCUSSION

The Ramsey Island brown rat eradication was one of the first eradications undertaken by the RSPB and a number of important lessons were learnt that helped with the planning and implementation of later eradications on Lundy Island, St Agnes and Gugh, Isles of Scilly and the Shiant Isles. Bait station design was adapted to suit local conditions and local non-target species.

The Ramsey Island operation was the first island-wide eradication that used a rodenticide containing the active ingredient difenacoum proving that this rodenticide could be used to successfully target all brown rats on an island. This toxin has since been used on a number of island eradication operations in the UK and around the world (Howald, et al., 2007; Jones, et al., 2008). Since the eradication of rats, there have been biosecurity protocols put in place to prevent a re-incursion on Ramsey Island and to outline how to respond if rats are ever detected on the island. It is important that these measures are maintained indefinitely.

Ramsey Island has seen dramatic changes since the removal of brown rats, not least the increase in the distribution and density of Manx shearwaters. The number of Manx shearwaters has multiplied by five times between

Table 2 The number of burrows of European storm petrels *Hydrobates pelagicus* on Ramsey Island between 2008 and 2016.

Year	Number of breeding burrows
2008	4
2009	Not surveyed
2010	6
2011	Not surveyed
2012	5
2013	5
2014	5
2015	8
2016	12

1998 and 2016 to almost 5,000 breeding pairs, representing a 560% increase. This proves that the brown rats were having a significant role in suppressing the number of breeding pairs on the island and their range across the island and provides more evidence that invasive rats have significant impacts on seabird populations on islands (Atkinson & Moors, 1984; Atkinson, 1985; Towns, et al., 2006; Jones, et al., 2008). A similar pattern was observed on Lundy Island following the rat eradication operation in 2004 (Brown, et al., 2011). It is suspected that although increased productivity will have occurred on Ramsey Island, given that the Manx shearwater does not breed until five or six years of age (Brooke, 1990), much of this increase may be due to immigration from the extremely large neighbouring colonies on Skomer and Skokholm. This theory was confirmed by the capture of an adult that had been ringed as a chick on Skomer in 1993 which was on its way to feed a chick on Ramsey Island in 2017 (GM, pers. obs.).

The greatest increases have occurred within the existing sub-colonies, but there has also been expansion into new areas. Nine sections that showed nil response in 1999 and 2007 contained breeding birds in 2012 and a further five new sections were occupied in 2016. There is limited habitat available on Ramsey Island away from the coastal areas. However, restoration of drystone walls, former rabbit warrens and artificial burrows have all provided more nest-sites. However, the presence of rabbits may affect the distribution of Manx shearwaters on Ramsey Island. Competition for burrows with a small number of birds may account for restricted range and densities in specific locations on the island. The development of an artificial study colony on Ramsey Island has proved successful with up to seven birds nesting in the man-made burrows in 2017, of which five successfully fledged chicks.

European storm petrels have also started breeding on the island for the first time since records began. Although storm petrels are known to breed on two offshore islands, the Bishops and Clerks (163 apparent occupied sites in 2017; G.M., pers. obs.), it was not until 2008 that they were confirmed on Ramsey Island itself. Six birds were recorded breeding in 2012 and this increased to 12 pairs in 2016. It is important to note that these estimates are the minimum number of storm petrels present on the island as not all adults may respond to the recorded calls. This has been shown to be the case in a number of other studies (Insley, et al., 2002; Brown, 2006; Hounsome, et al., 2006) and, as these studies have also shown that correction factors for storm petrels are known to be highly variable between sites and even between years, the use of recorded calls and corrections have not been used to estimate the current Ramsey Island storm petrel population. As the population increases, an island-specific correction factor will be calculated for Ramsey Island and used to estimate the population size in the future. Currently, the minimum estimate is used (i.e. the known response to taped calls).

However, the basic playback-response method is widely used, standardised and is comparable between years and across sites. It is also a low-impact method, completed during the day, and provides spatial information on breeding burrows. The storm petrel population on Ramsey Island is likely to increase into a range of available habitat including drystone walls, rabbit burrows and rock tumbles.

The success on Ramsey Island provided valuable information and techniques for later eradication operations in the UK, particularly those with important non-target species. It also showed that ground-based eradication techniques developed in New Zealand could be adapted and used on islands in the UK, and Ramsey Island serves as a good example of the significant long-term benefits that can be achieved through short-term investment.

ACKNOWLEDGEMENTS

This project was carried out with funding from RSPB. Noesorexa™ bait was donated by Sorex Ltd. We would like to thank all the volunteers who helped with all stages of the eradication and subsequent Manx shearwater and European storm petrel monitoring. Kelvin Floyd (WMIL) provided Figs 1 and 3. Two anonymous referees commented on this paper.

Abstract Monitoring provides important evidence to evaluate if invasive mammal eradications on islands achieved conservation goals and to inform future allocation of conservation funds. However, monitoring can be costly, and compete with management actions for resources, so it is important that efforts are targeted. It can be difficult to obtain results of monitoring from previous projects, which puts future projects at a disadvantage when projecting possible conservation outcomes. In this short paper we discuss practical considerations for designing monitoring associated with an eradication programme. We focus on the ecological outcomes of invasive species eradication, as opposed to specifically monitoring if an eradication was successful or not. We identify major motivations for undertaking monitoring and present a decision tree intended to improve the efficiency of monitoring by supporting project managers determining when and what to monitor, and how to incorporate monitoring into project planning.

Keywords: decision tree, monitoring, post-eradication, project planning

INTRODUCTION

There is a substantial shortfall between the investment in conservation worldwide and the amount required to tackle the current biodiversity crisis (McCarthy, et al., 2012). It is well established that this necessitates prioritised, efficient allocation of resources, with evidence-based management (Sutherland, et al., 2004; Wilson, et al., 2006; Kapos, et al., 2008; Underwood, et al., 2008). Monitoring, defined as the collection and analysis of repeated field-based empirical measurements (Lindenmayer & Likens, 2010), provides this evidence. Over the past fifty years the eradication of invasive mammals from islands has developed into a reliable and effective conservation tool, resulting in substantial conservation gains (Veitch, et al., 2011; Jones, et al., 2016). There has been noteworthy progress in determining why, what, when and where to eradicate mammals from islands. Prioritisation of management is more robust and evidence-based than ever. When and how much to invest, how to balance different outcomes, and dealing with uncertainty of outcomes have all been addressed in recent literature (Donlan & Wilcox, 2007; Dawson, et al., 2015; Donlan, et al., 2015; Helmstedt, et al., 2016). Yet why, what, when and where to *monitor* following eradication is not always apparent. Recent assessments have highlighted that data on native species' responses to eradication are rare, often not quantitative, and not readily available through published sources, suggesting that monitoring, or reporting on monitoring, following eradication is uncommon (Jones, et al., 2016; Brooke, et al., 2017; Towns, 2018). Both eradication, and monitoring the outcomes that result, can be costly (e.g. Helmstedt, et al., 2016; Springer, 2016). Assuming both activities are being funded from the same combined budget, there is a potential trade-off between spending on eradication versus spending on monitoring (Possingham, et al., 2012). This paper discusses what to consider when designing monitoring of eradication projects. We focus on monitoring the wider ecological impacts of invasive species eradication, rather than short-term post-eradication monitoring for signs of invasive species that determines whether an eradication project has succeeded or failed. The paper incorporates inputs from the Island Invasives 2017 workshop: "Effective monitoring of response to eradications" attended by 60 conference participants. We aim to outline the main considerations for practitioners assessing the monitoring needs for projects they are involved in.

WHY, WHEN AND WHAT SHOULD WE MONITOR?

Possingham, et al. (2012) identified five separate benefits of long-term monitoring. Three of them—auditing the outcomes of a project (Case study 1), detecting unanticipated outcomes and researching mechanisms for those outcomes—have ecological benefits. The other two

CASE STUDY 1: AUDITING THE OUTCOMES OF RAT ERADICATION AT ANACAPA, CALIFORNIA, USA

Black rats (*Rattus rattus*) were successfully eradicated from the three islands of Anacapa in the Channel Islands, California USA, in 2001–2002. The goal of the eradication project was to improve seabird nesting habitat, and aid recovery of Scripps's murrelet (*Synthliboramphus scrippsi*, formerly Xantus's murrelet) and ashy storm-petrel (*Oceanodroma homochroa*) (NPS, 2000). The project was funded via oil-spill restoration resources, and an additional goal was to offset impacts that had occurred to these two species during the 1990 American Trader spill (ATTC, 2001). Monitoring included tracking artificial eggs (mimicking Scripps's murrelet eggs) before the eradication to quantify rat predation on this life history stage, and after the eradication to confirm the expected outcome of removing that impact (Jones, et al., 2005). Long-term monitoring of focal seabird species ensued for a decade including the hatching success, distribution and abundance of Scripps's murrelet on the island, which saw a three-fold increase in hatching success and expansion of nesting (Whitworth, et al., 2013). The ashy storm-petrel was discovered breeding on the island 10 years post-eradication, highlighting the contribution of the project towards stated goals (Whitworth, et al., 2013; Newton, et al., 2016). The operation was also the first aerial broadcast of rodenticide in the USA, and short-term non-target monitoring was undertaken to follow expected impacts (Howald, et al., 2010), and improve knowledge for further planning of this activity in the USA. Surveillance monitoring of other taxa also occurred, including endemic deer mice, herpetofauna and inter-tidal communities, to understand the broader impacts that occurred as a consequence of the eradication.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 545–551. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

– informing stakeholders of outcomes and engaging the public – have social benefits. Whether ecological or social, several of these benefits involve measuring or reporting against targets, so clearly defining the target outcomes of eradications is often a prerequisite for designing monitoring.

Monitoring may yield diminishing returns in terms of advancing our ecological knowledge, when the same outcome is monitored repeatedly. It can, therefore, detract from investment in future management action. This is an important consideration for repeated monitoring of the same island or site (Possingham, et al., 2012), but also for monitoring across projects where islands share similar habitat types, and invasive mammal-native species interactions. The target outcome of an eradication of a particular invasive species e.g. population recovery of a threatened species, may be confidently predicted if it is driven by a simple mechanistic relationship or there is sufficient evidence from previous eradications that benefited the same or ecologically similar species. The decision whether to monitor should, therefore, be informed by the current state of evidence: what prior knowledge exists and is it sufficient to confidently predict outcomes? For invasive mammal eradications, the evidence-base for predicting different outcomes is mixed. Individual outcomes have been reported for several projects but not consistently or comprehensively.

A key recommendation made during the Island Invasives 2017 monitoring workshop was to compile a synthesis of monitoring efforts to date, to identify taxonomic or geographic gaps in coverage that will help target future monitoring efforts. Although no comprehensive synthesis exists currently, some studies have collated and synthesised monitoring, either at a regional level (e.g. Russell, et al., 2016; Towns, et al., 2016), or globally for a taxonomic group. Schweizer, et al., (2016) reviewed available evidence of vegetation responses to goat (*Capra hircus*) and European rabbit (*Oryctolagus cuniculus*) eradications. Although there was evidence that vegetation responded following herbivore removal, variation in monitoring methods, timeframe and accounting for native versus non-native vegetation response hindered the drawing of conclusions. Thus, the authors recommended further monitoring to develop a general model of expected vegetation responses. Brooke, et al., (2017) collated seabird demographic responses following invasive mammalian predator eradication, highlighting that, in general, seabird populations increase following invasive mammal eradications. However, not all populations grew, insufficient data were available to distinguish between threatened and non-threatened species, and variation in response among major seabird taxa was evident. Thus, while generally seabirds can be predicted to respond positively following invasive mammal eradication, we lack sufficient knowledge to predict how and why this circumstance occurs, hence the recommendation for systematic long-term monitoring to improve understanding of the mechanisms of seabird population recovery (Brooke, et al., 2018).

The social benefits that accrue from monitoring–stakeholder feedback and public engagement–are more linear because, while ecological knowledge grows cumulatively from all projects that monitor, the social returns are primarily project specific. Foreseeably, the ecological need for monitoring may be low but, if the operation had high public or stakeholder interest, monitoring will be necessary.

Beyond a theoretical framework for monitoring, The Nature Conservancy is one organisation looking at their motivations for monitoring at an institutional level (Montambault & Groves, 2009). They found monitoring was a tool for managing risk and securing future investment–the greater a project's risk or higher the likelihood it could lead to follow-on funding, the higher the investment that should be made in monitoring (Case study 2). Eradication operations with considerable ecological uncertainty, or reputational risk, and those whose success could leverage additional public, political or financial support for future operations therefore all warrant a significant investment in monitoring (Table 1).

Having identified the motivations for monitoring, and decided on that basis whether monitoring is needed, it becomes easier for a project team to decide what to monitor and how. When the aim is to confirm that an eradication achieved target outcomes, monitoring focusses on those target beneficiaries. When the risk of unexpected outcomes is high, broader surveillance monitoring is appropriate. Both rely on assessing *the state* of target or non-target species or habitats, whereas understanding broader ecosystem responses is likely to require more detailed research into ecological mechanisms.

The goal and audience for reporting ecological outcomes of an eradication can influence the type of monitoring undertaken. When there is a need to report outcomes in a peer-reviewed publication to a technical or scientific audience, a different approach such as a quantified before-after comparison, may be required than for projects reporting to non-technical audiences such as donors or local communities (Case study 3), for which qualitative approaches like photo-monitoring vegetation changes may be sufficient. Further, the stakeholders using Traditional Ecological Knowledge will require a different approach

CASE STUDY 2: LEVERAGING CONSERVATION GAINS THROUGH GOAT ERADICATIONS IN THE GALÁPAGOS, ECUADOR

The ultimate goal of Project Isabela, initiated in 1997 and completed in 2006, was to facilitate the restoration of Pinta (5,940 ha) and Santiago (58,465 ha) Islands and the larger, northern portion of Isabela Island (approximately 250,000 ha; the whole island encompasses 458,812 ha). The project began in response to the massive destruction by introduced goats of both native vegetation and terrain (Galápagos Conservancy, 2017). Long-term vegetation monitoring was established on six of the 12 islands in the Galápagos where goats had been introduced (Tye, 2006). Permanent plots and transects showed that eradication or reduction of goat populations led to regeneration of native vegetation (Hamann, 1993; 1979), with a return to a near natural state in most cases after 20 years (Tye, 2006). The monitoring programme successfully fulfilled a number of roles. It confirmed, overall, the success of goat eradication in facilitating recovery of native vegetation and it provided lessons for subsequent eradication operations. In doing this, monitoring helped to manage the risk associated with the operation. The programme highlighted cases where individual species did not recover following goat eradication or exclusion so additional conservation management was required, including the tree fern (*Cyathea weatherbyana*) on Alcedo, whose last two remnant populations were protected by fences in 1997 (Tye, 2006). Perhaps most importantly monitoring demonstrated to public, state and donor audiences the benefits of invasive species management helping to leverage future investment. This led to the Charles Darwin Foundation (CDF) and the Galápagos National Park Service (GNPS) convening a workshop in 2007, on the completion of Project Isabela, to develop an action plan for managing rodents within the Galápagos (Galápagos Conservancy, 2017).

Table 1 Motivations and conditions for monitoring biodiversity outcomes of invasive species eradications.

Why?	When?	What?
Confirm target outcomes[1]	Outcomes are complex and difficult to predict, or poorly studied	Target beneficiaries – quantitative studies
Detect non-target outcomes[1]	Large or complex systems where outcomes are unpredictable	Non-target surveillance – quantitative studies
Learn about whole ecosystem responses[1]	Ecosystem responses remain poorly studied.	Ecological mechanisms of change – quantitative question-driven research. Community ecology
Inform stakeholders[1]	If required, especially for larger operations	Target beneficiaries – qualitative studies (see Case Study 1)
Engage the public[1]	Inhabited islands, regularly visited islands, large operations, publicly funded operations. Projects involving beneficiary species with a high public profile	Target beneficiaries – qualitative participatory monitoring
Ecological risk and uncertainty[2]	Threatened species involved and outcomes uncertain e.g. complex systems	Target beneficiaries – empirical studies
Reputational risk[2]	Large operations funded by key donors, or receiving political and public backing	Target beneficiaries – qualitative studies?
Leverage[2]	Exemplars and trial operations in new geographies paving the way for subsequent repetition/scaling-up	Target beneficiaries – empirical studies

than non-Western science frameworks. Thus, identifying early the key audiences and their needs is recommended as this will influence the cost and approach of monitoring.

Finally, there are a number of practical considerations which may predispose projects to monitor, namely: when existing baseline data are particularly good; when there are existing established monitoring programmes e.g. run by rangers, universities or participatory groups; and/or when funding for monitoring does not compete with management.

Integrating monitoring into project planning

Fundamentally, monitoring should be considered in the earliest stages of project planning. This allows for additional baseline data to be collected if existing data are insufficient for a robust before-after comparison, and for monitoring to be costed and potentially included in the project budget.

There is a wide spectrum of possible monitoring investment for invasive mammal eradication projects, ranging from not monitoring at all, through to comprehensive whole ecosystem monitoring. The few whole ecosystem studies that exist (e.g. Towns, et al., 2016; Griffiths, et al., 2019) provide detailed learning into how systems respond to the eradication of particular species and provide a model for planning equivalent exercises elsewhere. Although these excellent studies represent the optimum approach for eradication monitoring, they are not achievable for all projects, nor may they be necessary to achieve project goals. Here, we aim to provide general guidelines for deciding what level of monitoring is required.

Fig. 1 presents a decision tree outlining the key considerations which determine whether monitoring is necessary, what needs to be monitored and the type of monitoring needed. Although it is presented as a workflow, several steps are inter-related and feed into one another.

1. Defining the desired outcomes of eradication

The most common motivation for monitoring is to confirm the expected outcomes for native taxa after removing a pest species from an island. It is therefore essential that projects clearly define their objectives (Prior, et al., 2018): why is eradication proposed?; what is it expected to achieve? Outcomes should be explicitly split into proximal outcomes, which will typically include the removal of an invasive species and the undesirable interactions with native species (e.g. predation), and ultimate outcomes such as the recovery of a native species. These ultimate outcomes are sometimes referred to as impacts (Nam, et al., 2013). Conceptually, post-eradication outcomes like improved survival and recruitment can lead to impacts like population growth. Where possible, outcomes should be specific, measurable, agreed-upon by those involved in the project, realistic (i.e. ecologically viable), and time-bound (Doran, 1981).

CASE STUDY 3: MONITORING ON ST AGNES AND GUGH, ISLES OF SCILLY, UK

Brown rats (*Rattus norvegicus*) were successfully eradicated from the islands of St Agnes and Gugh in 2013 (Thomas, et al., 2017). The islands have a combined area of 142 ha and a population of 82 people, making it the largest community-led rat eradication project in the world to date. Engaging the community in all aspects of the project including monitoring – and keeping them engaged throughout the life span of the project – was key to the project's success. Community members, especially schoolchildren, were involved in the work, with many people volunteering to take part in monitoring of native shrews, invertebrates, plants and birdlife. The islands' seabirds are of particular value to the community, and islanders are involved in ongoing 'chick check' walks which monitor the breeding success of Manx shearwaters (*Puffinus puffinus*) and European storm-petrels (*Hydrobates pelagicus*) two species which have bred on the islands for the first time in living memory following the eradication of rats. The monitoring activities associated with the eradication project have therefore fulfilled several roles – they have provided ongoing scientific data on the wider ecological impacts of rat eradication and have provided powerful publicity and advocacy information regarding the immediate benefits of eradication on species preyed upon by rodents, such as shearwaters and storm-petrels. The monitoring has also galvanised and helped maintain ongoing community support for the project and ownership of its long-term outcomes.

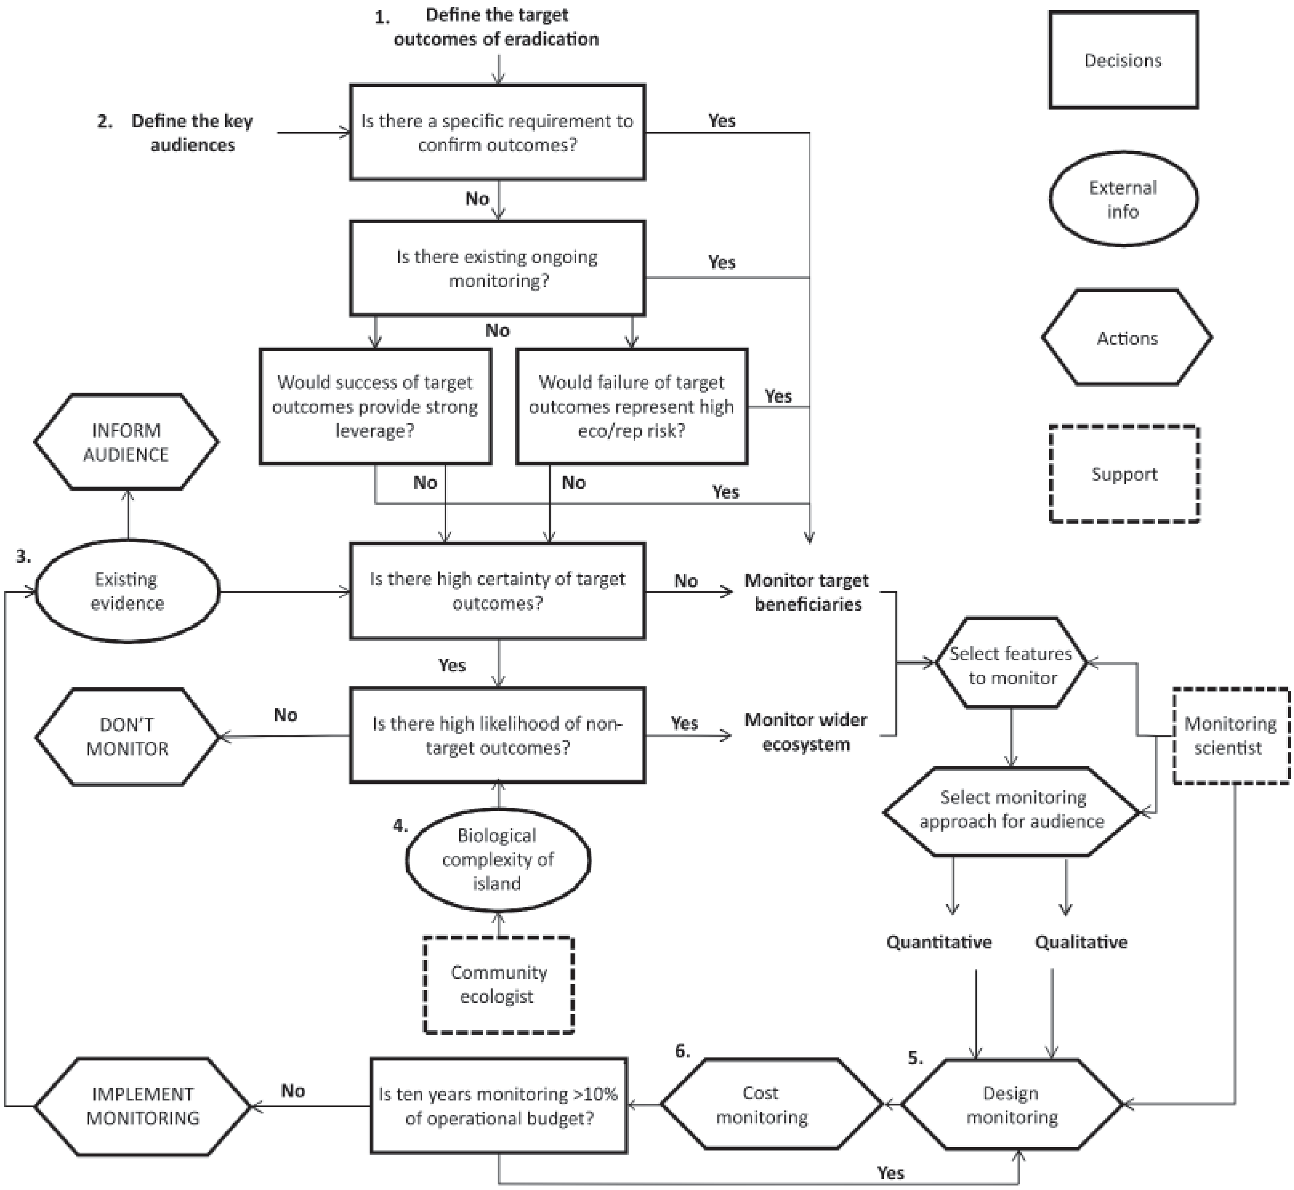

Fig. 1 A decision tree to assist with planning biodiversity monitoring in relation to eradication programmes. After the target outcomes of the eradication and the key audiences are defined, gathering existing evidence and answering a number of questions will inform the scope that monitoring needs to encompass, as well as guide selection of monitoring targets and the required approach to monitoring. Numbered points are discussed in the text.

2. Defining the key audiences

Just as *what* is monitored is driven by project goals (e.g. seabird protection), to *whom* monitoring results should be communicated should also be defined as a part of project planning. For each project, target audiences should be identified: a relevant group for whom the results of ecological monitoring will be of interest, some of whom may actively request the information, while others may be informed more for advocacy and education purposes. By defining these audiences, managers can prioritise and determine what messages and products (e.g. peer-reviewed publications, images, webpages, reports or public lectures) monitoring needs to inform and, in a feedback loop, can identify what to monitor. Key audiences may include the local community, especially island residents or communities close to the island; permit providers such as statutory bodies and island managers wanting to understand the wider ramifications of eradication; conservation scientists and technical communities wishing to use monitoring data to highlight ecological benefits of projects to advocate for similar work; donors vetting project outcomes and return on investment; and decision makers at local and regional levels. At a higher level, the data may also be used to lobby policy makers to enact or amend legislation relating to invasive species and their management. Finally, project managers may wish to engage the wider public with the results of their monitoring work, seeking to develop more broadly society's understanding of the issues posed by invasive species on islands.

3. Identifying existing resources

Determining the presence and suitability of existing baseline data for the target island is an important activity. Existing baseline information may satisfy pre-eradication information needs and can inform future monitoring to replicate the baseline methodology. This exercise may identify stakeholders already engaged in monitoring on the target island, or nearby control islands, whose ongoing work may be tailored to inform eradication outcomes.

It is also valuable to assess the outcomes of other eradication projects that benefited similar species or ecosystems, for example ground-nesting seabirds like terns (*Sterna* spp.) perform well after the removal of all invasive mammalian predators (Brooke, et al., 2017). The consistency with which previous eradications delivered particular outcomes will establish the level of confidence in achieving desired management goals. Syntheses have been undertaken for some taxa that outline broad-scale responses (e.g. Jones, et al., 2016; Schweizer, et al., 2016; Brooke, et al., 2017). Williams, et al., (2017) synthesised information from 16 before-and-after studies documenting seabird responses to predator removal and provide practitioners with effectiveness and certainty ratings for invasive mammal control as a conservation intervention. If the results among projects vary considerably, or there is a specific requirement for reporting to an audience on localised information, then monitoring is warranted.

4. Adopting a whole-ecosystem approach

When planning and designing monitoring, ecosystem processes and community structure should be considered (Zavaleta, et al., 2001; Prior, et al., 2018). By modelling the trophic interactions in a system, flow-on effects can be anticipated, reducing the likelihood of unexpected outcomes (e.g. Baker, et al., 2017). There is a gradient of approaches available to achieve this process, ranging from simple food web diagrams through to models with input from community/ecosystem ecologists. Generating sophisticated models is challenging for many sites owing to a lack of baseline information. However, even simple exercises capturing current and projected interactions within an ecosystem could aid planning. By considering the trophic interactions on an island, those component taxa of interest which are most likely to be impacted can be identified and elevated to monitoring targets. This will also clarify the complexity of the system which highlights the potential need for wider surveillance monitoring beyond anticipated outcomes.

5. Designing monitoring

There is a whole suite of taxa- and site-specific monitoring methods that projects can utilise—it is not our aim to discuss them here. Rather, we focus on three key elements of monitoring design: i) choosing between quantitative and qualitative monitoring methods; ii) determining what to monitor; and iii) allowing for pre- and post-eradication comparison.

The need for quantitative or qualitative monitoring is influenced by the audience to whom monitoring results will be communicated. As described above, a spectrum exists. At one end, are projects for which quantitative monitoring is required: for example, those with quantitative targets such as percentage population changes or reductions in negative trends; or those aiming to quantify outcomes to inform other eradication operations (e.g. by providing evidence for syntheses like Williams, et al., 2017). Further along the spectrum are projects that may need only to provide qualitative evidence of outcomes to laypersons' audiences: perhaps photo-plots illustrating the growth in vegetation following an eradication; or "traffic-light" assessments of ecological integrity (e.g. Tierney, et al., 2009) of an island system following eradication.

To serve most purposes, monitoring can likely focus on taxa or habitats identified when the target outcomes of the eradication were defined. But, when potential secondary outcomes have been identified, such as increases in invasive invertebrates or prey-switching by meso-predators, taxa or habitats predicted to be affected can also be selected as monitoring targets. When outcomes are highly uncertain, we recommend wider surveillance monitoring is undertaken to detect hard-to-predict secondary outcomes. In that case, taxa can be selected for monitoring based first upon need (they are predicted to be affected, but with unknown consequences), and then opportunity, e.g. continued monitoring is worthwhile because baseline data exist and monitoring can be continued easily; there are people involved in the project with particular expertise; there are taxa present for which monitoring is likely to be particularly cost-effective.

Sampling design should ideally occur before eradication. In some instances a Before-After-Control-Impact (BACI) approach may be possible (Quinn & Keough, 2002), whereby control islands (either those with invasive species but where no eradication is carried out, or those with no comparable invasive species at all) can be compared to experimental islands (those with the eradication e.g. Samaniego-Herrera, et al., 2017).

6. Monitoring cost

A major determinant of monitoring design is the economic cost, relative to available budget. For monitoring planned shortly after an eradication, an opportunity for cost saving is to combine efforts with activities to confirm the success or failure of the operation itself.

The amount invested should increase relative to risk and leverage potential (Montambault & Groves, 2009), but there are no clear guidelines on what proportion of a budget to allocate for monitoring and evaluation. There has been no review of proportional expenditures by conservation projects on monitoring and evaluation, but within the development sector and across major foundations typical expenditure is 3–5% of programme costs (Austrian Development Agency, 2009; Twersky & Arbreton, 2014), rising to an upper ceiling of 10% (Zondag, 2009). Establishing a fixed limit for monitoring budgets helps to guide monitoring design, and may result in iterative design to keep monitoring within budget. Including monitoring costs in the overall eradication budget is perhaps the most straightforward way of funding monitoring, when it is a relatively small component of the overall fund-raising target. However, funds secured in this way are often time-bound and not goal dependent—they often expire before monitoring has been conducted for enough years to demonstrate that a target outcome has been reached. Addressing this issue by exploring financial mechanisms such as endowment funds to separate and safeguard monitoring budgets and ongoing biosecurity, or integrate ecosystem monitoring with biosecurity monitoring, could help future projects and improve upon the current approach that relies on post-eradication fund-raising specifically for monitoring.

Making the most of monitoring results

With so many eradication projects now being carried out worldwide and many of them generating data through associated monitoring, it is increasingly difficult for scientists, managers and field officers to keep up to date with new findings, and they can be hampered by language barriers. Furthermore, the data generated are not always disseminated widely. Understandably, positive changes to target beneficiaries and to flagship species, are the most widely reported. Changes in the abundance of other taxa, especially plants and invertebrates, are less often reported, or likely monitored (Jones, et al., 2016; Towns, 2018).

Understanding the outcome of previous eradication projects' pre- and post-eradication monitoring may help new projects gain support for their work, may help to identify and thus allow minimisation of negative secondary impacts, and may help to optimise the allocation of resources to conservation actions where monitoring can be reduced. It is very important, therefore, that first the results from any monitoring that has occurred are disseminated, and second that the information is curated in a readily accessible and searchable manner accessible to technicians, land managers, scientists, conservation bodies, educators and other interested parties. Ideally, they would all be available via a single repository but nothing exists currently (although there is a searchable database of island eradications; Holmes, et al., 2019). Although the outcomes of individual eradications may not be considered sufficiently novel for higher profile journals (Brooke, et al., 2018), a number of journals specifically promote the dissemination of evidence by promoting publication of the outcomes of conservation interventions (Sutherland, et al., 2017). There are opportunities for open access publishing with no limit on the number of papers publishable or the geographies covered, and a streamlined submission and review process. There is a range of ways in which results can then be disseminated more widely (Table 2).

Monitoring informs future conservation practice; it enables us to increase our likelihood of success and reduces uncertainty. We believe that there is a need to broaden information availability and shared resources through diverse platforms, in order to facilitate knowledge exchange. To date, the findings of post-eradication monitoring have not been consistently disseminated, so a behavioural change must be supported and requires incentivising. Including these costs in eradication budgets and encouraging donors to support the collection of evidence that confirms return on investment are first steps in tackling the problem.

ACKNOWLEDGEMENTS

We thank all those involved in organising and participating in the Island Invasives 2017 workshop: "Effective monitoring of response to eradications". We also thank the Editorial team of the Conference Proceedings, and two anonymous referees who provided valuable feedback during the development of this paper.

Table 2 Summary of dissemination routes for pre- and post-eradication monitoring data, particularly to the invasive species-specific technical community.

Media	Dissemination route	Target audience
Raw data	Inter-agency scientific collaborations	Invasive species practitioners and scientists
	Small organisations collaborating with larger ones who can support with data analysis and interpretation	Any
Analysed results	Journals reporting outcomes of conservation intervention in a searchable database	Invasive species-specific scientific and technical community
	Aliens-l listserver	Invasive species-specific scientific and technical community
	Held in central database (e.g. Database of Island Invasive Species Eradications—subject to copyright issues)	Invasive species-specific scientific and technical community
	Eradication project/ organisation websites	Invasive species-specific technical community
Technical reports	Briefing documents, e.g. POST (Parliamentary Office of Science and Technology) notes	Local, regional and national government
	Aliens-l listserver	Invasive species-specific technical community
	Regional websites, e.g. Pacific Invasives Learning Network, PestSmart Connect	
	Annual compendium	Invasive species-specific technical community
	Island Invasives Conference proceedings	Scientific and academic community, invasive species-specific scientific and technical community
	Community forums (newsletters, magazines, websites)	Community in which eradication project was conducted, communities in which similar projects are planned
Layperson reports	Through Aliens-l listserver	Invasive species-specific technical community
	Held in central database?	Invasive species-specific technical community
	Schools	Primary and secondary school children, and teachers
Educational materials	Universities (use examples in lectures on island restoration and species recovery)	Students
	Talks/presentations	Community in which eradication project was conducted, communities in which similar projects are planned, special interest groups (e.g. local bird or mammal groups)
	Web sites	
Social media	Projects own Facebook pages, and links to reports via twitter and instagram	Scientific and academic community, invasive species-specific scientific and technical community. Community in which eradication project was conducted, communities in which similar projects are planned, special interest groups (e.g. local bird or mammal groups)

Abstract The small uninhabited island of Monuriki (40.4 ha) in western Fiji is of national and international conservation concern for its several protected species. Exotic invasive species and a Category 5 cyclone have exacerbated conservation challenges. The cooperation of local, national, and international stakeholders continues to be crucial in restoration of the island's native flora and fauna. This summary presents a timeline of restoration efforts and current status of the recovery programme for Monuriki. The critically endangered dry forest habitat of Fiji is only found in a few isolated patches on disparate islands. The Fijian crested iguana (*Brachylophus* cf. *vitiensis*) is a critically endangered species restricted to a few small islands in this dry forest zone of western Fiji. The population of crested iguanas on Monuriki Island is the third largest remaining population. Even before iguanas were first documented on the island in the early 1980s, individuals had been removed by local resorts for display purposes, a practice that was previously unregulated. In the late 1990s, the first efforts to conserve and restore Monuriki Island were discussed, but conservation initiatives were not implemented until the development of the Crested Iguana Recovery Plan in 2008. In 2011, domestic goats (*Capra hircus*) and non-native rats (*Rattus exulans*) were removed from the island, and 10 pairs of iguanas were brought into captive breeding facilities within Fiji. In 2015, the first 32 captive-bred crested iguanas were released back on Monuriki Island. More than half of these iguanas (N=26) were radio-tracked for 56 days post-release in order to assess survivorship and help provide insights into their short-term movement patterns. Of the 26 iguanas that were tracked, nearly 70% (N=18) were found after 56 days indicating excellent short-term survival. In February 2016, Tropical Cyclone Winston, a Category 5 storm passed through Fiji and devastated some of the tropical dry forest habitat on Monuriki. With sustained winds of up to 230 km/hr nearly all of the canopy leaves from trees on Monuriki Island were removed and large amounts of debris covered the forest floor. Following the cyclone, a brief wildlife survey revealed Monuriki's iguana and bird populations were still present. In 2017, the crested iguana captive breeding programme was brought to an end when 16 of the original 20 iguana founders, and an additional 32 captive bred offspring, were reintroduced onto Monuriki. This was accomplished, in part, due to successful breeding and reestablishment of the remaining wild iguanas on the island. Despite a major storm event, reestablishment likely resulted from reduced egg and hatchling predation by the rats, and excellent habitat recovery after goat removal. Overall these invasive species eradications have proven highly successful for the recovery of the iguanas, wedge-tailed shearwaters (*Puffinus pacificus*), and several other non-target species including the banded rail (*Gallirallus philippensis*) and endangered Fijian peregrine falcon (*Falco peregrinus*). Furthermore, eradication of non-native species has also helped the recovery of the highly threatened tropical dry forest ecosystem in which these species exist.

Keywords: *Brachylophus* cf. *vitiensis*, eradication, Fijian crested iguanas, goats, island restoration, Pacific rats, *Puffinus pacificus*, wedge-tailed shearwater

INTRODUCTION

Tropical dry forest habitats are globally rare and often contain highly endemic faunas. These forests are typically impacted by anthropogenic fires to convert them into lands for agriculture on mainland regions and degraded by multiple invasive alien species such as grazing and predatory mammals, and various invertebrates on islands. In Fiji, most of the dry forest on the two large islands of Viti Levu and Vanua Levu has been transitioned into sugar cane, cattle grazing, or invasive grasslands (Olson, et al., 2010). Dry forest persists only on some of the smaller islands, or in very limited patches on larger islands. Of the smaller islands Monuriki and Monu have been identified as Key Biodiversity Areas (KBA's) by Conservation International because of their significance as critical refugia for the Fijian crested iguana (*Brachylophus* cf. *vitiensis*) and tropical dry forest (Conservation International, 2005; Olson, et al., 2010). These islands, and particularly Monuriki, also support the largest wedge-tailed shearwater (*Puffinus pacificus*) population in Fiji. This paper outlines progress made with the restoration of Monuriki Island by working with the traditional land owners through an innovative and inclusive conservation partnership.

Location

The uninhabited Monuriki Island (12.610° S, 177.034° E) lies within the Mamanuca group in the province of Nadroga, western Fiji (Fig. 1). This 40.4 ha volcanic island reaches its peak at 177 m above sea level (Fig. 2). Monuriki is owned by the Mataqali Vunaivi, the traditional Fijian clan living on the nearby island of Yanuya. Monuriki is listed under the National Biodiversity Strategic Action Plan as a site of national significance due to its tropical dry forest and two particular species of international or national conservation concern, the Fijian crested iguana (*Brachylophus* cf. *vitiensis*) and the wedge-tailed shearwater (*Puffinus pacificus*) (Coulston, et al., 2010; Olson, et al., 2010). Monuriki is the location of the third largest population of the endemic Fijian crested iguana (IUCN, 2014). This iguana is listed on CITES Appendix I, as Critically Endangered by the IUCN Red List (IUCN, 2014), and Endangered by the US Fish and Wildlife Service; it is protected in Fiji under the Endangered and Protected Species Act (2002). Monuriki Island crested iguanas are genetically distinct from all other crested iguana populations (Keogh, et al., 2008), and the 2008 Iguana Species Recovery Plan (Harlow, et al., 2008) prioritised Monuriki as the single most important site

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 552–557. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

for immediate conservation action for this taxon. These iguanas were discovered only in 1980. At that time there was "a high density of iguanas" on Monuriki (Gibbons, 1984); however, less than 20 years later a survey revealed fewer than 100 iguanas remained (Harlow & Biciloa, 2001). A more recent survey indicated the population had dropped precipitously further with more extensive surveys reporting only eight individuals found in 2003 (Harlow, et al., 2007). The island also hosts several nesting colonies of the wedge-tailed shearwater (*Puffinus pacificus*), a species known from seven islands in Fiji and among which Monuriki supports the most significant population. These sea birds excavate burrows, often in the fragile coastal strand substrates, to rear their chicks. It was estimated that more than a thousand pairs of wedge-tailed shearwaters annually breed on this island (Rasalato, et al., 2012). Exotic faunal and floral species have invaded many of the islands in Fiji and pose a serious environmental threat to Monuriki's native biodiversity.

Threats to native species

Fire is an anthropogenic threat to Monuriki, due to the island's small size and lack of natural ignition sources. Exacerbating this is the threat of exotic non-native species. The history of exotics on the island of Monuriki may date back more than 3000 YBP. Pacific rats (*Rattus exulans*) were the first exotic species introduced to this island, most likely as stowaways with the early human arrivals (Roberts, 1991). This adaptable species has been able to sustain itself on most islands left unchecked until eradication is implemented. Rats are known to prey on eggs and chicks of nesting birds, as well as lizards, juvenile tuatara (*Sphenodon punctatus*), and seeds (Towns, et al., 2006). Domesticated goats (*Capra hircus*) were established on Monuriki during the 1970s. Originally brought as livestock, they provided an income for the Yanuya owners of the island. As voracious grazers, goats denuded the island of its undergrowth and ate the seedlings of forest trees, and leaf litter causing serious habitat degradation and severe erosion. The dry forest habitat may recover from infrequent dry season burning in the next rainy season provided seedlings are left intact. However, when goats are present the seedlings are grazed, preventing the regeneration of these native plants and trees. This causes the endangered dry forest habitat to convert to a mostly non-native composition while any remaining mature native trees senesce and eventually die. Following this cycle with fire and goat grazing on Monuriki, the lack of native food plants posed a threat to the diminished population of iguanas. Most of the surviving vegetation was unpalatable to both goats and iguanas. The open ground left by the continual grazing created space for opportunistic invasive exotic and unpalatable plants to take hold, including the native but invasive vaō (*Neisoperma oppositifolium*). Normally found in low abundance, vaō became overabundant with disturbance and an increase in light through the canopy increasing its representation in the forest composition. Goats also threatened the ground-nesting shearwaters by trampling nests, and causing the collapse of fragile burrows containing eggs, chicks, and nesting adults. The loss of insulating vegetation (leaf litter and understorey structure), moderating water runoff and erosion during heavy rain events, also potentially reduced shearwater breeding success due to inundation of burrows and nests. Most documented extinctions and current causes of declining numbers of Pacific island birds result from the effects of invasive alien species, and particularly vertebrates such as rats and goats (McCreless, et al., 2016).

Tourism and poaching are additional disturbances to this island which greatly impact iguanas, and increased foot traffic during the breeding season might impact wedge-tailed shearwaters, and other natives such as the banded rail (*Gallirallus phillippensis*), and peregrine falcon (*Falco peregrinus*). Monuriki is the site where the award-winning 1999 Dreamworks movie "Castaway" was filmed, and subsequently the island has become popular as a tourist stop with the remaining movie set maintained as a primary attraction. Ecotourism is the major contributor to Fiji's economy in this region. An estimated 70–100 tourists visit the island daily although the number could be much larger some days. Local resorts are still removing iguanas for display on other nearby islands as an "ecotourism" prop to draw in customers, and for tourist activities such as staged photos.

Restoration plans and community conservation

In the late 1990s, the first efforts to conserve and restore Monuriki were discussed. In 1998, 2000, and 2003, surveys of Monuriki detected a rapid decline in the iguana population as a result of continued major habitat degradation by goats, with only adult iguanas being detected and no evidence of recent recruitment (Harlow, et al., 2007). The landowners were approached on at least three occasions to remove goats from Monuriki, but declined to participate each time. In 2004 the IUCN Iguana Specialist Group (ISG) met in Fiji to discuss the current impacts on Monuriki, as part of identifying potential conservation actions possible for the species, including captive breeding. Through the development of the IUCN Crested Iguana Recovery Plan in 2008, conservation action steps for Monuriki were fully-developed and finally implemented. In 2009, BirdLife International undertook surveys that documented rats and goats to be major threats to nesting seabirds on Monuriki and nearby Monu and Kodomo islands (NTF, 2012). It was concluded that, if left unchecked, the persistence of rats and goats would lead to the loss of the dry forest and nesting seabirds on Monuriki. With the endorsement of the Yanuya

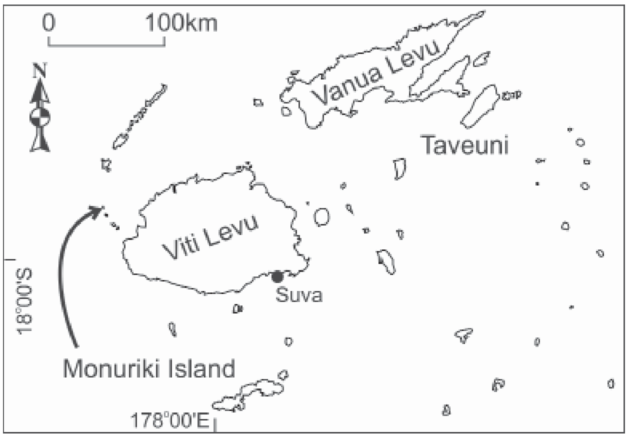

Fig. 1 Map of Fiji with arrow showing the location of Monuriki Island.

Fig. 2 View of Monuriki Island from 2017, looking to the south-west.

Village Chief and chief landowner, Sitiveni Drigi, an eradication programme was therefore implemented during 2010–2011, specifically targeting invasive rats and feral goats remaining on Monuriki (NTF, 2012). The goal of this programme was to restore an ecosystem suitable for the wedge-tailed shearwater, birds native to Fiji's tropical dry forest, and the critically endangered crested iguana. Regular post-eradication monitoring, along with environmental education campaigns specifically targeting biosecurity among island users including tourists and fishermen, were critical components to sustaining the eradication results and restoration outcomes (Donlan & Keitt, 1999). The eradications were designed in collaboration with eradication experts (i.e., Pacific Invasives Initiative), local land owners, the Provincial and National government, and consultants. Two years of monitoring on Monuriki (and Kodomo) did not detect rats and goats and by the end of 2013 their eradication was confirmed.

METHODS

Consultation

Many stakeholders were included in discussions regarding the invasive species eradication plan. The plan was launched as a community-based effort to successfully restore and protect the natural state of Monuriki. The involvement of the landowning unit in the village of Yanuya (the Mataqali Vunaivi) and their chief, the late Taukei Yanuya (Ratu Sitiveni Drigi) played a pivotal role in ensuring the restoration and protection of Monuriki was supported by the Yanuya community.

Other stakeholders since 2009 include (but are not limited to):

- BirdLife International
- Commissioner Western's office of the Fiji Government
- Community members and village groups
- Critical Ecosystem Partnership Fund
- David & Lucile Packard Foundation
- Department of Heritage and Arts
- Disney Conservation Fund
- School of Geography at the University of the South Pacific
- Iguana Specialist Group (IUCN)
- International Iguana Foundation
- Kula Wild Adventure Park
- Mamanuca Environment Society
- Ministry of Agriculture (Fiji)
- Ministry of Local Government, Housing & Environment (Fiji)
- Nadroga/Navosa Provincial Office
- National Trust of Fiji Islands
- NatureFiji-MareqetiViti
- New Zealand Department of Conservation
- Pacific Invasives Initiative
- San Diego Zoo Global
- South Sea Cruises
- Survivor Entertainment Group
- Taronga Conservation Society Australia
- US Embassy Suva, Fiji, Regional Environmental Affairs Office
- US Geological Survey, Western Ecological Research Center
- Yanuya Rugby Team.

Consultations with landowners were (and will continue to be) conducted before, during and after each activity or site visit. Transparency of all information and intentions of any actions are disclosed to stakeholders (BirdLife, 2011b).

From 2009–2010, discussions that addressed goat grazing on the island were held with landowners. Although the BirdLife surveys in 2009 confirmed goats to be a significant factor in the decline of the native species, goats were also a contributor to the village of Yanuya's financial income through market sale or occasional harvest for meat. Therefore, compensation for the village of Yanuya to halt goat grazing was agreed upon by the community and supported by various stakeholders. In 2010 a Memorandum of Understanding (MOU) was signed with the Mataqali Vunaivi, National Trust, and Kula Eco Park (now Kula Wild Adventure Park) for rat and goat removal, and iguana harvest for the captive breeding programme. The National Trust of Fiji and BirdLife International jointly carried out operations to eradicate rats in August of 2011 and goats between June 2010 and November 2011. At the same time, it was decided the best way to conserve the crested Fijian iguana was to harvest 10 sexually mature adult pairs (N = 20) from the remaining iguanas on the island for captive breeding and subsequent reintroduction. From April 2010 to February 2012 Monuriki iguanas were collected and brought to captive breeding facilities located at Kula Eco Park as part of the MOU.

Goat removal and eradication

The local Yanuya Rugby Team was employed to muster and catch goats on the island utilising mustering routes and techniques established by the local communities from decades of catching goats on Monuriki. From June to November 2010, 151 goats were mustered from the island over 12 days, and as of January 2011 an estimated 20 goats remained (BirdLife, 2011a). Captured goats were taken to the Viti Levu mainland for sale. Two professional hunters from New Zealand using trained dogs eliminated more than 50 additional goats over an 11-day period in September 2011. A final four day follow up hunting effort in November 2011 detected no additional goats (BirdLife, 2011a). To compensate for expected revenue loss of these animals, the owners received FJ$100 per goat. Post-eradication monitoring of the forest vegetation using fixed photo points and of the wedge-tailed shearwater population was conducted to assess the response to the goat eradication (Rasalato, et al., 2012).

Rat eradication

Eradication of Pacific rats (*Rattus exulans*) was carried out by delivering specially formulated rodenticide (brodifacoum at 20 ppm) baits (PestOff 20R) from a helicopter using standard procedures and equipment including a specifically designed spreader bucket calibrated to the required application rate (20 kg/ha) and GPS (Seniloli, et al., 2011). To determine the success of the rat eradication, a series of transects with rat-trap (Victor Professional) and rat-detection stations were created in two to three main locations across the island for each monitoring event in 2012, 2013, 2015, 2016, and 2017. The transects were set up in areas of the eastern, northern, and south-western beaches with between 10 and 20 stations for each transect (Rasalato, et al., 2012; Fig. 3). Each station comprised at least one snap trap, but the first assessments also included a peanut butter wax tag, a tracking tunnel and a second snap trap. The peanut butter wax tags were nailed to trees at random heights so as to reduce hermit crab access. Ink pads were placed in tracking tunnels with roasted coconut placed on the pads to act as baits. Snap traps were also baited with roasted coconuts and positioned to minimise non-target interference (e.g. hermit crabs).

These monitoring stations were set-up for three trap nights and were maintained and checked daily for any signs of rat activity (Rasalato, et al., 2012).

Biosecurity control

There is on-going training and outreach to the local tour companies about the conservation activities on Monuriki Island. Furthermore, biosecurity protocols were established to help reduce the potential negative impacts of the tours and other visitations to the island. A biosecurity plan prepared in 2013 (Thaman & Niukula, 2013) is reviewed and updated every two years (Seniloli, et al., 2015). The plan includes three main biosecurity procedures: preventing the entry of invasive alien species, systematic checking for such species, and rapid response procedures if any are found. Measures include the establishment of a community-based ranger programme to train local rangers on invasive species surveys, response methods and the prevention of wildlife poaching.

Kula Eco Park captive breeding programme

Concurrently with the rat and goat eradication efforts (2010–2011), 20 Monuriki iguanas were harvested and brought to Kula Eco Park, on the main Fijian island of Viti Levu, to develop a captive breeding colony. Pairs were successfully bred in managed care with the intention of re-introducing the offspring to their home island once the forest vegetation had recovered from grazing.

Species recovery

Monitoring for native species recovery has taken place so comparisons to pre-eradication surveys can be conducted. This includes using standard protocols for the iguanas and shearwaters, and recording other incidental species recoveries (Harlow, et al., 2007; Rasalato, et al., 2012). Vegetation surveys were conducted in fixed plots prior to the mammal eradications, and these plots were resurveyed in 2016, after the eradications, following the same survey protocols (Harlow, et al., 2007).

RESULTS

Goat removal and eradication

Since the goat removal and eradication was undertaken, there have been no detections of goats on the island during the last five years (through to 2017), confirming this action to be a success.

Rat eradication

In March 2012, five months after the helicopter spread of rodenticide, no rats were trapped nor were there any obvious signs of rat presence such as droppings, gnawed fruits or sightings (Rasalato, et al., 2012). Similarly, no indications of rat presence were found during subsequent assessments to date (2013, 2015, 2016, 2017), confirming eradication of Pacific rats from Monuriki Island and an ongoing rat free status generally.

Fig. 3 Monuriki Island showing the transects with the rat sampling stations on the west and east beaches.

Biosecurity control

Ships/vessels, commercial and private, are required to abide by the biosecurity measures detailed in the most recent version of the biosecurity plan (Seniloli, et al., 2015). These measures include setting up and maintaining bait and trap stations near wharfs and landing sites, regular checks of vessels for alien species stowaways, proper storage of food and regular decontamination of equipment including footwear; detection of any alien species on the island requires immediate reporting to a designated regional support centre. Although outlined, implementation of all of these actions has been slow, due to lack of resources. Camera stations to detect and assess risk of reinvasion, especially by rodents, were set up to monitor tourist visitations at designated areas of Monuriki. Some cameras are obvious and others are hidden; this programme helped identify what items are being brought ashore. Community awareness and involvement in implementing and enforcing biosecurity measures has been important in preventing additional invasive species from establishing on the island. This includes the cooperation of tour boats and yachts that must now follow biosecurity guidelines by having to report to local landowners or designated personnel and crew for a biosecurity briefing before anchoring near the island, although this is still to be fully enforced (NTF, 2012).

Kula Eco Park captive breeding programme

After four wet seasons following goat removal, the vegetation of Monuriki showed significant recovery, so we initiated the reintroduction of iguanas from Kula Eco Park. In mid-May 2015, 32 captive-bred crested iguanas, all implanted with unique PIT tags, were released into four different areas on Monuriki Island (Chand, et al., 2016) after a major community ceremony highlighting this milestone in the programme. Community members participated in the release of the iguanas and the event has been recorded in a video documenting the story (<https://vimeo.com/163325268>). In February 2017, 32 additional captive bred juveniles along with 16 of the original wild caught adults were released; 10 of each group were tracked for five months to measure post-release survivorship. Because this event signalled the end of the captive breeding programme and to thank the community for their permission and participation, a second major community event involving many levels of the Government was planned around the release. Only a few young iguanas remain in captivity for release in 2018 or 2019.

Released iguanas were monitored in 2017 and any wild captured individuals or recaptures from the 2015 release were measured and weighed to document post-release growth and general health. Transmitters used to help track released iguanas were removed before final re-release after the five-month period. Currently, the crested iguana population on Monuriki is recovering with the release of captive breeding programme animals, and naturally with existing wild animals (see below). Due to this success the captive breeding programme was ended on 24 February 2017, after the final release of the remaining 16 wild founder iguanas. Overall, between 2015 and 2017, a total of 80 iguanas, including the founders, were released into the wild.

Species recovery

Between February and June 2017, 35 wild iguanas (not passing through captivity) were caught and marked. Many of these were young animals that would have hatched after the rat eradication was completed. This sample of iguanas revealed that, within five years, the small remaining population of iguanas is reproducing and recruiting back into the recovering habitat.

A monitoring survey was conducted for wedge-tailed shearwater nests post-eradication. Out of the 159 burrows searched, 110 (69%) were occupied by chicks and one had an egg. Pre-eradication wedge-tailed shearwater nest site occupancy was 41% whereas post-eradication this had risen to 69% occupancy (Rasalato, et al., 2012). The size of the wedge-tailed shearwater population on the south-western beach colony during the 2011–2012 seasons was estimated to be 1383 breeding pairs (Rasalato, et al., 2012). As an additional positive outcome, banded rails (*Gallirallus philippensis*) and peregrine falcons (*Falco peregrinus*; critically endangered in Fiji) are more frequently encountered on Monuriki following rat and goat eradications.

Habitat monitoring to document terrestrial dry forest habitat recovery following goat removal was conducted in 10 previously established 100 m^2 plots in the lowlands behind Rogua Beach. Vaō trees dominated the forests on Monuriki before the eradications. This species is unpalatable to both goats and iguanas. However due to goats' removal of the edible understory and lower branches of the taller edible trees, the goats were now starting to chew on the stems of the vaō. During the presence of goats and rats, vaō comprised 91.3% of the seedlings per plot, but only 58.7% of the seedlings per plot after goats and rats were removed. Individual vaō trees (> 2 m in height) had decreased from 155 to 78 individuals across the plots after mammal removal. Although this plant is native, it spreads like an invasive with disturbance. There is no plan to control it, but the recovery of the other native forest diversity will reduce its cover over time. For example, only three other tree species seedlings were documented when goats were present; now there are about 11 species of seedlings present per plot including *Hibiscus*, *Diospyros*, and *Pongomia*. Ground cover of vine (some invasive but edible such as *Passiflora foetida*) increased from 0% with goats to 30.2% after goats were removed. Habitat recovery was determined to be successful through these habitat surveys, although no similar repeated surveys have been done on the higher slopes where a greater diversity of dry forest trees are present.

DISCUSSION

Overall, the Monuriki Island restoration programme has been a great success and a model for Fiji and other nations in the region. Table 1 is a timeline that reviews the overall impacts to the island and the major milestones relevant to the plan. Monitoring will continue over the next decade as the tree canopy expands and invasive plants continue to be removed from the island. On the two main beaches, invasive plants are being removed manually and dry-forest trees are being planted within the coconut groves that persist. Over time these areas will recover to dry forest also. Most of the obvious habitat damage from cyclone Winston was on these coconut groves, breaking them in half, and the native trees on the ridges that were damaged seem to be recovering well from the event.

Table 1 Timeline of impacts and recovery actions on Monuriki Island.

Rattus exulans introduced to Fiji	ca. 3,000 years ago
Goats introduced to Monuriki	1970s
Iguanas discovered on Monuriki	1980
Iguanas captured for resort displays	1980s–2000s
Castaway was filmed	1999
IUCN Iguana Specialist Group Suva, Fiji	2004
Crested Iguana Species Recovery Plan	2008
Discussions with landowners over goats	2009–2010
Goat eradication operation	2010–2011
20 Monuriki iguanas harvested for captive colony	2010–2012
Rat eradication operation	2011
Goat and rat eradication confirmed	2013
32 captive-bred iguanas released	2015
Cyclone Winston (Category 5)	2016
Reality TV Show now being filmed on Monuriki	2016–2017
32 captive-bred iguanas released	2017
16 remaining original founder iguanas released	2017

Community engagement

This programme has continued with renewed investment in the local community through the development of a regional Ranger Programme for Fiji iguana conservation. Various stakeholders have supported the development and training of local residents to act as regional iguana experts and habitat managers. This programme includes capacity building by training local rangers in field survey techniques, habitat management methods, reforestation efforts, guest experience training for tourist interactions, and anti-poaching. Support for the Rangers and other local level science educators to attend conferences and workshops (such as the IUCN Iguana Specialists Group) geared toward engagement in conservation initiatives for threatened species has continued to provide valuable training and resources for long-term capacity building within Fiji. Education and outreach materials have been developed with the goal of reaching the regional children through programmes for the classrooms. Visits to the local communities to conduct outreach programmes have provided additional opportunities to reach the local communities and encourage their continued support in the conservation of the native threatened species.

To protect the regenerating forest, the community Rangers also established tourist hiking paths with the intent of educating visitors about tropical dry forest habitat while keeping their impacts on the island to a minimum. Interpretive kiosks are being developed and will be installed at the tourist beach.

Additional threats

In February of 2016, Tropical Cyclone Winston passed through Fiji with a peak intensity of ten-minute sustained winds of 230 km/hr that removed a significant proportion of the canopy leaves from trees on Monuriki Island (Fig. 4). Terrestrial surveys conducted in March 2016, indicated that the iguanas and birds were still present and increasing, but that long-term studies after this storm event would be critical for helping to understand species resiliency and recovery in the wake of massive tropical storms. BirdLife continues to monitor the wedge-tailed shearwater population and, while no assessment was made following cyclone Winston (which occurred during the chick feeding phase), population measures assessed will inform recruitment trends. The final 16 original founding iguanas, along with their 32 offspring produced as part of the captive breeding programme, were released after this extreme weather event (Table 1). Robust population monitoring for the iguanas will take place during 2018 to assess the longer-term survivorship of the released iguanas and track recovery of the remaining wild individuals.

2016–2017 Reality TV show, Survivor, now being filmed on Monuriki

Regional conservation efforts for Fijian iguanas have continued and grown to include additional partners. One such collaborator, Survivor Entertainment Group, has been strongly supportive of the programme since their arrival to the region. Although this partner may not be conventional when considering species conservation and habitat restoration, they have embraced and supported our efforts to save the Fijian iguanas from extinction and have assisted in efforts to continue local level engagement. There might be impacts of the filming activities on the shearwaters, but these are hard to measure, and are being minimised by marking active nest sites and putting in avoidance trails to move film crews and contestants around these sensitive sites. By providing significant local employment opportunities and incorporating and investing in biosecurity training methods and native species conservation as part of their local strategic plan they have become an advocate for these restoration and recovery efforts in the region.

ACKNOWLEDGEMENTS

The following people helped in the field to accomplish this work, these include: B. Nagle, G. Coulston, P. Biciloa, A. Naikatini, T. Tuamotu, C. Rochester, S. Pasachnik, S. Hathaway, E. Matatia, N. Felstead, S. Anstey, M. Glaser, K. Waga, M. Segaidina, and B. Rashni. Additional help was received from the National Trust of Fiji Islands, Nadroga Provincial Office, Mataqali Vunaivi, and Mamanuca Environment Society. Funding was provided by the Polynesia/Micronesia CEPF, International Iguana Foundation, Dutch Iguana Society, San Diego Zoo Global, Taronga Conservation Society Australia, Survivor Entertainment Group, and the USGS Ecosystems Mission Area. BirdLife International would like to thank the David and Lucile Packard Foundation for supporting this work and for the goat eradication, Glen Coulston, and, in its implementation, Ian Warfe and Luke Robertson from the Department of Conservation, New Zealand. The professional services of John Oakes, Otago, New Zealand for supporting technically the aerial baiting operation and the team of Island Hoppers, Nadi, Fiji for the provision of helicopter services.

Abstract Considerable benefits can be achieved for indigenous biodiversity when invasive vertebrates are removed from islands. In New Zealand, two logistically challenging eradications were undertaken, one to remove cats (*Felis catus*) and the other Pacific rats (*Rattus exulans*) from Te Hauturu-o-Toi/Little Barrier Island (Hauturu). Here we document the short- and long-term impacts of these interventions on the biodiversity of Hauturu. We also assess the extent to which predicted outcomes were reflected in the measured responses for a wide range of species. Short-term impacts of the eradication program encompassed individual mortality for some native species but no measurable impact to populations. In contrast, at least 11 native vertebrates and one native invertebrate species increased in abundance after rat and cat removal. Fifteen of 34 plant species monitored had significantly more seedlings on Hauturu after rat eradication compared with control islands, indicating future changes in forest composition. Several native species previously not recorded on the island were discovered, including the New Zealand storm petrel (*Fregetta maoriana*) (formerly considered extinct), the forest ringlet butterfly (*Dodonidia helmsi*) and eight species of aquatic invertebrate. The chevron skink (*Oligosoma homalonotum*) has been found in increasing numbers and tuatara (*Sphenodon punctatus*), raised in captivity on the island, are now re-established and breeding in the wild. These results illustrate an island gradually recovering after a long period of modification. We conclude that more success stories such as Hauturu must be told if we are to allay the public's concerns about such eradication campaigns. And more public support is required if the conservation community is to tackle invasive species at a scale commensurate with the threats they pose.

Keywords: conservation management, ecosystem, restoration, species recovery

INTRODUCTION

Worldwide, more than 1,000 invasive vertebrate eradications have been successfully completed to prevent biodiversity loss (DIISE, 2017) and many benefits to species and ecosystems have been documented (Jones, et al., 2016). However, eradication projects continue to attract controversy (e.g. Howald, et al., 2010; Griffiths, et al., 2012; Capizzi, et al., 2019) suggesting that, despite transparent consultation processes, sectors of the public remain unconvinced of the relative cost benefits of this conservation strategy.

To illustrate the value of invasive vertebrate eradication, we present the short- and long-term impacts on biodiversity following the removal of cats (*Felis catus*) and Pacific rats (*Rattus exulans*) from Te Hauturu-o-Toi/Little Barrier Island (hereafter referred to as Hauturu). Specifically, we ask whether the claimed benefits of cat and Pacific rat eradication were met.

The eradication of cats from Hauturu raised little public concern and, under New Zealand environmental law, did not require consent. In contrast, the proposed rat eradication raised cultural and environmental concerns and, because rodent bait was broadcast by helicopter, required local government consent (Resource Management Act 1991). Some members of the public were opposed to the aerial application of rodent bait and some Māori iwi (tribes) contested the removal of rats because of their cultural significance. Consequently, public hearings were held and an Assessment of Environmental Effects (AEE) (Griffiths, 2002) was presented to a panel of independent commissioners. The AEE identified the legal mandate for the removal of rats and the risk to native species if rats remained. The application was approved as the potential benefits to native biodiversity were judged to outweigh the short-term environmental costs.

Cats were removed from Hauturu in an operation that spanned four years from 1977 to 1980. To support this work, a 67 km long track network was established across the island and three huts built at strategic locations (Veitch, 2001). Leg-hold traps and baits containing the toxin 1080 were the principal methods employed to remove cats, although cage traps, the introduction of pathogens and dogs were also used (Veitch, 2001). Mitigation of potential impacts on non-target species was undertaken through careful placement of traps.

Rats were eradicated in 2004 by the New Zealand Department of Conservation (DOC) in an operation utilising the aerial application of Pestoff 20R™ rodent bait containing brodifacoum at 20 ppm (Griffiths, 2004). Rodent bait was applied twice by three helicopters in two successive operations during winter, the first on 8 and 9 June and the second on 12 July. At the same time, baits were placed in bait stations within all buildings and huts on the island. The operation used a total of 55 tonnes of rodent bait with rates for the first and second bait applications averaging 11.7 kg/ha (ca. 1 bait per 1.7 m^2) and 6.16 kg/ha (ca. 1 bait per 3.2 m^2), respectively, across the island. The success of the eradication operation was confirmed in January 2006 after extensive monitoring both on and off the track network across the island with tracking tunnels, spotlight searches and indicator dogs (Griffiths, 2006).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 558–567. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Our findings are based on research and monitoring completed on the island from 1962 to the present. We review published and unpublished studies, but also present new data that illustrate changes following rat and cat removal.

STUDY AREA

Hauturu (3,083 ha), 36°11′56.76″S, 175°4′53.04″E is almost midway between Great Barrier Island/Aotea and the mainland (Fig. 1). Rugged and steeply dissected, the island arose from the partly eroded core of a composite volcanic cone that formed 1.5–3 Ma (Lindsay & Moore, 1995)(Fig. 2). Hauturu was first settled around the 14th C by the descendants of the Maori ancestor and voyager Toi te Huatahi and was occupied continuously until the arrival of Europeans in the 1800s. Over this and the ensuing period of European settlement, approximately one third of the island (the south-west) was cleared, burnt and subjected to grazing by sheep (*Ovis aries*) and cattle (*Bos taurus*) (most of these areas have since reverted to native vegetation and are now secondary successional forest or older). Because of its unique forest and threats to the diverse birdlife, the island was gazetted as New Zealand's first Nature Reserve in 1896 (Young, 2004).

Except for feral cats and rats, the island escaped many of the invasive vertebrate introductions to the main islands of New Zealand and, consequently, its fauna is still largely representative of northern New Zealand prior to European colonisation. By area, the island supports a greater diversity of native birds and reptiles than any other part of of New Zealand. Nonetheless, the introduction of rats and cats to Hauturu had a huge impact. Pacific rats, considered to have arrived early during the period of Maori settlement (Campbell, 2011), likely extirpated most of the small seabird species still seen on nearby rat-free islands. Rat predation may also explain the absence of milk tree (*Streblus banksii*), coastal maire (*Nestegis apetala*) (Campbell, 2011), large land snails and slugs on the island (Campbell, 2011). The introduction of cats sometime around 1867 resulted in the extinction of the last population of North Island snipe (*Coenocorypha barrierensis*) and extirpation of the tieke (*Philesturnus rufusater*), grey-faced petrel (*Pterodroma macroptera*), and probably other seabirds. It is likely that other species such as the black petrel (*Procellaria parkinsoni*) would have suffered a similar fate had cats not been removed.

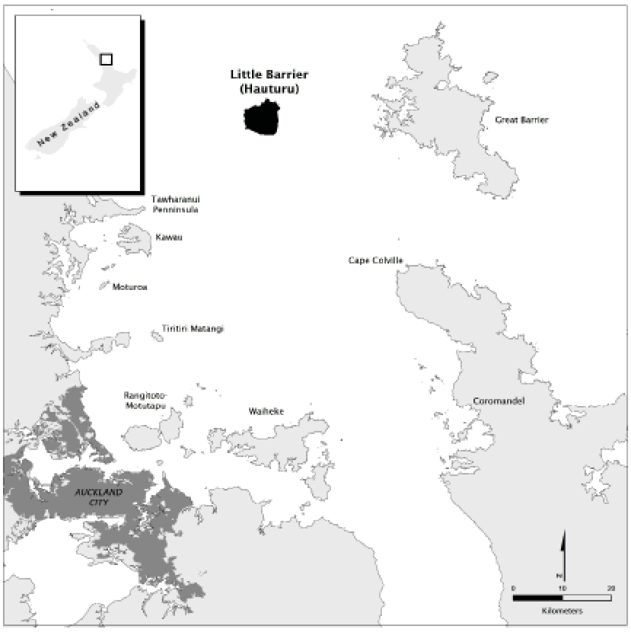

Fig. 1 Map showing the location of Hauturu.

METHODS

A literature search of published and unpublished monitoring, undertaken to measure the environmental impacts of cat and rat eradication, was conducted but also included general research and monitoring completed on Hauturu for other reasons. We assessed impacts as measured costs, measured benefits, and unknown costs or benefits to biodiversity. Unknown costs and benefits were largely a function of an absence of monitoring prior to and following eradication, and/or due to environmental changes unrelated to the eradications. For example, Hauturu supports breeding populations of the New Zealand lesser short-tailed bat (*Mystacina tuberculata*) and long-tailed bat (*Chalinolobus tuberculatus*), both endemic to New Zealand. Bat populations were not monitored before, during or after cat and rat eradication.

We first summarise the predicted outcomes (Tables 1 and 2), then collate previously published monitoring results obtained from a Web of Science and Google Scholar search completed on 24 January 2017 using the key words 'Little Barrier Island' and 'Hauturu'. We then summarise unpublished research and monitoring reports and other unpublished data including the methods used (Table 3) and analyse data on terrestrial birds (see mist-netting below). Changes in island species composition after rat and cat eradication were determined by comparing recent literature with historical reports. For simplicity, results are grouped by taxa: marine birds, terrestrial birds, reptiles, freshwater fish, terrestrial invertebrates, aquatic invertebrates and terrestrial plants.

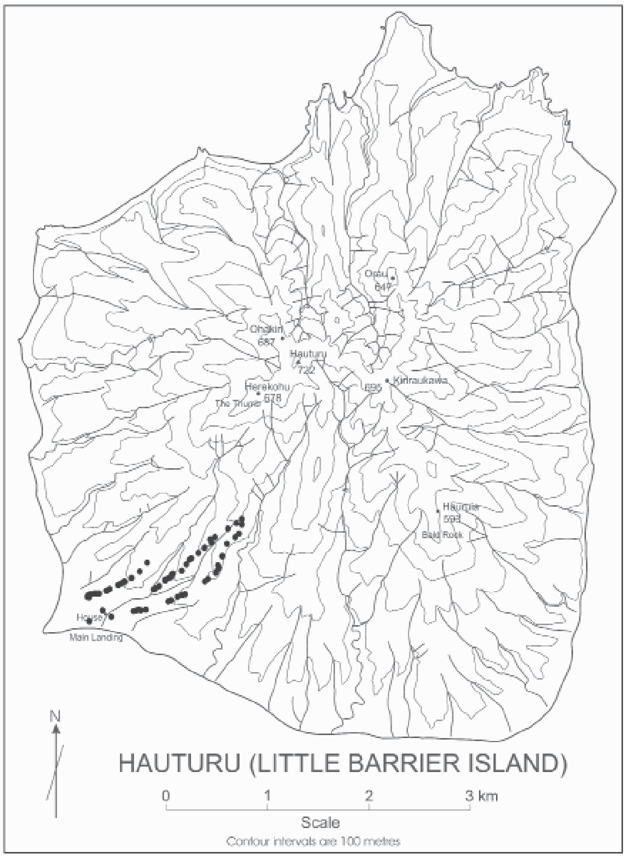

Fig. 2 The rugged nature of Hauturu and locations of mist nets (black dots) used to sample forest bird abundance before and after rat eradication.

Table 1 Predicted benefits of cat eradication from Hauturu with species marked* identified in Recovery Plans for threatened species.

Native biodiversity	Evidence	References
Black petrel	Direct evidence of cat predation and declining breeding distribution	(Girardet, et al., 2001)
Cook's petrel/titi	Direct evidence of cat predation and declining breeding distribution	(Imber, et al., 2003a)
Tieke	Potential for reintroduction	(Girardet, et al., 2001; Hoosen & Jamieson, 2003)
Kakapo*	Potential for ex-situ management of Stewart Island population heavily impacted by feral cats	(Lloyd & Powlesland, 1994; Anon., 1996; Elliott, et al., 2001)
Kokako*	Potential for reintroduction	(Innes & Flux, 1999)
Grey-faced petrel	Recolonisation expected	(Girardet, et al., 2001)

Table 2 Predicted responses to rat removal from Hauturu as identified in the assessment of environmental effects (Griffiths, 2002), with conventions as in Table 1.

Native biodiversity	Evidence	References
Species that faced local extinction in the absence of intervention		
Cook's petrel	Fledgling recruitment on Whenua Hou (Codfish Island) increased to 90% following rat eradication	(Imber, et al., 2003a)
Tuatara*	Documented impacts on juvenile recruitment. Local extinction predicted by population models completed for Marotere and Taranga Islands	(Gaze, 2001; Towns, et al., 2007; Cree, 2014)
Wetapunga*	No off-site data but examples of localised extinctions in other flightless crickets e.g. tusked weta (*Motuweta isolata*; Mercury Islands)	(Towns, et al., 1990; Sherley, 1998; Towns, et al., 2006)
*Dactylanthus taylorii**	No off-site data on impacts by Pacific rats on this species but video evidence of inflorescence destruction by rats on Hauturu	(Eckroyd, 1995)
Giant-flowered broom	Examples of localised extinctions from other archipelagos (e.g. Marotere Islands)	(Towns, et al., 2003)
Species predicted to benefit from intervention		
Grey-faced petrel	Increases in abundance documented elsewhere after Pacific rat removal (e.g. Korapuki Island, Stanley Island)	(Towns & Atkinson, 2004; G Taylor pers. comm.)
Diving petrel	Localised extinctions reported in other archipelagos and increased abundance following Pacific rat removal (e.g. Mercury Islands)	(Towns & Atkinson, 2004; G Taylor, pers. comm.)
Tieke	Evidence of increased abundance after Pacific rat removal (e.g. Red Mercury Island)	(Robertson, et al., 1993)
Towns' skink	Examples of localised extinctions in other archipelagos (e.g. Mokohinau, Marotere Islands) or confinement to refugia (Hauturu)	(Towns, et al., 2003)
Duvaucel's gecko	Confined to refugia in presence of Pacific rat (Hauturu). More terrestrial activity and increased abundance after Pacific rat removed (e.g. Mercury, Marotere and Ohinau Islands)	(Towns, 1996; Hoare, et al., 2007)
Pisonia brunoniana and 10 other plant species	Examples of recovery after Pacific rat removal (e.g. Mercury Islands)	(Campbell & Atkinson, 2002)
Species that will possibly benefit from intervention		
Short-tailed bats	No off-site models for this species. Potential release from competition for invertebrates and *Dactylanthus taylorii* inflorescences	
Long-tailed bats	No off-site models for this species. Potential release from competition for invertebrates	
Smaller native passerine birds	No off-site models for these species. Potential release from competition for invertebrates and nectar sources	
Day-active skinks	Increased abundance of selected species when Pacific rats removed (e.g. Mercury Islands) but no models for chevron and striped skinks present on Hauturu	(Towns, 1991)

Table 3 Methods used to evaluate short- and long-term changes to biodiversity subsequent to cat and rat eradication on Hauturu.

Species Group	Indicator	Methods	Sources
Bats	Species composition	Literature review	(Daniel & Williams, 1984)
	Species abundance	Anecdotal reports	
	Short term mortality over the course of eradication operations	Cat trapping data and carcass searches before and after rat eradication.	(Veitch, 2001; Griffiths, 2004)
Marine birds	Species composition	Literature review	(Hutton, 1868; Turbott, 1947; Girardet, et al., 2001; Stephenson, et al., 2008; Rayner, et al., 2009; Gaskin & Rayner, 2013; Rayner, et al., 2015)
	Cooks petrel breeding success and distribution	Monitoring of marked burrows 1971 to present	(Imber, et al., 2003a; Rayner, et al., 2007b)
	Black petrel breeding success	Monitoring of marked burrows 1971 to present	(E. Bell, unpubl. data; Imber, 1987; Imber, et al., 2003b)
	New Zealand storm petrel	Monitoring of marked burrows	(M.J. Rayner, unpubl. data; Ismar, et al., 2015)
	Short term mortality over the course of eradication operations	Cat trapping data and carcass searches before and after rat eradication	(Veitch, 2001; Griffiths, 2004)
Terrestrial birds	Species composition	Literature review and bird counts	(Hutton, 1868; Turbott, 1947; Girardet, et al., 2001; Veitch, et al., 2019)
	General species abundance	Mist-netting capture rates and bird counts	(Girardet, et al., 2001; Veitch, et al., 2019). Data analysis of unpublished mist-netting data described below.
	Tieke, hihi and tui abundance.	Distance sampling and bird counts	(Toy, et al., in press; Veitch, et al., 2019)
	Kiwi	Call counts	(Wade 2009; Wade 2014a)
	Short term mortality over the course of eradication operations	Cat trapping data and carcass searches pre and post rat eradication	(Veitch, 2001; Griffiths, 2004)
Reptiles	Species abundance and distribution.	Pitfall trapping (10 L plastic buckets baited 24 h with tinned pear) and search effort	(Brown, 2013)
	Short term mortality over the course of eradication operations	Cat trapping data and carcass searches before and after rat eradication	(Veitch, 2001; Griffiths, 2004)
Freshwater fish	Species composition	Trapping and spotlight surveys	(Winterbourn, 1964; Wade, 2014b)
Terrestrial invertebrates	Species composition	Anecdotal observations	(S.Wheatley, pers. comm.; R. Walle, pers. obs.)
	Wetapunga abundance	Detections per unit of search effort	(Green, et al., 2011)
Aquatic invertebrates	Species composition	Benthic sampling and light trapping	(Winterbourn, 1964; Wade, 2014b)
Threatened native and invasive alien plants	See production, seedling recruitment; abundance and distribution	Monitoring of seed set for *D. taylorii*; search effort for other threatened species and priority weeds	(D. Havell, unpubl. data; Campbell, 2011)
Canopy trees, palms and lianes	Juvenile recruitment on rat-inhabited versus rat-free islands, post-eradication response, seedling response in exclosures	Seedling numbers of 34 species counted on marked linear plots, twice before rat eradication and two years after on Hauturu and on two control islands with rats	(Campbell, 2011)

Mist-netting

Data collected from mist-netting completed before and after rat eradication were used to assess the impact of the application of rodent bait on the abundance and composition of forest birds. As these data are not published we summarise it here. Four trips were completed, one prior (January 2004) and three subsequent (August/September 2004, February 2005, August 2005) to the eradication comprising 413 mist-netting events at 69 sites across five valleys in an area of approximately 350 ha on the south-west side of the island (Fig. 2). Each trip lasted for between five and seven whole days of mist-netting. Each mist-netting event had an average duration (±sd) of 399 minutes (6 hours 39 minutes) ± 170 minutes and ranged from 06:11

(opening time) to 19:47 (closing time). On average, the median time a net remained open was 11:44 hrs.

In the analyses we assessed whether temporal factors (e.g. year, season, day, time of day) were directly associated with variability in the number of individuals and species caught in mist-nets. All analyses were compiled in SAS V.9.0. Generalised linear mixed models (with Poisson distributed errors) were used to assess the variability between both the total number of individuals (bird abundance) and the number of species (species richness) caught per mist-netting event with respect to temporal factors.

With the data assumed to follow a Poisson distribution due to its non-negative, count nature, we used Basic Generalised Linear Models followed by a more complicated Generalised Linear Mixed Effects Model to tease out changes between years for individual species. Richness and Shannon diversity were the variables being predicted, with Year, Season, Total Number of Birds, and Corrected Net Length as explanatory variables. Site and Net were included in the model as random effects, separately and together. The 'best' model was then used to fit the six species most commonly caught as the predictor variable.

RESULTS

Potential and actual costs to native biodiversity

Seabirds

Thirteen Cook's petrel (*Pterodroma cookii*) were trapped in cat leg-hold traps and euthanised (Veitch, 2001). The breeding success of Cook's petrel decreased following the removal of cats then increased after rat eradication. This was hypothesised to be a function of mesopredator release resulting in higher numbers of rats at higher elevations after cat eradication leading to greater impacts on Cook's petrel breeding success (Rayner, et al., 2007b). No other short term negative impacts on seabirds as a result of cat and rat eradication were observed.

Terrestrial birds

Thirty-two kiwi (*Apteryx mantelli*) were caught in traps during the cat eradication. Two were euthanised, the rest released unharmed (Veitch, 2001). Three kiwi were found dead after application of rodent bait (Fisher, et al., 2011) and are presumed, based on the necropsy of one individual, to have died from secondary poisoning. Despite the loss of these individuals, no change in calling frequency was observed in kiwi call count surveys completed after the rat eradication (Wade, 2009).

Individual mortality following bait application to target rats was documented for eight other terrestrial bird species including blackbird (*Turdus merula*), robin (*Petroica australis*), pukeko (*Porphyrio porphyrio*), kakariki (*Cynoramphus novaezelandiae* and *C. auriceps*), harrier (*Circus approximans*), kaka (*Nestor meridionalis*) and morepork (*Ninox novaeseelandiae*) (Veitch, 2001; Fisher, et al., 2011). Numbers of each species found after the rat eradication are presented in Fisher et al. (2011). However, no significant short-term population impacts were detected in an analysis of bird count data collected over the course of the cat eradication (Girardet, et al., 2001). Bird counts from 2012 to 2017, after rat eradication, using the same methods as Girardet, et al. (2001), showed no significant change in overall abundance but significant changes in the abundance of some species (C.R. Veitch unpubl. data).

Data collected from mist-netting conducted before and after rat eradication showed no significant change (either increase or decline) in any of three components of catchability (bird abundance, species richness, species composition) analysed for forest bird species. The only change measured was a significant increase in the number of both bellbird *Anthornis melanura* and parakeet (*Cyanoramphus novaezelandiae* and/or *C. auriceps*) captured. In total, 1,570 birds (twenty-three species) were caught in mist-nets. The total number of birds (bird abundance) caught varied between seasons ($F_{1,374} = 5.53$, $P = 0.02$) but did not differ between periods of mist-netting completed before and after the bait applications targeting rats ($F_{1,374} = 0.34$, $P = 0.56$). Number of species (species richness) ($F_{1,374} = 0.01$, $P = 0.93$) and relative similarity in the composition of forest birds caught in mist nets ($F_{1,4} = 0.53$, $P = 0.51$) did not differ significantly over the course of the rat eradication. These data correspond with the findings of a non-toxic bait trial completed ahead of the rat eradication, that determined the risk to terrestrial bird populations to be low (Greene & Dilks, 2004).

Reptiles

No individual mortality as a result of the cat and rat eradications was documented. However, anecdotal evidence and pitfall trapping (Fig. 3) suggest an unexplained decline in skink numbers following cat eradication, prior to rats being removed.

Freshwater fish

A freshwater fish survey conducted in 2000 detected redfin bullies (*Gobiomorphus huttoni*), banded kokopu (*Galaxias fasciatus*) and longfin eel (*Anguilla dieffenbachii*) (McGlynn, et al., 2000). No mortality following bait application for rats was observed, but a less extensive survey completed in 2009 detected only banded kokopu and longfin eels (Wade, 2014b).

Invertebrates

As predicted, no negative impacts on invertebrates were observed.

Plants

Aside from small-scale clearance of vegetation to form the trail network to complete cat eradication, no negative impacts on plants were observed but a greater impact on some plant species may have resulted from the release of rats from cat predation.

Potential and measured benefits to native biodiversity

Seabirds

Cooks petrel breeding success in high altitude habitats (with 90% of the population), averaged 5% prior to rat eradication but increased to approximately

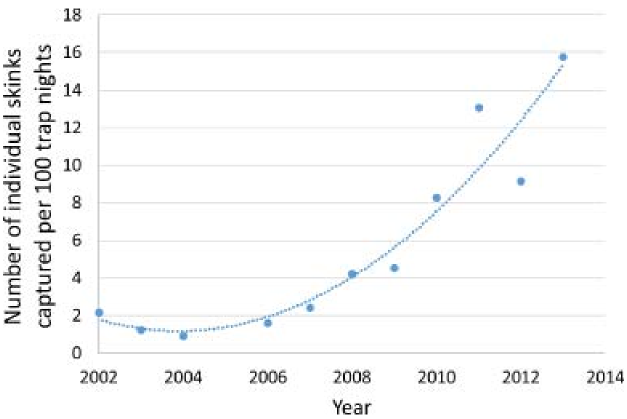

Fig. 3 Catch per unit effort for all skink species combined on Hauturu between 2002 and 2013 (Source: Department of Conservation, Warkworth, New Zealand).

60% the following breeding season as a result of reduced predation pressure (Rayner, et al., 2007a; Rayner, et al., 2007b). Improved Cook's petrel breeding success was also circumstantially reflected in a tenfold increase in the number of recently fledged chicks presented at bird rescue centres on the adjoining mainland the season following eradication and ongoing (M.J. Rayner, unpubl. data). An obvious massive increase in the extent and volume of nocturnal vocalisation by Cook's petrels has been observed over the last 12 years suggesting ongoing population recovery facilitated by increased breeding success and recruitment (M.J. Rayner, pers. obs.).

Up to 600 pairs of black petrel are now thought to breed on Hauturu (Bell, et al., 2016) up from the 50–100 pairs estimated by Imber (1987) prior to cat eradication. Similarly, breeding success increased from 1977 (50%), 1978 (60%) and 1996 (71.8%) (Imber, unpubl. data) to 2015/16 (85%). Before 1980 up to 67% of fledglings emerging from burrows were killed by cats and fewer than 5% of chicks were expected to have fledged (Imber, 1987). Between 1 and 28% of adult black petrels were also killed by cats at the colony between 1972 and 1976 (Imber, 1987). Comparisons of breeding activity within the same burrows during 1996/97 and 2015/16 showed a stable occupation rate of ca. 57% over the 19-year period and ca. 3% decline in breeding activity (Bell, et al., 2016).

New Zealand storm petrels (*Fregetta maoriana*), thought to be extinct for 110 years, were rediscovered at sea in 2003 and, after much effort, were located breeding on Hauturu in 2013 (Stephenson, et al., 2008; Rayner, et al., 2015). Mark recapture data collected between 2015 and 2017 suggest a minimum population size of 1,000 individuals (M.J. Rayner unpubl. data) and, based on at sea sightings, the population is steadily increasing.

Grey-faced petrels were discovered breeding after an apparent 60-year absence in 2009 and anecdotal observations of old colony sites suggest a gradual increase in these populations (M.J. Rayner, unpubl. data; Rayner, et al., 2009). The calls of other seabird species, such as common diving petrels (*Pelecanoides urinatrix*) and fluttering shearwaters (*Puffinus gavia*), have been also documented subsequent to rat eradication (M.J. Rayner unpubl. data) and may reflect recolonisation of the island's coastline by these predator-sensitive species.

Terrestrial birds

Three bird species have been introduced or reintroduced to Hauturu since the removal of cats: kakapo (*Strigops habroptilus*) during 1982, kokako (*Callaeus wilsoni*) during 1980–1988 and tieke during 1984–1988. Following their reintroduction, both tieke and kokako populations expanded rapidly and are now abundant across the island (K. Parker & I. Flux, pers. comm.). Kakapo were removed from the island in 1998 due to ongoing nest predation by rats but were re-established in 2012. Breeding by some individuals has subsequently been documented but whether the population will ever become self-supporting is at present unknown (L. Joyce, unpubl. data).

Annual distance sampling completed between 2005 and 2013 in the south-west of the island initially charted a decrease in numbers of hihi (*Notiomystis cincta*) and tui (*Prosthemadera novaeseelandiae*) (Toy, et al., 2018). Hihi numbers appeared to stabilise from 2009 onwards but the density of tui continued to vary. The recorded density of tieke changed little over the survey period. Forest bird counts undertaken between 2013 and 2017 within the same area recorded significantly higher numbers of bellbird, tomtit (*Petroica macrocephala*), parakeets, robin, kokako and tieke and a decline in numbers of whitehead (*Mohoua albicilla*), tui, hihi, rifleman (*Acanthisitta chloris*), grey warbler (*Gerygone igata*), blackbird and silvereye (*Zosterops lateralis*) when compared to counts undertaken before and during the cat eradication and prior to the rat eradication (C.R. Veitch, unpubl. data). No significant change was detected in the overall number of forest birds (C.R. Veitch, unpubl. data).

No significant change in calling frequency was detected in kiwi call count surveys over the period 1993 to 2014 although frequencies recorded were consistently higher than sites monitored on the North Island of New Zealand (Wade, 2014a). Despite the return of the brown teal (*Anas chlorotis*) that were removed during the rat eradication and the introduction of additional individuals, the brown teal population has not expanded. The brown teal population is considered permanent, but numbers present may be more a reflection of the species' breeding success on nearby Great Barrier Island (Aotea).

Banded rail (*Gallirallus philippensis*), last seen on the island in 1946 (Sibson, 1947), have returned to the island and reared young (C.R. Veitch, unpubl. data) and spotless crake (*Porzana tabuensis*), never previously recorded on the island, are now present and breeding (C.R. Veitch, unpubl. data). Another short-term impact worthy of note is the appearance and establishment of bellbirds at Tawharanui Regional Park subsequent to rat eradication (Brunton, et al., 2008). Invasive vertebrates were removed from Tawharanui at the same time as the rat eradication on Hauturu and this coupled with an increase in the number of bellbirds (as indicated by mist-netting data) may have created conditions suitable for dispersal and subsequent population establishment.

Reptiles

Following rat removal, numbers of reptiles caught in pitfall traps steadily increased (Fig. 3). Towns (*Oligosoma townsi*), moko (*O. moko*) and shore skink (*O. smithi*) showed the biggest increase (see Fig. 4), contributing to an 18-fold increase in the total number of skinks caught per 100 trap nights since the rat eradication (Brown, 2013). Although numbers are too low to quantify changes to the island's chevron skink (*Oligosoma homalonotum*) population, the number of additional skinks found after rat eradication may indicate population recovery. Prior to the rat eradication only one chevron skink had ever been found on the island. Four have been found since rats were removed.

Limited monitoring of the island's gecko populations was undertaken, but spotlight surveys completed in 2009 and 2013 suggest populations are recovering

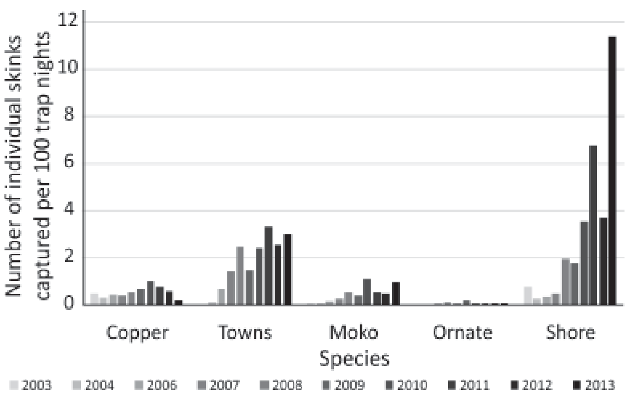

Fig. 4 Catch per unit effort for five species of skinks on Hauturu between 2002 and 2013 (Source: Department of Conservation, Warkworth, New Zealand).

from pre-eradication declines. Sighting rates of Pacific (*Dactylocnemis pacificus*), forest (*Mokopirirakau granulatus*) and common (*Woodworthia maculatus*) gecko in 2013 more than doubled relative to 2009 (Brown, 2013) and Duvaucel's gecko (*Hoplodactylus duvaucelli)* have been sighted more frequently (Hoare, 2009).

Tuatara (*Sphenodon punctatus*) were thought to be extinct on Hauturu until the species was rediscovered in 1991–1992 (Whitaker & Daugherty, 1991). Nine adults were taken into captivity on the island to ensure the relict population did not go extinct before rats were removed (Moore, et al., 2008). Since the rat eradication was confirmed successful in 2006 more than 196 young tuatara, raised in captivity, have been released at three sites and all captive adult tuatara have been returned to the wild. Additional adult survivors have been detected, breeding in the wild population has been noted and the population appears to be expanding (S. Keall, pers. comm.).

Aquatic invertebrates

A survey of aquatic invertebrates completed in 1963 was repeated in 2014 to identify changes in faunal composition. In total, 33 macroinvertebrate taxa from 12 orders were recorded from benthic samples. Six species of mayfly (*Mauiulus luma, Isothraulus abditus, Zephlebia spectabilis, Arachnocolus phillipsi, Ichthybotus hudsoni* and *Neozephlebia scita*), and two species of caddisfly (Trichoptera) (*Oxyethira albiceps* and a Chathamiidae sp.) not recorded in the 1963 survey, were found in 2014 (Wade, 2014b).

Terrestrial invertebrates

An annual monitoring programme to assess the recovery of wetapunga (*Deinacrida heteracantha*), New Zealand's largest giant weta, was instigated in 2005, a year after rats were removed. Numbers of wetapunga found in each survey had more than doubled by 2009 (Green, et al., 2011). Results indicate that the numbers increased by 50% every second year. Subsequent captive breeding, for translocation to other islands, showed that wetapunga have a two to three-year life cycle (P. Barrett, pers. comm.), potentially explaining the stepped rate of increase on Hauturu. During the monitoring programme, occupancy of daytime refuge sites remained low, suggesting the population may increase further over time. A repeat of the programme would be required to verify the level of increase and thus give a longer-term measure of the benefit of the rat eradication.

In 2017, surveys throughout New Zealand for the endemic forest ringlet butterfly (*Dodonidia helmsii*) revealed the species' presence on Hauturu. This species was widespread throughout much of the country but is now rare or absent from many areas of its previous distribution (S. Wheatley, pers. comm.). Despite the presence of suitable habitat, the forest ringlet had not previously been recorded on the island. Multiple individuals were found, indicating a resident population (L. Wade, unpubl. data; J. Knight, pers. comm.). Gibbs (1980) highlights the potential for introduced social wasps, the German wasp (*Vespula germanica*) and European common wasp (*V. vulgaris*), as a cause for the decline in forest ringlet populations. Interestingly, the European common wasp was noted by previous island rangers as a significant nuisance on Hauturu (C. Smuts-Kennedy, pers. comm.) but subsequent to the rat eradication social wasps have not been reported. The relationship between rat eradication and social wasp populations is currently the subject of a PhD study at the University of Auckland (J. Schmack, pers. comm.).

Plants

Nineteen of 34 plant species monitored on fixed plots had more than 20 seedlings and were analysed further (Campbell, 2011). Significantly more seedlings were found for 14 species following rat eradication, *Pisonia brunoniana*, *Coprosma macrocarpa*, *Ixerba brexioides*, *Knightia excelsa*, *Rhopalostylis sapida*, *Phyllocladus trichomanoides*, *Nestegis lanceolata*, *Dacrycarpus dacrydioides*, *Ripogonum scandens*, *Hedycarya arborea*, *Dysoxylum spectabile*, *Pittosporum umbellatum*, *Macropiper excelsum* and *Corynocarpus laevigatus* (Fig. 5). Seedlings of 11 others were searched for in 2008 and 2009. In 2009 *Coprosma arborea* seedlings were very abundant. Fewer seedlings were counted of *Agathis australis*, *Beilschmiedia tarairi*, *B. tawa*, *Prumnopitys ferruginea* and *Vitex lucens*. A few species that Pacific rats severely affect (e.g. *Coprosma repens*, *Elaeocarpus dentatus*, *Melicytus novae-zelandiae*, *Pouteria costata*), showed little early response because of their initial rarity (Campbell & Atkinson 2002; Campbell, 2011).

Prior to rat eradication, seedlings of *N. lanceolata*, *R. sapida* and *R. scandens* were rare, but in 2008, *N. lanceolata* was found on most plots, and *R. sapida* and *R. scandens* seedlings were common in moister sites. The number of seedlings of other tree species had also significantly increased. Seedlings of *B. tarairi*, *C. laevigatus* and *P. trichomanoides* were twice as numerous in *Kunzea ericoides* stands after rat eradication, *D. spectabile* was five times more common and *R. scandens* 41 times.

Threatened plants also showed a positive response to the removal of rats. Improved seed set by the endangered *Carmichaelia williamsii* was noted and the endangered *Euphorbia glauca* colonised new areas. Seed production

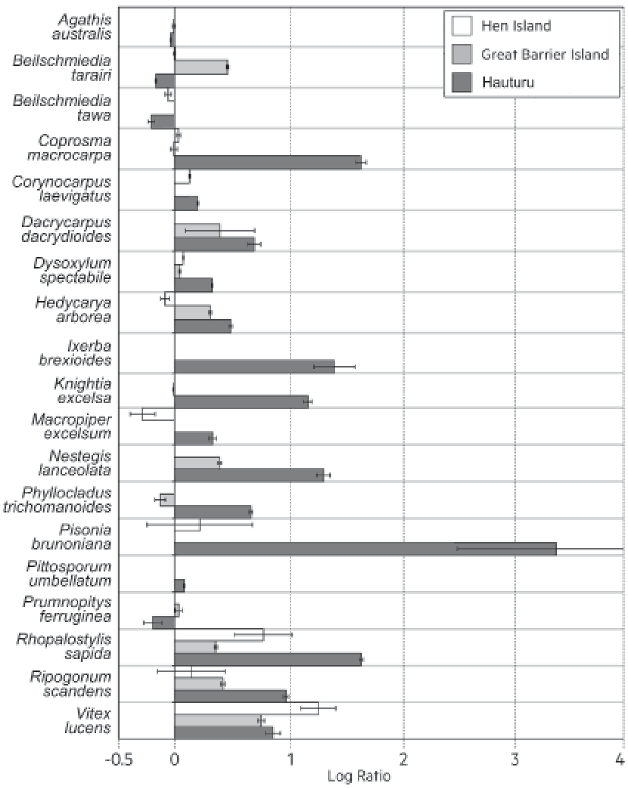

Fig. 5 Log ratios of seedling numbers on Hauturu (after eradication) and control islands with rats, with 95% confidence intervals. Log ratios of < 0, 0, > 0 indicate seedling counts that decreased, remained the same or increased, respectively.

in the endangered *Dactylanthus taylorii* increased and individuals have been discovered at new locations on the island including a site where seeds were hand sown (D. Havell, pers. comm.). No increase in seedling recruitment was noted for the invasive plant species *Asparagus scandens, Cortaderia jubata*, *C. selloana* and *Araujia hortorum* (managed as part of an ongoing eradication/ control programme) following rat and cat eradication.

DISCUSSION

The legislation that defines the management of Nature Reserves such as Hauturu, the Reserves Act 1977, mandates the removal of exotic species to protect native ecosystems. Cat and rat eradication on Hauturu became a matter of urgency because of their impacts on individual species. For cats, these impacts included extirpation of tieke and grey faced petrels as well as threats to other seabird species. The effects of rats were much wider and included impacts on seabirds, tuatara, lizards, invertebrates and an array of plants (Griffiths, 2002). Cats, rats or the two in combination were probably also responsible for the extinction of the last population of North Island snipe (Tennyson & Martinson, 2006).

Short term negative impacts from the cat eradication operation on Hauturu were minor and limited to the mortality of some non-target bird species caught in traps, apparent declines in skink populations and the removal of relatively small amounts of vegetation as a consequence of track and hut construction. An unanticipated outcome of the cat eradication, was a reduction in breeding success of Cook's petrel nesting at higher elevations. This was attributed to mesopredator release leading to increased predation pressure by a rat population no longer suppressed by cats (Rayner, et al., 2007b). This mechanism may also explain why pitfall trapping charted a decline in skink capture rates between cat and rat removal. Increased pressure on other rat foods (invertebrates, seeds and seedlings) may also have been sustained, but was not monitored.

As predicted in the AEE for rat eradication (Griffiths, 2002), negative impacts of the application of rodent bait were short-lived and minor and included no more than the loss of some individuals of at least eight bird species. Monitoring could not detect changes in abundance for these species indicating that they were not affected at the population level. The only native species not detected subsequent to the rat eradication was the red-finned bully. The absence of this species in the survey completed 10 years after the rat eradication could have been a consequence of the application of rodent bait for rats but equally the species could have been extirpated by a storm event or simply that insufficient search effort has been undertaken. This species is diadromous and likely to recolonise or could be reintroduced provided that suitable habitat on Hauturu is still available.

In contrast, the benefits of cat and rat eradication have been significant, and all species deemed vulnerable to extinction have since recovered. Tieke and kokako were successfully established following cat removal. Rat eradication resulted in recolonisation of the island by grey faced petrels and immediate recovery of the island's Cook's petrel population. As predicted by Griffiths (2002), there were increases in the abundance of skinks, geckos and invertebrates such as the wetapunga and in seedling recruitment by numerous tree species. All but one of the species identified as likely to benefit from rat eradication have shown evidence of recovery. The exception is the reintroduced tieke which could have reached carrying capacity ahead of the rat eradication.

Some species previously not recorded from Hauturu have made remarkable appearances. Examples include the New Zealand storm petrel, forest ringlet butterfly and eight new aquatic invertebrates. All such species were likely present in refugia but undetectable until rats were removed. It is unlikely that these will be the last discoveries to be made on the island. Several seabird species are expected to recolonise and highly cryptic species are still likely waiting discovery or rediscovery on Hauturu in the future. For example, only one record of striped skink has been made on the island, but this cryptic species will likely be found again in the future. As noteworthy as unexpected appearances is the disappearance of German and common wasps following rat eradication. The disappearance of these two highly invasive species may have enabled the recovery of the forest ringlet.

Other ecological changes post rat and cat eradication have been unclear. Predicted increases in the abundance of forest birds after cat and rat removal have yet to eventuate. Some species undoubtedly benefited following the removal of cats, but monitoring methods were insufficiently sensitive to detect population changes; bird counts were too variable to discern significant trends (Girardet, et al., 2001). It is also likely that some of the potential benefits of cat removal were confounded by the presence of rats. Attempts to manage kakapo on the island post cat eradication, for example, were thwarted by the continued presence of rats that preyed upon eggs and chicks.

After the removal of rats, initial positive trends for species such as hihi and tui were followed by declines to pre-eradication levels. Whether, this was a result of insufficient sampling effort, inadequacy of the methods used, changes in inter-specific competition among birds, or simply that the removal of cats and rats had little effect is not well understood. Forest birds were also monitored in the most accessible part of the island, the island's SW corner, which had been subject to the greatest impacts of logging and grazing. Consequently, ongoing forest successional changes may confound monitoring results. The most recent set of bird counts completed in 2017 suggest that some forest bird species have increased in abundance whereas others have declined (Veitch unpubl. data). Further monitoring is needed to confirm these trends. The effects of cat and rat removal on black petrel is also less straightforward. Although petrel numbers appear stable and breeding success has improved, the influence of other factors such as birds fledged from Hauturu being lured away to the much larger and noisier colony on Great Barrier Island (E. Bell, unpubl. data) may be affecting population recruitment.

As evidenced by altered patterns of seedling recruitment following rat eradication, changes in forest composition will occur. Future changes within the island's plant, invertebrate and reptile communities are likely to be strongly influenced by the recovery of Cook's petrel and the return of other seabirds. The enormous influence of seabirds on ecological communities has been well described (e.g. Jones, 2010; Smith, et al., 2011). However, given the large size of Hauturu and the extent of its forest communities, the full impact of these 'ecosystem engineers' is at present unknown.

On a global scale, there are no comparative invasive mammal eradications that have been completed in such a complex environment. The value of these eradications thus derives not only from the responses of resident species and recolonisation of those lost, but also in increasing our understanding of the ways invasive species influence island community structure. The changes reported here have been documented over only 13 years, but the removal of cats and rats has instigated a process of recovery that for many species on Hauturu will not be realised for decades. For those species reduced to relict populations and with low reproductive output, the post-eradication response will be slow. Other species such as snipe and some large species of lizards have been lost and will not contribute to Hauturu's ecosystems without intervention to re-establish them. The timescales involved for the recovery process are daunting. For example, the release of the near extinct tuatara population has begun a process of recovery for this species that may require centuries to play out.

From a social perspective, the islands of Auckland's Hauraki Gulf have been a source of inspiration for many members of the public. The removal of rats and subsequent reforestation of Tiritiri Matangi Island inspired volunteers to invest tens of thousands of hours to plant trees (Galbraith & Cooper, 2013). Hauturu has been no exception with its own Community Trust formed in 1997. The Little Barrier Island/Hauturu Supporters Trust provides on average $100,000 NZD annually to conservation programmes on the island. Visitors to Hauturu often return awe struck (R. Griffiths, pers. obs.) from their first view of 'primeval' New Zealand.

It is now important that the story of Hauturu, the impact that invasive species had on the island, and the recovery witnessed subsequent to cat and rat removal is shared on the world stage. It is only through the telling of such stories that the public's imagination will be captured along with the attention of government and private agencies. This and other projects have served to cement a sense of pride in New Zealand's biodiversity and have culminated in a pledge by New Zealand's Government for the country to be free of introduced predators by 2050 (Parkes, et al., 2017).

ACKNOWLEDGEMENTS

We would like to dedicate this paper to the many organisations and individuals that contributed to the protection of Hauturu. The legacy that stands on the horizon today serves as a fitting tribute to your efforts. Thank you also to the many individuals that contributed to the development of this paper, in particular David Wilson, David Havell and Alicia Warren.

Restoring plant-pollinator communities: using a network approach to monitor pollination function

C.N. Kaiser-Bunbury[1,2]

[1]Centre for Ecology and Conservation, Biosciences, University of Exeter, Penryn Campus, Penryn, Cornwall, TR10 9FE, UK. [2]Ecological Networks, Department of Biology, TU Darmstadt, 64287 Darmstadt, Germany. <C.Kaiser-Bunbury@exeter.ac.uk>.

Abstract Ecological restoration is a common tool to mitigate the loss of species and habitats, ultimately aiming to restore ecosystem functioning. Large-scale experimental evidence is lacking, however, on whether standard management techniques, e.g. the removal of invasive alien plants, indeed restore ecosystem functions at the community level. One key ecosystem function is animal mediated pollination. Based on findings from an experimental network study on rocky outcrops (inselbergs) on the island of Mahé in the Seychelles, I present recommendations for conservation practitioners about how to incorporate a network approach into an evaluation of management effectiveness. Responses to restoration actions by plant-pollinator communities and pollination functions lead to several conclusions regarding the resilience of native fauna and flora and ecosystem functioning. Pollination network structure appears to be directly related to the quality and resilience of pollination services, which suggests that network analysis can be used to monitor management efficacy. I provide recommendations and advice to encourage the uptake of a network approach by conservation practitioners seeking to restore ecosystem functions.

Keywords: biomonitoring, management effectiveness, pollination networks, Seychelles, vegetation restoration

INTRODUCTION

Despite recent efforts to slow biodiversity decline worldwide, habitat degradation continues to degrade and simplify ecosystems, especially in the species-rich tropics (Butchart, et al., 2010). To mitigate the effects of habitat modification on ecosystems and assist species and ecosystem functions to adapt to changing environmental conditions, conservation practitioners employ a diverse set of management tools, including ecological restoration (Sodhi & Ehrlich, 2010). Such management tools often rely on a few well-studied target species to assess their outcomes, primarily because of limited time and resources. However, too little is known about the efficacy of restoration for achieving self-sustaining species communities and functioning ecosystems. Habitat restoration usually modifies ecosystems with the purpose of providing suitable habitat for target native species (Miller & Hobbs, 2007). Non-target species, however, can serve essential functional roles in the restored habitat and failure to recognise these species and the ecosystem-level interactions and processes that they are involved in may compromise restoration efforts and assessment (Ehrenfeld, 2000). Pollination is one such key ecosystem function; most tropical plants and crops heavily rely on pollination services for reproduction (Klein, et al., 2007; Ollerton, et al., 2011). Pollinators are rarely targets of habitat restoration (Williams, 2011), although this is slowly changing in agricultural areas where the benefits of wild bees in crop pollination have been considered (Kremen & M'Gonigle, 2015). Given that ecosystems are characterised by networks of interactions between organisms (McCann, 2007), the effect of habitat restoration on pollination interactions is often best studied with a network approach (Jordano, 1987; Proulx, et al., 2005). Thus, to assess the impact of habitat restoration on integrity of pollination services, an understanding of the implications of structural changes of pollination networks on functional performance is critical. Recent work proposed close links between network structure and ecosystem functioning (Coux, et al., 2016; Gómez, et al., 2011; Schleuning, et al., 2015), but field experiments at the community level are required to shed light on the relationships between habitat restoration, pollination network structure, the resilience of plant-pollinator communities, and the quality of pollination services.

Restoration practitioners worldwide place vegetation rehabilitation at the centre of habitat restoration, which often involves removal of exotic plants and assisted recovery of native plant communities (Clewell & Aronson, 2013). Assistance takes the form of fencing off native habitat against large herbivores or exotic seed predators (see e.g. Florens & Baider, 2013), or the reintroduction of large herbivores to replace now extinct seed dispersers (Hansen, 2015). These interventions enable native vegetation and their mutualists to establish and adapt to subtle changes in native and novel processes, which increase resilience against future disturbance. One important prerequisite for a self-sustaining restored plant community is a large and diverse native fruit crop, which is dependent to some degree on the quality and quantity of pollination services. To provide optimal functional performance, plant-pollinator communities mutually rely on diverse and reliable resources (pollen and nectar) and services (pollination). Weighted network metrics, which take into account the quantitative importance of species for their mutualistic partners, have been developed to assess the consequences of vegetation rehabilitation on pollination services by teasing apart changes in abundance, species diversity and the topology of species interactions, e.g. species generalisations (Banašek-Richter, et al., 2004; Blüthgen, et al., 2006; Tylianakis, et al., 2007).

RESTORING PLANT-POLLINATOR COMMUNITIES

In a recent study, Kaiser-Bunbury, et al. (2017) showed for the first time, with a large-scale field experiment, that not only were species communities fundamentally changed by restoration (the removal of invasive alien shrubs), but also plant-pollinator interactions became more resilient as a result of restoration. Restoration altered pollinator behaviour and increased pollinator species richness (Kaiser-Bunbury, et al., 2017). In this instance, the removal of invasive plants modified pollinator foraging patterns, which increased pollinator efficiency (i.e. more pollen delivered per visit) and frequency (i.e. higher visitation rate per flower) of native plants in the restored community (see Fig. 3 in Kaiser-Bunbury, et al., 2017). Simultaneously,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 568–570. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

pollinator species became more generalised in restored communities, creating greater functional redundancy and lower mutual dependencies. These results appeared at first contradictory, as specialised pollinators tend to be more effective pollinators than generalists, due to lower interspecific pollen transfer (see Morales & Traveset, 2008 and references within). However, the data also suggested that while pollinator species became more generalised as a result of restoration, individual pollinators had increased floral constancy, providing high quality pollination services even at relatively low visitation frequencies (Kaiser-Bunbury, et al., 2017). Several plant species at the restored sites (nine species at restored vs. two species at unrestored sites) further benefitted from attracting more pollinator species – on average an increase in pollinator species richness by approximately 114% compared to the same plant species at the unrestored sites, thereby lowering their dependency on a few pollinator species for reproduction.

The effects of restoration on the plant-pollinator community and pollination services were reflected by changes in pollination network structure (Kaiser-Bunbury, et al., 2017). The findings on the connection between network structure and ecological processes are important for two reasons. Firstly, they corroborate previous theoretical and empirical, non-experimental work that suggested a direct relationship between network properties and ecosystem functioning (Gómez, et al., 2011; Schleuning, et al., 2015; Coux, et al., 2016). Secondly, network metrics, which are commonly used to characterise network properties, can now be employed to inform scientists and practitioners about the ecological and conservation status of communities and ecosystem functions when, for example, compared to baseline data. With future shifts in conservation approaches towards the protection of ecosystem services and functions (Harvey, et al., 2017), suitable tools and methods need to be developed that allow conservation biologists and practitioners to monitor and evaluate such processes. The Kaiser-Bunbury, et al. (2017) study provided an important cornerstone for interpreting processes in ecological communities by using a network approach.

Network ecologists have advocated for some time the potential of a network approach in applied ecology, based on advances in understanding the processes that shape community level interactions (e.g. Memmott, 2009; Kaiser-Bunbury, et al., 2010; Tylianakis, et al., 2010). More recently, a selection of network indicators, i.e. aggregate network metrics describing community properties, was proposed, which characterise the diversity and distribution of interactions at the species, guild (e.g. plants, pollinators) and network level (Kaiser-Bunbury & Blüthgen, 2015). These network indicators were selected because of ecological characteristics, sound empirical and theoretical support, conceptual similarities to well-established diversity indicators, and computational ease with which they can be generated (Kaiser-Bunbury & Blüthgen, 2015). The authors presented a conceptual framework on how to use network indicators to guide conservation decisions by evaluating management effectiveness, and proposed island ecosystems as suitable model system. Island biotas are not only in urgent need of extensive conservation action, but the simplicity of island ecosystems also facilitates comprehensive studies on interaction networks (Kaiser-Bunbury, et al., 2010). Thus, how can the insights gained from studies on network structure and ecosystem functioning (e.g., Kaiser-Bunbury, et al., 2017) be applied to biomonitoring and assessments of management effectiveness by island conservation practitioners?

IMPLICATIONS FOR ECOLOGICAL RESTORATION

Biotic interactions (here I refer to mutualistic interactions such as pollination and seed dispersal, but antagonistic i.e., trophic, interactions may equally be used) can be short-lived and highly variable across seasons, years or even longer time spans (Medan, et al., 2006; Olesen, et al., 2010; CaraDonna, et al., 2017). Network indicators that describe the ecological processes determining network structure may be most suitable to monitor ecologically meaningful changes in biotic interactions that reflect community-wide adaptations to specific restoration actions, for example, the removal of invasive species, reforestation with native plants, or landscape modifications. Methodological and ecological advances, however, are rarely used to their full potential for evaluating and monitoring conservation progress (Gardener, et al., 2010). To benefit from such advances, network indicators could be used to inform managers on whether conservation interventions actually restore or maintain ecosystem integrity (Noss, 2004). In the Seychelles, the positive effects of restoration on pollinator communities and native plant reproduction were reflected in corresponding changes in network indicators (Kaiser-Bunbury & Blüthgen, 2015). These included the total number of visits and interactions, interaction diversity and evenness, and the degree of network- (H_2') and species-level (d') specialisation (Kaiser-Bunbury, et al., 2017). Thus, recording community-wide biotic interactions and calculating network indicators for observed biotic interactions can provide restoration practitioners with a measure of effectiveness for achieving the overall goal of restoring ecosystem functioning.

A network approach may appear challenging, overly complicated and costly to most conservation practitioners. Instead of providing comprehensive instructions on how to apply a network approach in restoration, I aim to illustrate that using biotic interactions and network analyses are viable and effective tools to monitor conservation progress and adapt management approaches based on the outcome of the performance assessment. Below I outline four recommendations for consideration by practitioners who are interested in embracing a network approach in biodiversity conservation.

1) *Clearly define conservation goals that can be validated with network indicators*. Network indicators can only illustrate the properties of one specific ecosystem function at a time, for example, pollination, seed dispersal, or predation. It is therefore important to identify the ecosystem function to be targeted by the conservation intervention (Kaiser-Bunbury & Blüthgen, 2015). Decision-making tools that take into account multiple ecosystem functions may be required to prioritise conservation action (McCarthy & Possingham, 2007). Clear conservation objectives and outcomes will then provide the basis for selecting network indicators and setting threshold values of conservation targets (Kaiser-Bunbury & Blüthgen, 2015).

2) *Actively engage with applied network ecologists* who can assist with establishing data recording protocols and conducting network analysis, possibly via electronic data collection in the field and automated analysis (Kaiser-Bunbury & Blüthgen, 2015). At first, the network approach may appear dauntingly complex. However, the involvement of network ecologists in the planning phase of any conservation action will ensure that a suitable sampling protocol is developed, facilitating data analysis and interpretation to evaluate management effectiveness. Network ecologists are also more likely to follow advances in the field and can update protocols, sampling techniques and analyses based on the most up-to-date research. In return for the time invested, ecologists will have access to

empirical data for publications and contribute actively to maximising the impact of their research.

3) *Be realistic in sampling design.* Collecting data on biotic interactions involving all species in the community is often considered extremely time and labour intensive, and therefore costly. It is not necessary, however, to record 'every single interaction'. Interaction networks are inherently under-sampled (Vázquez, et al., 2009) but still provide meaningful insights into ecosystem complexity and functioning. It is more important to identify the most time and cost efficient sampling method (see e.g. Hegland, et al., 2010) and assess sampling completeness with appropriate extrapolation techniques (Colwell & Coddington, 1994). Depending on the conservation goals, sampling of subsets or at a lower frequency/density may suffice to reveal changes in network structure as a result of the restoration intervention.

4) *Select the most suitable sampling approach* for your habitat, available resources, and the accessibility of the management site. For example, pollination interactions can be observed using standardised transects, which is a time-efficient sampling method most suited to meadows, heathlands and other low-growing plant communities. Alternatively, by observing target plants for a set amount of time, pollination interactions can be recorded in a forest or shrubland habitat with a 3-dimensional structure and a patchy distribution of flowers (for a comparison of the methods see Gibson, et al., 2011).

Why should conservation practitioners and ecologists invest extra time and resources into monitoring processes? In short, moving conservation actions towards an ecosystem functions oriented approach (sensu Harvey, et al., 2017) will require tools that can monitor and evaluate the multi-facetted dimensions of biodiversity. The network approach can generate detailed insights into the functioning of ecological communities, is developing rapidly, and presents a promising and exciting method for improving biodiversity conservation in the 21st century.

Abstract As the first step towards the ecological restoration of its islands, Mexico has completed 60 eradications of invasive mammals thanks to a strong partnership between *Grupo de Ecología y Conservación de Islas, A.C.* (GECI), the federal government, local fishing communities, academia, and private donors. The removal of invasive mammals has led to the dramatic recovery of the islands' ecosystems. On Guadalupe Island, after completing the goat eradication in 2007, the native vegetation started to recover. Plants considered extinct or extirpated have been rediscovered, and plant species new to the island have been recorded. However, in order to achieve the island's full recovery, the active restoration of degraded soils and vegetation are needed. To date, GECI, in collaboration with the National Forestry Commission (CONAFOR) and the National Commission for Natural Protected Areas (CONANP), is implementing a 700 ha project to accelerate the restoration of the native vegetation communities. The project involves reforestation, erosion control, and fire prevention actions on different plant communities: forests and sage scrub. An on-site nursery has been established, seedlings—mostly from endemic trees—are being grown, and on-site reforestation planting has started. Up to June 2018, we have planted almost 40,000 trees, and will produce 160,000 seedlings during this year. Mechanical methods to control and prevent erosion have been used as we have installed more than 2,400 m of contour barriers, 57 m^3 of dams, and rehabilitated firebreaks. The actions will continue: the long-term goal being the comprehensive restoration of the vegetation communities devastated by feral goats. The Guadalupe Island experience will be useful to inform the restoration of other Mexican islands.

Keywords: erosion control, Guadalupe cypress, Guadalupe pine, reforestation, vegetation recovery

INTRODUCTION

Islands support a disproportionate amount of biodiversity in relation to their area (Myers, et al., 2000), but also are vulnerable ecosystems, highly susceptible to any alteration to their fragile equilibria (Holdgate, 1967; Simberloff, 1995; Whittaker & Fernández-Palacios, 2007). The trophic webs of oceanic islands have been described as "very simplified, with little ecological or taxonomical redundancy" (Courchamp, et al., 2003). This is one of the reasons why invasive alien species are considered one of the biggest threats to insular ecosystems and the main cause of insular biodiversity loss, as well as the alteration of ecosystem functions (Reaser, et al., 2007; Veitch, et al., 2011). Native insular species normally lack evolutionary defences, having traits that evolved in the absence of regular immigrants, and in consequence they fail to adapt to new threats posed by invasive species (Brook, et al., 2008; Berglund, et al., 2009). In contrast, invasive species have attributes that facilitate their establishment in novel environments due to their broad ecological niche (generalists) and high degree of behavioural flexibility. Consequently, they normally thrive when introduced to new environments (Mack, et al., 2000; Courchamp, et al., 2003; Sol, 2007). Among invasive mammals, feral goats (*Capra hircus*) are one of the most destructive species. Their effects include overgrazing, soil compaction, and tree and shrub damage through browsing (Coblentz, 1978; Parkes, et al., 1996; Campbell & Donlan, 2005; Chynoweth, et al., 2013).

Guadalupe Island is a priority site in terms of biodiversity conservation. It is a Biosphere Reserve, as well as an Important Bird Area (IBA; Vidal, et al., 2009) and an Alliance for Zero Extinction site (AZE, 2010). In addition, it is categorised as a Marine Priority Conservation Area by the Commission for Environmental Cooperation of North America (Morgan, et al., 2005), and it is included in the Southern Californian Pacific Marine Ecoregion (Wilkinson, et al., 2009). Unfortunately, invasive mammals – including feral goats – were introduced in the 19th century with devastating consequences for the island's flora and fauna. Goats depleted entire vegetation communities. Moran (1996) stated that "…it is most important before plants are lost, to remove all goats from the island, reversing the process of degradation and encouraging in every way the renewal of the natural vegetation. Even at best, some rare plants may die out unless propagated and replanted...". Other authors agreed, claiming that conservation actions for the island must begin by removing the feral goats and be followed with a plan of active restoration (León de la Luz, et al., 2003, Aguirre-Muñoz, et al., 2005). Also, for the Mexican Government there was an understanding that urgent restoration actions were needed. As a result, in terms of ecological restoration, much has been done during the past decade to tackle the threats posed to Guadalupe's biodiversity, particularly those from introduced species (Aguirre-Muñoz, et al., 2011; Luna-Mendoza, et al., 2007). Therefore, a long-term restoration and conservation programme has been developed for the island, aimed at removing invasive mammals to protect Guadalupe's native flora and fauna – especially seabirds – and preventing more extinctions. The successful eradication of goats, in a collaboration between GECI, federal government agencies and private donors, was the beginning of the island's recovery. The next phase is to do active restoration, mostly through reforestation of several vegetation communities.

SITE DESCRIPTION

Guadalupe Island is a 242 km^2 remote oceanic island located in the Pacific Ocean, 260 km off the Baja California peninsula, Mexico (29° N, 118° 20'W). It represents Mexico's last frontier on its western and northern margins; a unique territory in many ways, particularly in terms of biodiversity, a "naturalists' paradise" in the words of Dr Edward Palmer after his 1875 visit to Guadalupe (Huey, 1925).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 571–575. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Guadalupe is a 5.8 km high seamount that emerges from a depth of 4.5 km, with a maximum elevation of 1.3 km above sea level (Delgado-Argote, et al., 1993). It comprises a main island, three islets and several offshore rocks. Guadalupe was discovered in 1602 by Spanish explorer Juan Sebastían Vizcaíno (León Portilla, 1989). Yet, it remained pristine and uninhabited until the beginning of the 19th century when Russian, English and American fur hunters visited the island in search of fur seals, sea otters and elephant seals (Hanna, 1925; Huey, 1925).

Guadalupe is a protected area decreed as a Biosphere Reserve by the Mexican government in 2005. The Reserve is managed by the National Commission of Natural Protected Areas (CONANP), and is safeguarded by the Ministry of the Navy, which has been watching over this important territory since the early 1900s. Besides the Navy base on the southern tip of the island, there are two more settlements: a settlement of the *Abuloneros y Langosteros* fishing cooperative on the west coast, and a biological field station of the Mexican NGO *Grupo de Ecología y Conservación de Islas, A.C.* (GECI, for its Spanish acronym) at about 1,200 m above sea level on the north-west portion of the island. Also, CONANP personnel are present permanently on site. A total of 100 people inhabit Guadalupe (CONANP, 2013). The only economic activity on the island is commercial fishing, carried out solely by the fishing cooperative to sustainably harvest valuable marine resources such as abalone (*Haliotis* spp.) and lobster (*Panulirus interruptus*) (Searcy-Bernal, et al., 2010; Méndez-Sánchez, 2012).

Climate

Guadalupe has a Mediterranean climate, characterised by hot, dry summers and cool, wet winters (Camps & Ramos, 2012; Granda, et al., 2014). Temperature is relatively stable throughout the year, with a mean of 17.2 ± 2 ºC. Relative humidity oscillates between 69 ± 8% to 82 ± 5% without a well-defined seasonal pattern (Castro, et al., 2005) and average annual cumulative precipitation is 193 ± 119 mm (CONAGUA-SARH Delgadillo in Moran, 1996; SARH-Colegio de Postgraduados, 2010). However, given the islands' complex topography, some microclimates are also recognised. The south end of Guadalupe is drier compared to the rest of the island, and the humidity increases northwards with elevation, mostly due to the fog influence. There are some records of ice and snow in winter, restricted to the cypress forest at the higher elevations (Moran, 1996; N. Silva-Estudillo, pers. comm.). It is also likely that rainfall is relatively more abundant at higher elevations (Moran, 1996). Guadalupe Island's local climate can also be influenced by regional climatic conditions. Occasional tropical storms from the south bring heavy rainfall to the island between summer and autumn (August to October) (Moran, 1996). In addition, the normal precipitation pattern can be disrupted by irregular El Niño or La Niña events, associated with supra- and subnormal precipitation, respectively, between December and March (winter and spring) (Minnich, et al., 2009). This oceanic island is heavily influenced by the California Current, which generates a peculiar pattern of wind, fog, and rainfall (León de la Luz, et al., 2003; Garcillán, et al., 2012). Winds prevail from the north-west, while the island's climate is influenced by a near-permanent fog system which allows the presence of forests on the island despite the low precipitation.

Flora

In a classification of Mexican Biogeographic Provinces, Guadalupe Island is considered as a separate province (i.e. Guadalupe Island province) within the Baja California Province, which is part of the Nearctic Region (Morrone, et al., 2002). This classification is based on distributional patterns of plants, invertebrates and birds (Morrone, et al., 1999). Floristically, it is very similar to the Channel Islands, USA (Raven, 1965). Originally, the island was home to a rich flora that included several insular and Guadalupe endemics. In total, 225 vascular plant species have been recorded on the island, 7% insular endemic (shared with other islands of the region) and 12% endemic to Guadalupe (Junak, et al., 2005; Rebman, et al., 2005; GECI, unpublished data). In addition, 36 non-vascular plants have been recorded for the site (Crum & Miller, 1956; Crum, 1972 in Moran, 1996) as well as 104 lichen species (Weber, 1994 in Moran, 1996).

Several original vegetation communities have been described, based on historic records (Moran, 1996;León de la Luz, et al., 2005; Oberbauer, 2005). The communities include forests, woodlands, chaparral (shrubs), native grassland and communities dominated by low shrubs. Some of the representative species of these vegetation communities are the endemic Guadalupe cypress (*Cupressus guadalupensis*), Monterey pine (*Pinus radiata* var. *binata*) and Guadalupe palm (*Brahea edulis*). Several native species such as the juniper (*Juniperus californica* - now restricted to <10 individuals), and the shrubs island redberry (*Rhamnus pirifolia*), and laurel sumac (*Malosma laurina*) were also characteristic of some communities, along with endemic succulents such as cistanthe (*Cistanthe guadalupensis*) and liveforever (*Dudleya guadalupensis*), the endemic Guadalupe senecio (*Senecio pameri*); and three endemic species of shrubby tarweeds (*Deinandra* spp.). Some insular endemics were also representative of these environments, such as the island hazardia (*Hazardia cana*; only present on San Clemente Island, USA and Guadalupe) and the insular oak (*Quercus tomentella*; only present on five of the Channel Islands, USA and Guadalupe).

INTRODUCTION OF INVASIVE MAMMALS

Guadalupe Island remained pristine and uninhabited until the beginning of the 19th century when fur hunters arrived (Hanna, 1925; Huey, 1925). It is likely that house mice (*Mus musculus*) and feral cats (*Felis catus*) were introduced following these first human settlements (Hanna, 1925; Huey, 1925; Moran, 1996). Both species were introduced around 1880, rapidly establishing feral populations (Moran, 1996). In addition, whalers, in order to have a source of fresh meat during their voyages, introduced goats (Moran, 1996). Together, goats and cats have been responsible for the extinction and extirpation of many native and endemic species (e.g. Jehl Jr & Everett, 1985; León de la Luz, et al., 2003), and the impacts of house mice remain to be evaluated. In addition, feral dogs (*Canis familiaris*) also established a population on the island (Moran, 1996). Other mammals, such as cows (*Bos taurus*), were also introduced but never established feral populations (Aguirre-Muñoz, et al., 2011; J. Rico-Cerda pers. comm.).

Effects of feral goats on native flora

After goats were introduced, only one of the original vegetation communities, comprising low shrubs present on islets where goats or mice never were introduced, remained pristine. The other plant communities either disappeared, became restricted to a very patchy distribution, or were represented only by isolated individual plants. At least 26 plant taxa became extinct or were extirpated due to feral goats (Moran, 1996; León de la Luz, et al., 2003; Oberbauer, 2005; GECI, unpublished data). Not only were entire vegetation communities depleted, and many endemic species lost, but also many non-native species have been introduced. Since 1875, at least 69 plant species have been introduced to the island, mostly European grasses and forbs (Junak, et al., 2005; Rebman, et al., 2005; GECI, unpublished data). The heavy modification of the ecosystem caused by the feral goats, in combination with the arrival of invasive plants, resulted in a vast extension of bare ground and vegetation dominated by European grasses (grassland community), such as slender wild oat (*Avena barbata*) and red brome (*Bromus rubens*).

CURRENT RESTORATION AND CONSERVATION ACTIONS

Ecosystem resilience – passive restoration

On Guadalupe Island, after completing the goat eradication in 2007, native vegetation started to naturally recover. Plants considered extinct or extirpated have been rediscovered and there have been new plant records for the island, including at least one undescribed species. A survey conducted in 2001 on the endemic variety of the Monterey pine—there are five endemic varieties: three in the USA and two in Mexico, all the original seed source for plantations around the world—estimated that there were only 220 adult pines left (Rogers, et al., 2006). Since the goats were eradicated, the number of new seedlings has increased to several thousands (Fig. 1). Not only have the trees have recovered, but shrubs are also returning with full strength, competing well with invasive grasses. *Ceanothus arboreus*, a shrub able to reach 6 or 7 m and a new record for the island (Junak, et al., 2005), is now very common around the cypress and pine-oak forests. Also, the maritime desert scrub in the area most impacted by the goats' presence has changed from almost 0% native vegetation coverage (areas dominated by European grasses) to 52% (Ceceña-Sánchez, 2014).

Active restoration of plant communities

In a review of passive vs active restoration effects on forest recovery, Meli, et al. (2017) suggest observing the system for a few years after intervention to inform better decisions regarding active restoration actions. In the case of Guadalupe Island, feral goat eradication was completed in 2007. The active restoration project started in 2015. Over a period of almost 10 years we documented and measured the recovery of species. Not all recovered at the same speed. Some trees, shrubs, and forbs are recovering at a fast pace. However, there are many species that still remain very fragile, given their low numbers (*Juniperus californica* < 10 known individuals; insular oak, *Quercus tomentella* < 50 adult trees; *Cistanthe guadalupensis*, almost absent from the main island and surviving only on islets), and there are others whose distribution has decreased historically from forests to small isolated patches (e.g. *Cupressus guadalupensis*).

In order to achieve the island's full recovery, the active restoration of vegetation and eroded and degraded soils was the next conservation step. The negative effects of overgrazing and soil compaction are exacerbated on a volcanic island where soil (even some of the most productive soil (Ugolini & Dahlgren, 2002)) is limited and very susceptible to loss due to erosion. A study focused on the cypress forest on Guadalupe Island concluded than the erosion rates were exceptionally high, with a minimum recorded loss of 44 ton/ha/year and the maximum 142 ton/ha/year (Ramos Franco, 2007). Although it was estimated only for the cypress forest, the erosion problem is evident across the whole island, especially at higher elevations. To date, GECI in collaboration with the National Forestry Commission (CONAFOR) and CONANP, and other partners, such as the Mexican Navy (SEMAR) and the local fishermen's cooperative *Abuloneros y Langosteros*, is implementing a 700 ha project to accelerate the recovery of native vegetation communities.

The project involves reforestation, erosion control, and fire prevention actions for different plant communities. Reforestation is being implemented over 583 ha: 33 ha of palm forest; 120 ha of pine-oak forest; 261 ha of cypress forest, 60 ha of juniper woodland and 109 ha of maritime desert scrub. Erosion control actions (17 ha) are focused only on the cypress forest, in an area with slopes of 27%, loss of around 75% of the superficial soil layer, and deep gullies (Ramos Franco 2007), which is considered as extreme degradation (CONAFOR, 2004). On the other hand, due to a fire which occurred in 2008 in the cypress forest, the quantity of accumulated fuel was alarming, around 110 t/ha on average, with a maximum of 1,000 t/ha in certain areas (Luna-Mendoza et al. 2016). For this reason, fire management actions were focused here. The goal is to carry out fuel reduction (through manual removal of surface fuels and increasing the height to live crown) in 100 ha and to restore 10 km of firebreaks.

An on-site nursery was built as part of the project (Fig. 2). The nursery (480 m^2) is surrounded by a mouse-proof, galvanised steel fence of 50 m × 30 m, as mice are responsible for the loss of huge amounts of seed and seedlings at early stages. Around 15 species of native and endemic species are being produced: Guadalupe pine, Guadalupe cypress, Guadalupe palm, insular oak, island hazardia, Guadalupe lupin (*Lupinus niveus*), Guadalupe phacelia (*Phacelia phyllomanica*), island malva (*Malva occidentalis*), Guadalupe rock daisy (*Perityle incana*), among others. Species produced were chosen based on their rarity on the island (e.g. *Leptosyne gigantea* and *Cistanthe guadalupensis*); endangerment (e.g. juniper); propagation material available; potential as nurse plant (e.g. *Sphaeralcea* spp.); importance as food or shelter for native invertebrates and landbirds (e.g. *Senecio palmeri*) and effectiveness at retaining soil (e.g. *Calystegia macrostegia* ssp. *macrostegia*). Their allocation was based on historic information of former vegetation communities as well as observations of where there has been natural recruitment.

Fig. 1 Recovery of Guadalupe pine (*Pinus radiata* var. *binata*) from 220 individuals (adult trees) to several thousands in ten years. Photo credits: GECI Archive/J.A. Soriano.

Fig. 2 Plant nursery on Guadalupe Island with the capacity to produce over 60,000 plants per year. Photo credits: GECI Archive/J.A. Soriano.

For example, goat removal allowed the recovery of the island *Ceanothus* from seed surviving in the seed bank. Now the species grows close to the cypress and pine-oak forests, but individuals are sparse. However, for this species, as seed is not capable of long distance dispersal by itself (Minnich, 1982), it can take a long time to recover its original coverage. Another species, the Guadalupe lupin, is spreading at a fast pace, but being a legume with big seed depends on rainfall to disperse seed downslope. On Guadalupe the dispersal pathways are limited, as seed-eating birds are few and native terrestrial mammals are absent. In the case of the endemic cistanthe, although the species is very common on the islets, on the main island only three individuals have been recorded in the last 10 years. This is one of the lost species of the maritime desert scrub, and a goal of this project is to reintroduce it to this vegetation community.

Up to June 2018, 90,000 plants have been produced in the nursery. The final goal is to produce 160,000 plants, mostly trees and shrubs. We have planted almost 40,000 plants, most of them trees. To date we have nearly completed reforestation of the pine-oak and cypress areas (Fig. 3). Some challenges have arisen: logistics linked to working on an island; lack of plant propagation information for some species (especially endemics); limited amount of seed (insular-endemic or Guadalupe-endemic species and very few individuals left); diseases; and limited amount of water (relying mostly on the fog). In the last rainy season there was virtually no rainfall and fog has been very intermittent and scarce. We are therefore using resources such as the commercial hydrophilic polymer based on polyacrylamide, called Lluvia sólida®. We add 1.5 to 2 l of this hydrated polymer to each plant. So far, results are encouraging, as survivorship of planted individuals is above 85%. Regarding soil restoration, mechanical methods to control and prevent erosion, such as check dams and contour barriers, have been implemented. More than 1,500 m of contour barriers of rocks and logs have been built as well as 66 m^3 of rock and log check dams. So far, 27 hectares have been cleared of fuel and 1,500 m^3 of material has been removed.

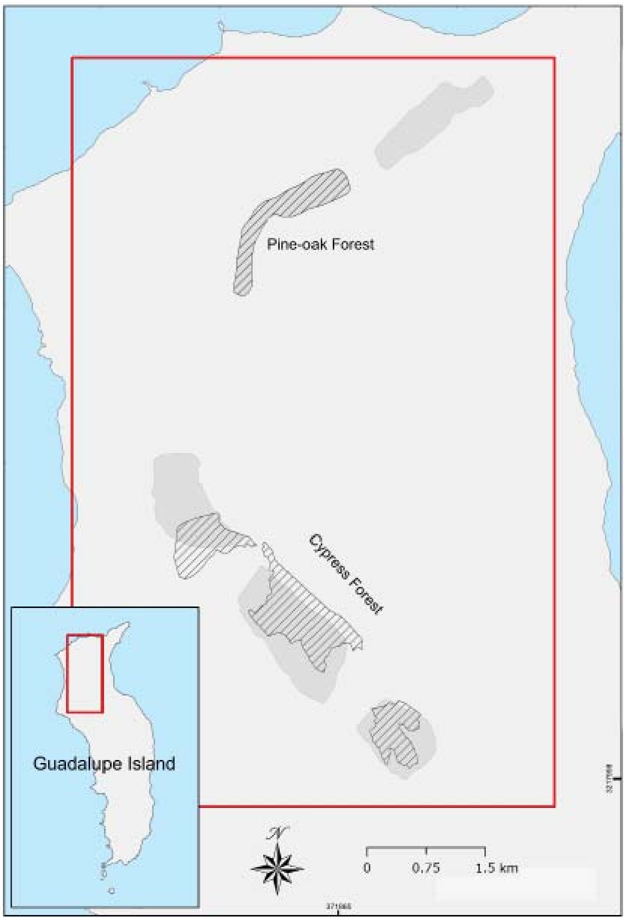

Fig. 3 Reforested areas on Guadalupe Island. The polygon in the north relates to pine-oak forest and the three polygons in the south are in the cypress forest area. Shaded (grey) areas are the original areas proposed in the project and striped areas are the ones completed (up to June 2018).

WHAT'S NEXT?

There still much to be done on Guadalupe Island. A period of 130 years of feral goats on the island caused severe ecosystem degradation. However, with collaborative projects, such as the one described here, we are heading in the right direction to restore the island's ecosystem services and biodiversity. Future projects, conducted in collaboration with CONANP, are to continue with fuel reduction actions in the cypress and pine-oak forests, to collect seed of endemic species to be stored at national seed banks and to estimate carbon sequestration in forest ecosystems. As a country, Mexico is now fully committed to the recovery of its islands, going a step further than eradication actions. On Socorro Island (Revillagigedo Archipelago; Pacific Ocean), feral sheep were removed a few years ago. This island is very similar to Guadalupe and faces the same challenges: soil degradation and a need to do some active restoration of the forest, not only for the vegetation itself but to restore the habitat for many endemic land birds which were close to extinction. In some cases we cannot wait for the islands to recover naturally, especially where other threats are still present (other invasive mammals). Currently other islands in Mexico, such as Espíritu Santo Island (Gulf of California), and María Cleofas Island (Las Marías Archipelago, Pacific Ocean), are being cleared of herbivores, and hopefully more active restoration actions could be established on these sites in the near future.

ACKNOWLEDGEMENTS

We would like to thank government agencies, private corporations and non-governmental associations that have assisted with this project: Abuloneros y Langosteros, Agroproductores de Zacualpan, Alianza WWF- Fundación Carlos Slim, Colegio de Postgraduados-Campus Montecillo, Comisión Nacional de Áreas Naturales Protegidas, Comisión Nacional de Áreas Naturales Protegidas-Reserva de la Biósfera Isla Guadalupe, Comisión Nacional Forestal, Comisión Nacional para el Conocimiento y Uso de la Biodiversidad, Instituto Nacional de Ecología y Cambio Climático, Marisla Foundation, Secretaría de Gobernación, Secretaría de Marina, Secretaría de Medio Ambiente y Recursos Naturales-DGVS and DGGIMAR, the David and Lucile Packard Foundation, The Nature Conservancy, US National Park Service and Universidad Autónoma Chapingo. Thanks also to the editors and anonymous reviewers whose comments greatly improved this manuscript.

Abstract Rats were eradicated in 2005–2006 from the islands of Canna and Sanday, Scotland (total area 1,320 ha). Poison bait was laid from December 2005 onwards and the last rat was killed in February 2006. An intensive period of monitoring over the next two years confirmed that no rats remained on the islands. Seabirds have been monitored on Canna for nearly 50 years and some species have shown good evidence of recovery since the eradication. Other species have not recovered and this may have been due to mortality caused by food shortages or storm events which have been impacting seabirds in the region. These regional changes in pressures affecting the seabird populations make the interpretation of the impacts of the rat eradication programme much more difficult. Atlantic puffins, formerly confined to offshore stacks, have recolonised sites on the mainland of Canna and a count of over 2,000 was recorded in 2016. Manx shearwaters, which had ceased nesting in the monitored colony have made a slow recovery to one or two pairs in 2016. Productivity has also increased from a low of 0.2 chicks per nest in the 1990s to 0.74 in 2017. European shags nesting in boulder colonies were most susceptible to rat predation. One such colony has recovered from 45 nests in 2005 to 75 in 2016 and productivity increased from less than 0.7 chicks per nest to an average of 1.6 following eradication. Populations of shags nesting in cliff locations have shown no recovery or have declined. Mew gulls, which nest along the shoreline, have increased from five to over 30 pairs. Other seabirds, such as common guillemots and black-legged kittiwakes, have shown no clear trends and are probably affected by other factors. Rabbit populations have increased on both islands, reaching an estimated 15,500 animals in 2013 that were causing considerable damage through grazing, erosion, and disturbance of archaeological remains. It is unclear whether the increase in rabbit numbers can be attributed to rat eradication. An intensive control programme has brought the rabbit population under control. While some seabirds have responded positively to the rat eradication, the response of some has been slow and others have not responded, probably as a result of regional pressures on their survival. It is important that monitoring of both seabirds and rabbits continues to track the success of this important seabird colony.

Keywords: contingency plans, invasive species, monitoring, quarantine, rabbits, rat eradication

INTRODUCTION

The islands of Canna and Sanday, which are connected at low tide (total area 1,320 ha) are in the Inner Hebrides, off western Scotland. They are owned and managed by the National Trust for Scotland and are designated as a Special Protection Area because of their internationally important seabird colony. Seabird populations and breeding success have been monitored on the islands since 1969 by the Highland Ringing Group, making this one of the best monitored sites in Scotland. The main species present are common guillemot (*Uria aalge*), razorbill (*Alca torda*), black-legged kittiwake (*Rissa tridactyla*), northern fulmar (*Fulmaris glacialis*), European shag (*Phalacrocorax aristotelis*) and Atlantic puffin (*Fratercula arctica*). Manx shearwater (*Puffinus puffinus*) used to be present in large numbers (1,500 apparently occupied burrows) but suffered very poor breeding success and, by 2000, had been virtually wiped out (Swann, 2002) Other seabirds were also recorded as declining. Predation by a large population of brown rats (*Rattus norvegicus*) was identified as the likely cause of this decline, from three types of evidence: 1. Direct observation of increasing numbers of rats foraging in the seabird colonies and of stashes of predated egg shells and carcases; 2. Declining numbers and decreasing breeding success of vulnerable species; and 3. Changing nesting behaviour of breeding seabirds moving to less accessible sites. After favourable feasibility studies (Bell & Bell, 2004), it was decided to eradicate the rats using poison bait, and funding was obtained from the EU LIFE fund, Scottish Natural Heritage and the National Trust for Scotland. The programme objective was to halt declines in breeding seabird populations on Canna and Sanday and to facilitate their recovery and long-term protection. It was carried out under contract by Wildlife Management International, starting in late 2005. By February 2006 the last rat sign was detected and, after a two-year period of intensive monitoring, the island was declared rat-free in 2008 (see Bell, et al., 2011).

Canna and Sanday are inhabited by a population of 15–20 people and are farmed with a mixture of sheep and cattle. They are served by a ferry service five days a week. The harbour and all houses are in the eastern portion of the islands, where there are a number of fenced pastures and some planted woodlands. There are high cliffs around much of the coast, particularly to the north and west, and the higher ground is mostly covered in wet heath. There is a population of distinctive, large (presumed introduced) field mice (*Apodemus sylvaticus*) that were not removed by the rat poisoning programme and a substantial (introduced) population of rabbits (*Oryctolagus cuniculus*). There is a small number of (introduced) hedgehogs (*Erinaceus europaeus*), and regular sightings of European otters (*Lutra lutra*), but no other ground predators. Two pairs of white-tailed eagles (*Haliaeetus albicilla*), one pair of golden eagles (*Aquila chrysaetos*), up to two pairs of peregrine falcons (*Falco peregrinus*), about 15 pairs of common buzzards (*Buteo buteo*) and ravens (*Corvus corax*) regularly breed on the island and there are small numbers of great skuas (*Catharacta skua*) and great black-backed gulls (*Larus marinus*). Predation by eagles, and possibly locally by otters, may impact populations of northern fulmar, while ravens may impact shags, particularly on the cliff-nesting colonies (Swann, 2008; Swann, et al., in press), but none of these predators exerts substantial pressure on other seabird populations.

Following the eradication programme, biosecurity measures were put in place, consisting of continuous monitoring (wax blocks and kill traps), quarantine and contingency plans. No incursions of rats have been detected.

The main post-eradication monitoring has been a continuation of the long-running seabird programme which can be used to detect any changes following the eradication of rats. A rapid expansion in the rabbit population was

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 576–579. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

noted in 2011–2013 which caused locally severe grazing and considerable erosion through collapsed burrows. This necessitated the introduction of control measures consisting of a rapid reduction cull in January–March 2014, followed by continuous lower level culling thereafter. There have been surveys of vegetation condition (SNH, 2014), grassland fungi (Murfitt & Macdonald, 2012), invertebrates (Rotheray & Lyszkowski, 2012) and lichens (Acton, 2011). Any changes in the vegetation are thought to be due to rabbit grazing or livestock management, rather than directly related to the removal of rats.

This paper reviews the changes in seabird population size and breeding success reported in Swann, et al. (in press) and discusses fluctuations in rabbit populations and the control measures employed.

MATERIAL AND METHODS

All seabird population and productivity estimates follow the methodology of Walsh, et al. (1995) and are described in Swann, et al. (in press). Seabird population estimates for the years 1995 to 2017, derived from Swann (2008) and Swann, et al. (in press), were analysed. For northern fulmar, European shag, black-legged kittiwake, mew gull, herring gull, lesser black-backed gull and greater black-backed gull, the population figures represent the number of apparently occupied territories or apparently occupied nest sites throughout the two islands. For common guillemots and razorbills, they are the number of nest sites at a small number of accessible monitoring plots. Nest sites were recognised by the presence of an egg, chick or, in the case of razorbill, a shell or dense mass of droppings. The data were divided into the 11 years prior to the eradication (1995–2005) and the 12 years following (2006–2017). Population trends were determined by fitting an exponential line to each set of data. The exponents shown on the graphs represent r in the equation $N = e^{rt}$, where N is the population size (pairs) and t is the time in years.

Productivity estimates represent large young/chicks per occupied nest within all the monitoring plots for northern fulmar and black-legged kittiwake. For great black-backed gulls and herring gulls, they represent large chicks per apparently occupied territory. For European shags, the breeding success (chicks per occupied nest) is separated into plots within the boulder colonies and plots on cliff sites. Productivity of Manx shearwaters was calculated as the number of large chicks produced per occupied burrow located.

In June 2013 and 2014 (the latter following a rabbit reduction programme in January–March 2014) rabbit populations were estimated by walking over the entire island using the Modified McLean scale, an 8-point scale based on the observation of rabbits and pellets (NPCA, 2012). Densities were estimated within different topographic or vegetation units and the area of each unit was calculated using GIS. The approximate population of rabbits was then calculated by multiplying the area of each unit by the densities corresponding with the McLean scale. Rabbit culls were recorded by the trappers on a weekly basis in different zones.

RESULTS

Seabird population size

Seabird population trends are shown in Fig. 1. Numbers of breeding pairs of almost all species, except the black-legged kittiwake were declining prior to 2005 but after 2006, three gull species were stable or slowly increasing and populations of all other species, except the northern fulmar, showed a reduced rate of decline. It should be noted that the correlation coefficients (R^2) were low, showing significant declines for most species prior to eradication but significant increases only for mew gull and lesser black-backed gull after eradication.

In the case of Manx shearwater, the population had already fallen to very low levels prior to 1995 from a high

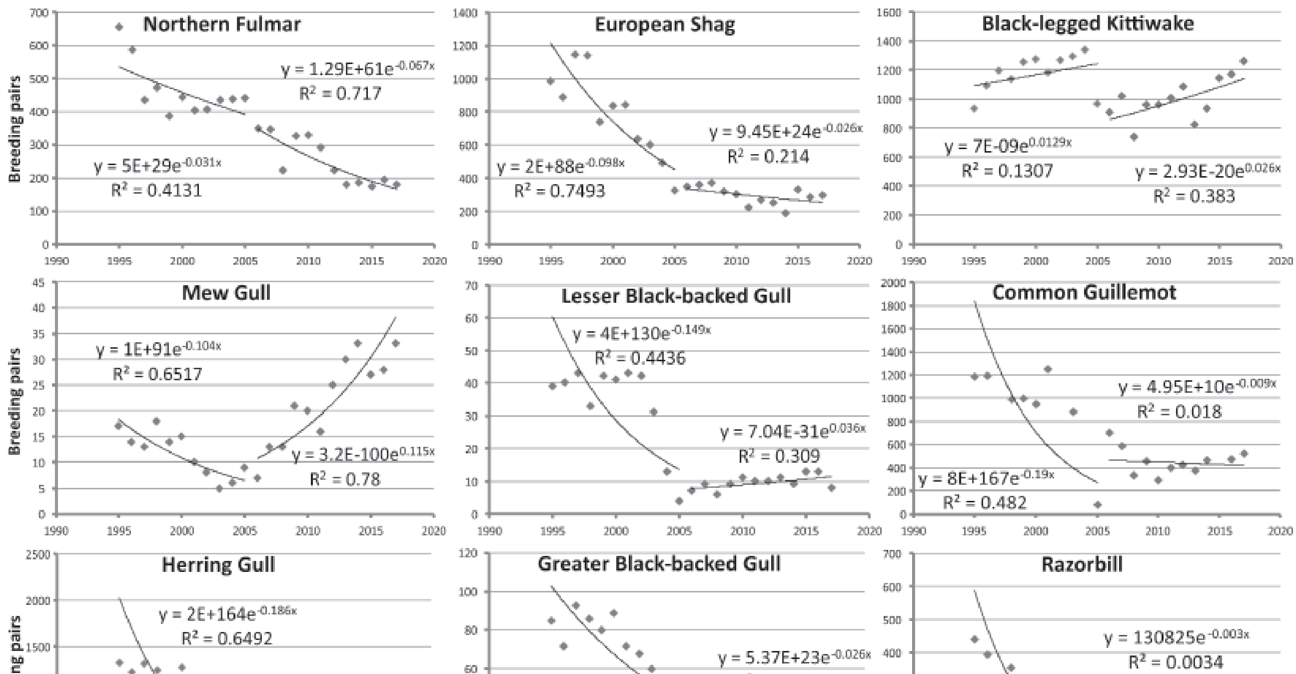

Fig. 1 Population trends in the numbers of breeding pairs of nine species of seabird on Canna during the period 1995–2017. Data were split into pre-eradication (1995–2005) and post-eradication (2006–2017) and exponential graphs fitted to each.

of 1,500 pairs in the mid-1970s. By 2000, no nests could be located in the main colony, along Tarbert Road (see Fig. 2). Following the rat eradication in 2006 the first nesting shearwater was detected again in the Tarbert Road colony, but by 2017 this had grown to only two nests. A further four nests were located at accessible locations in the west of the island and all of these nests were monitored for breeding success. Based on calling behaviour at night, it was estimated that there were more nests, possibly 10–20 pairs, in inaccessible locations (M. Carty, pers. comm.)

Mew gulls (*Larus canus*) nest along the shore on Canna. Numbers have increased from nine pairs at the time of the eradication to around 30 pairs in recent years. Other large gulls, especially herring gulls (*Larus argentatus*), declined rapidly in the 1990s and early 2000s similar to colonies elsewhere in Scotland. Since 2006, populations on Canna have remained low.

The overall number of breeding European shags had dropped to about 300 nests by 2005. Different sub-colonies have performed differently, with those nesting under boulders declining most rapidly (Swann, 2005). One boulder colony, Lamasgor, has subsequently shown an increase from 45 nests in 2005 to 75 in 2016. Other sub-colonies, particularly those on cliffs, however, have remained stable, or declined, so that overall the population has not increased. Nevertheless, the overall rate of decline of all of the nests on the island has slowed (Fig. 1).

Atlantic puffin breeding populations are difficult to monitor, especially because, prior to 2005, they were virtually confined to two inaccessible stacks. After 2006 they began to spread to sites along the north coast of Canna at Guegasgor (see Fig. 2). Where more accurate census methods are not practical, Walsh, et al. (1995) recommend counting puffins rafting on the sea near the colony. A count of rafting puffins in 1995 gave 1190 individuals while, in 2016, 2050 were counted. Though not conclusive, this is consistent with an increase in breeding numbers as well as the recorded expansion of the puffin colony to colonise previously unoccupied sites on the mainland of Canna.

Seabird breeding success

Between 1999 and 2004, breeding success of European shags in monitored nests in boulder colonies had dropped to <0.7 young per nest. Since the eradication breeding success has averaged 1.6 young per nest. In contrast, breeding success at colonies nesting on cliff ledges averaged 0.97 per nest over the years 2006–2017 (Table 1).

Manx shearwater breeding productivity has greatly improved. In the 1980s it averaged 0.6 young/nest, dropping to <0.2 young/nest in the mid-1990s. Since 2009. out of a total of 19 burrows that were known to contain an egg, 14 successfully produced a chick, an average of 0.74 young/nest.

Rabbit population

The rabbit population on Canna has routinely fluctuated in response to disease and weather conditions, but numbers had not been formally monitored. By 2013, rabbit numbers were causing serious damage to agricultural interests and

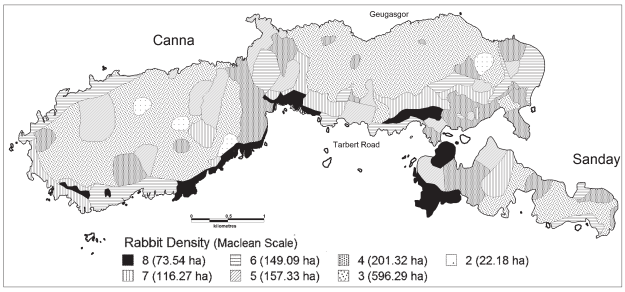

Fig. 2 Estimated rabbit density on Canna in July 2013. Densities relate to the Modified McLean Scale (NPCA, 2012).

were damaging archaeological remains. A rapid assessment of rabbit population density gave an overall population estimate of 15,500 (Fig. 2). As a consequence, a rabbit population reduction exercise was carried out in January–March 2014, with a total of 8,200 rabbits removed. This brought the population down to an estimated 7,000 by July 2014. Continuous culling of around 5,000 rabbits a year has maintained it at a level where agricultural damage is acceptable.

DISCUSSION

The response of Canna seabirds to the successful rat eradication in winter 2005/06 was species specific. For some populations, such as the Atlantic puffin, the mew gull and the boulder-nesting colonies of European shag, there have been apparent increases in numbers of breeding pairs. The colony of European shags on Canna is of international importance and formerly numbered 1,800 pairs. Many of them nest under boulders in relatively accessible locations and these birds were found to be particularly susceptible to rat predation, declining most rapidly. Simultaneously, there was a shift whereby a greater proportion of shags started nesting on more exposed cliff locations where they were less susceptible to rat predation but more exposed to avian predation (Swann, 2005). Following the eradication of rats, some boulder colonies have expanded rapidly but the cliff-nesting birds have continued to decline. The net effect has been a continuing decline in the overall shag population but at a reduced rate.

Similarly, although populations of common guillemots and razorbills have continued to decline there has been a slowing in the rate of decline. These two species of auk nest in similar locations to the European shags and were also affected by rat predation. Guillemots were badly affected by a severe period of stormy weather in western Scotland in late summer 2004 (Swann, 2004) which caused heavy mortality of both adults and chicks. Ringing studies showed that adult survival dropped from a long term average of 0.9 to 0.6 between 2004 and 2005. Breeding numbers of guillemots on Canna were very low in 2005 and breeding success remained low until 2008 probably as a result of subsequent food shortages. Breeding success improved in 2009 and the population has started to increase.

Numbers of breeding razorbills showed a sharp jump in 2006, and this was almost certainly due to a reduction

Table 1 Breeding productivity of Manx shearwaters at Tarbert Road colony and European shags in the boulder and cliff colonies on Canna, 2001–2017. "-" = Productivity not monitored.

Year	01	02	03	04	05	06	07	08	09	10	11	12	13	14	15	16	17
Manx shearwater	-	-	-	-	-	-	-	-	0	1	1	0.25	0.5	0.2	0.5	1	0.5
Shag – boulder colonies	0.1	0.26	0.16	0.01	0.7	1.2	1.4	1.5	1.8	-	1.4	-	1	1.5	1.8	2.2	1.3
Shag – cliff colonies	-	-	-	1.4	0.7	0.7	1.0	0.3	0.7	1.5	0.8	1.6	1.0	0.7	1.2	1.0	1.2

in predation by rats, eggs appearing in areas that had been clear of nesting for several years (Swann, 2008). However, the number of occupied breeding sites then remained roughly stable at this level until 2016, and the breeding success remained low, probably as a result of food shortage (Swann, et al., in press). Since occupied breeding sites in this species are identified by the presence of an egg or chick, failure to breed does not necessarily indicate the absence of adults attempting to breed – they may have laid an egg and then left again following predation of the egg. The population increase observed in 2006 may therefore indicate higher early survival of eggs rather than a greater number of adults attending the colony.

The large gulls, especially the lesser black-backed gull and the herring gull, suffered a particularly sharp decline in the period 2000–2005 and have since shown a slight increase. Foster, et al. (2017) have analysed this trend and shown that it is closely correlated with the commercial landings of fish in the nearby port of Mallaig, with the gulls feeding extensively on discards from the fishing industry. Since 2006, numbers have stabilised at a much lower level. It is unclear whether the subsequent slow increase of lesser black-backed gulls had anything to do with the reduction in rat predation.

The number of breeding pairs of other species, such as the northern fulmar, have continued to decline and there has been no reduction in the rate of decline. The fulmars nest largely in cliff locations and would have been less affected by rat predation, although it is possible that predation by eagles may be significant (Swann, 2008).

The black-legged kittiwake population has stayed roughly stable over the whole period, although it too suffered poor breeding success in the period 2005–2008, probably as a result of the food shortage experienced by other seabirds in the region. This species typically nests on near-vertical cliffs and is therefore probably the least susceptible to ground predators such as rats. The causes of any changes in population size or breeding success must therefore be sought elsewhere.

One species that was expected to benefit strongly from the removal of rats was the burrow-nesting Manx shearwater. Although there has been a tiny increase in breeding numbers and a clear improvement in breeding productivity, there are still thought to be fewer than 20 pairs nesting on the island. Shearwaters are long-lived and slow-maturing species, possibly not breeding until eight years of age and so endogenous growth of the surviving, relict population would be expected to be slow (Brooke, et al., 2018). However, Canna lies next to the larger Manx shearwater colony on Rum (estimated to be around 60,000 pairs) and is regularly visited by (presumably non-breeding) birds at night. It is apparent that these have not colonised the former colony on Canna to any great extent. The shearwater colony on Rum is subject to predation by a large population of brown rats. The impact of this predation is unclear and it is not known whether the colony is stable or declining (Lambert, et al., 2015). If predation is high, the pressure for emigration from Rum would be lower than from a colony that was limited by shortage of nest sites. An attempt was made to attract breeding birds to re-colonise Canna by playing recordings of shearwater calls at night in 2006 and 2007. This was discontinued because of a lack of obvious success.

It is possible that the growth in the rabbit population is attributable to the removal of rats as young rabbits would be likely to have suffered predation by rats. However, large fluctuations are a characteristic of rabbit populations and high numbers have been reported in previous years. Thus, while 15,500 may seem a high population for Canna, and it undoubtedly caused damage to agricultural interests, it may not be unprecedented. It has been necessary to control rabbits on Canna for many years prior to the eradication of rats although historically the rabbit populations used to cycle due to outbreaks of myxomatosis. Surprisingly, there has been no evidence of myxomatosis in recent years. Total eradication of rabbits has been deemed unfeasible (Bell, 2012) and so it is inevitable that control of rabbit populations will be necessary for the foreseeable future to prevent the build-up of excessive numbers. Although vacated rabbit burrows can provide nest sites for Manx shearwaters, at high densities there is likely to be competition for burrows and this will reduce sites available for shearwaters. The burrows have also caused severe erosion, including large landslips, in some of the former shearwater colonies (Bell, 2012).

Overall, the removal of rats from Canna has had some very beneficial impacts on some species of seabirds but this effect was masked for other species by some very difficult local conditions in the period 2004–2008, firstly by storm-related mortality and subsequently by regional food shortages. The gulls were also impacted by a lack of fisheries discards following a drop in commercial fisheries. Because these external factors occurred at approximately the same time as the rat eradication programme it may take many years for the full benefits to play out. It is clear that continued detailed monitoring of seabird populations and breeding success is vital in unravelling the complex interactions between local conditions on the breeding colony and regional changes in the marine ecosystem.

Abstract The Seychelles was one of the first tropical island nations to implement island restoration resulting in biodiversity gain. In the 2000s a series of rat eradication attempts was undertaken in the inner Seychelles islands which had mixed results. Three private islands with tourist resorts successfully eradicated rats: Frégate (2000), Denis Island (2003) and North Island (2005). Frégate Island was successful with the first eradication attempt whereas North and Denis Islands were initially unsuccessful, and both required second eradication operations. All three islands have developed conservation programmes including biosecurity, habitat rehabilitation, and species reintroductions, and have integrated nature into the tourism experience. Conservation actions, including rat and other invasive species eradications, on these three islands resulted in the creation of 560 ha of mammalian predator-free land, the reintroduction of seven populations of five globally threatened birds (GTB) and the safeguarding of two existing GTB populations and several reptile and invertebrate species. However, on these and many other islands in the Seychelles, the potential of this conservation "model", where island owners implement conservation programmes largely funded by the tourism businesses in collaboration with NGOs (Non Government Organisations), has not been fully realised. We review the rehabilitation on Frégate, Denis and North Islands from inception to the present, and assess factors that have facilitated the subsequent development of conservation programmes, the presence of receptive businesses and governmental/NGO/donor support and explore limitations on business-led island rehabilitation.

Keywords: eradications, invasive alien species, island conservation, rehabilitation Seychelles, tourism

INTRODUCTION

Islands harbour much of the world's endangered biodiversity (Kaiser-Bunbury, et al., 2010) and island species are very vulnerable to the impacts of Invasive Alien Species (IAS). Over the last 500 years, the majority of documented plant or vertebrate extinctions have occurred on islands (Tershy, et al., 2015). Causes include habitat modification and over exploitation; however, IAS have played a key role. In particular, invasive mammals such as rats (*Rattus* spp.) have been implicated in numerous bird extinctions, extirpations and population declines (Moors & Atkinson, 1984; Burger & Gochfeld, 1994; Hilton & Cuthbert, 2010) as well as reptile declines and impacts on other taxa (Towns, 1991; Harper & Bunbury, 2015; Thibault, et al., 2016).

The eradication of rats and other invasive mammals, often with concomitant habitat rehabilitation, was initially pioneered in New Zealand and other temperate areas but has become increasingly practiced in tropical regions, (Russell & Holmes, 2015; Russell & Broome, 2016). The understanding of the measures required to successfully execute mammal eradications on tropical islands has improved (Keitt, et al., 2015). In the late 1990s, the Seychelles was one of the first tropical island nations to implement rodent and multispecies eradications (Merton, et al., 2002)

The Seychelles archipelago in the Indian Ocean extends over an Exclusive Economic Zone of 1,374,000 km^2 (Fig. 1). The ancient "inner" islands are situated approximately 4^o S and 54^o E and are composed of continental rock, while the much more recently formed "outer" islands are formed from raised reefs and sand cays (Stoddart, 1984) scattered for approximately 1000 km to the south-west of the inner islands. The Seychelles have high endemism (Stoddart, 1984) and the inner islands are an Endemic Bird Area (EBA100); supporting 11 endemic species of bird (BirdLife International, 2017).

Since the human colonisation of the Seychelles in the late 18th century, IAS have caused range reductions, population declines, and extinctions of native species (BirdLife International, 2000). Alien predators are considered the most destructive species (Harper & Bunbury, 2015): most inner islands have had populations of black rat (*Rattus rattus*) and feral cat (*Felis catus*), and some have had brown rat (*R. norvegicus*). Only a few inner islands remained free of mammalian predators, and in the 1980s only four islands larger than 20 ha remained free of rats (Aride, Cousin, Cousine and Frégate), although feral cats were on Cousine and Frégate, and house mice (*Mus musculus*) on Aride and Frégate. Construction projects on islands resulted in the introduction of rats including black rat to Bird Island in 1968 and brown rat to Frégate in 1995.

Four Seychelles' bird species endemic to the inner islands were listed as Critically Endangered when at their lowest known population size: Seychelles magpie-robin (*Copsychus sechellarum*), Seychelles white-eye (*Zosterops modestus*), Seychelles paradise-flycatcher (*Terpsiphone corvine*), Seychelles scops-owl (*Otus insularis*). Four species were listed as Vulnerable: Seychelles warbler (*Acrocephalus sechellensis*), Seychelles fody (*Foudia sechellarum*), Seychelles kestrel (*Falco araea*) and Seychelles swiftlet (*Aerodramus elaphrus*) (BirdLife International, 2017) (Table 1).

Three species of bird that had been historically widespread (Gaymer, et al. 1969) became restricted to black rat-free islands: the Seychelles magpie-robin on Frégate (Gaymer, et al., 1969; Burt, et al., 2016), Seychelles warbler on Cousin (Komdeur, 2003), and Seychelles fody on Cousin, Cousine and Frégate (Vesey-Fitzgerald, 1940). The Seychelles white-eye had a small population in the uplands of Mahé and a larger population on Conception Island which had brown rats, but no black rats (Rocamora, 1997). Aride remained free of rats but did not retain

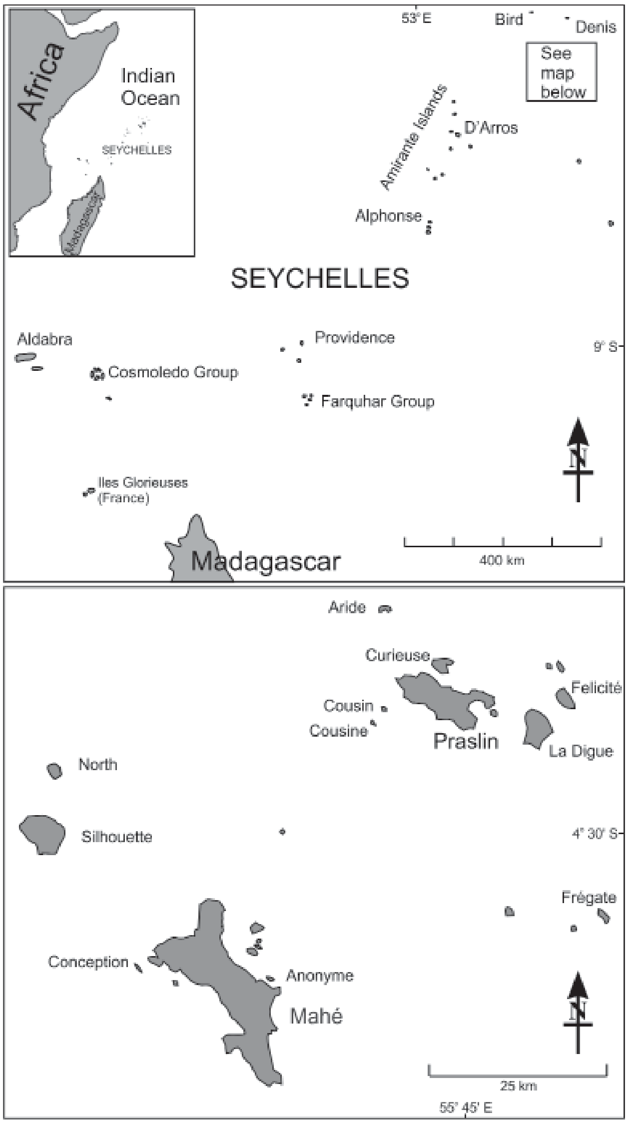

Fig. 1 The Seychelles showing islands mentioned in the text.

populations of endemic birds which may be attributed to forest loss and cat predation (eradicated in 1930s; Warman & Todd, 1984). The distributions of these endemic bird species suggest black rats were an important factor contributing to decline and extirpation of populations.

Initial conservation efforts focused on the purchase and protection of two rat-free islands (Cousin, 1968; Aride, 1973) by NGOs (Non Government Organisations). Successful attempts were made to reintroduce the Seychelles warbler to Aride and Cousine (Richardson, 2001; Komdeur, 2003). Attempts to introduce Seychelles magpie-robin to Cousin and Cousine met with success, but several introduction attempts to Aride were unsuccessful (Watson, 1978; Lucking & Ayrton, 1995).

Further progress was achieved with cat eradications on Frégate and Cousine during the 1980s (Rocamora & Henriette, 2015). Rodent eradications were not attempted in the Seychelles until 1996, when black rats were eradicated from Bird Island, and later in the early 2000s when a a series of rat and multispecies eradications were initiated that included privately owned Frégate, Denis and North Islands. Subsequent habitat rehabilitation and endemic bird reintroductions were implemented (Thorsen, et al., 2000; Merton, et al., 2002; Samways, et al., 2010).

This paper reviews the conservation programmes on three privately owned islands and the conservation outcomes.

ISLAND DESCRIPTIONS: NORTH, DENIS, AND FRÉGATE

North Island (Ile du Nord)

The native vegetation of North Island (201 ha) was replaced in the early 19th century by a coconut (*Cocos nucifera*) plantation, which was abandoned in the 1970s, and guano excavation left pits that are still present today. The island harboured black rats, cats, and feral cattle (*Bos taurus*). Hill (2002) identified the island as having a high rehabilitation potential; small enough to eradicate mammals, sufficiently isolated to manage reinvasion risk and a proportionally large coastal plateau that is likely to support rehabilitated forest suitable for Seychelles magpie-robins and Seychelles paradise-flycatchers (Currie, et al., 2003). The island was privately purchased in 1997 by an eco-tourism company, which opened an exclusive resort in 2005, with the intention to ultimately fund the rehabilitation of the island. Conservation is promoted through all aspects of the tourism operation, whereby guests and staff are educated and encouraged to participate in environmental activities such as guided hikes, presentations, and data collection.

Denis Island

Denis is a coralline island of 140 ha located 80 km north of the capital island of Mahé. Early descriptions mention abundant land tortoises and seabirds (Bradley, 1940). The original vegetation of the island, as described in 1773, was of open grassy areas and forest; probably *Pisonia grandis* (Stoddart & Fosberg, 1981). Extensive guano deposits indicated the historical presence of seabirds. The island has been altered profoundly, first through the cultivation of coconuts from around 1890 (Stoddart & Fosberg, 1981), then through guano extraction in the 1930s (Baker, 1963), followed by the replanting of coconuts in the 1940s. In 1975, a new owner built an airstrip and a small hotel and abandoned the coconut plantation. In 1998 the island changed ownership again and today it is managed as a luxury tourist resort with 30 villas.

Denis was considered a priority site for rehabilitation due to the large area of flat land conducive to rehabilitation, existing native woodland, and an owner who supported conservation, if black rats and feral cats were removed (Hill, 2002). The island appears to be in the natural range of some endemic birds as, in 2004, a Seychelles magpie-robin from Aride flew to Denis (Burt, et al., 2016) and in 2009 a Seychelles sunbird (*Cinnyris dussumieri*) flew from Bird Island to Denis (R. Bristol, pers. obs., 2009).

Frégate Island

The original vegetation of Frégate Island (219 ha) was removed to make way for spice and coconut plantations, that were abandoned in the 1980s, leaving coconut-dominated forest and several areas of the introduced tree sandragon (*Pterocarpus indicus*). The original vegetation is unknown; however, a few relict plants including *Pandanus balfourii* and *Euphorbia pyrifolia* survived on rocky glacis areas, indicating some of the vegetation that existed before plantations (J. Millett, pers. obs., 2000). The availability of canopy-forming sandragon forest and the absence of rats contributed to the survival of Seychelles fody, the last Seychelles magpie-robin population, and rich assemblages of reptiles, amphibians, and invertebrates including two single-island endemics: a beetle *Polposipus herculeanus*, and a snail *Pachnodus fregatensis* (Canning 2011b; Gerlach, 2006). Frégate was re-developed in 1995–1999 as an exclusive resort, and brown rats were accidentally introduced in 1995 at the time of hotel construction (Thorsen, et al., 2000; Merton, et al., 2002). Management of the island's biodiversity was initially not highly prioritised, but renewed interest in conservation was created through increased awareness amongst stakeholders over how nature can contribute to tourism. In 2003 the hotel appointed its own environment staff, who conducted biodiversity management and monitoring (J. Millett, pers. obs., 2003).

Vertebrate eradications

The islands of Frégate, Denis and North were amongst a series of islands that had rodents and /or cats eradicated between 1982 and 2005. In total six islands over 10 ha in size had black rats successfully removed, and three had brown rats successfully removed (Rocamora & Henriette, 2015). Some of the eradications were implemented in multi-island projects; however, the work was not planned as a phased programme. On the three islands central to this paper, the rodent eradications were, in part, motivated by business interests, and two required second attempts. The eradication of rodents has been an iterative (and at times faltering) process but was ultimately successful on most islands (Table 2).

Interest in eradicating rodents in the Seychelles was stimulated in 1995, when the introduction of brown rats to Frégate Island raised national and international concerns over the impact on Seychelles magpie robins (Merton, 1996). A proposal, led by the Ministry of Environment and

Table 2 Black rat, brown rat, mouse and cat eradications in the Seychelles.

Island	Size (ha)	Species	Invasion date	Eradication date	Method	Outcome	Prevention measures

North	201	Black rat	?	2005	Aerial Application	Success	Medium/ Good

Transport (MET), to eradicate rats and other mammals on several islands in a combined operation led to the eventual attempted eradication of black rats on Denis and Curieuse, brown rats on Frégate, and cats on Denis and Curieuse. House mice present on Frégate and Denis were not specific targets of eradication , but they were eradicated from the former during the operation.. The eradication operational costs on the private islands (Denis and Frégate) were financed by the island owners, and on Curieuse (state owned) it was funded by a grant from the Dutch Trust Fund (DTF) that also covered consultancy costs for the three islands (Merton, et al., 2002; United Nations, 2002; Rocamora & Henriette, 2015; John Nevill, pers. comm. 2018).

Rodent eradication operations commenced in June 2000 with two aerial applications of brodifacoum bait totalling 18 kg/ha applied to Denis with a nine day interval, and three aerial applications (23 kg/ha) to Frégate at five and 25 day intervals (Merton, et al., 2002). Areas that could not be covered through the aerial application, including buildings, work yards and hydroponic green houses were hand baited. The third application was in response to a lactating female rat trapped in an agricultural plot after the second application (J. Millett, pers. obs., 2000) after which no further rats were observed and the eradication on Frégate was successful. Cat eradication on Denis proceeded one week after the second rat-bait application using trapping and baiting with Compound 1080 (Merton, et al., 2002). The last cat on Denis was killed 14 months after the eradication started. On the same day the last cat was killed, black rats were confirmed as being present again and breeding on Denis (J. Millett, pers. obs., 2001). It was not possible to conclude if the population arose from survivors or reintroduction. However, given the short time duration between eradication and discovery and better understanding of factors influencing tropical island rodent eradications, eradication survival is likely (Rocamora & Henriette, 2015; Keitt, et al., 2015). Subsequently it was discovered the eradication attempt on Curieuse had also been unsuccessful (G. Climo, pers. comm., 2001), possibly due to reinvasion and/or survival (Rocamora & Henriette, 2015).

The owners of Denis Island decided to undertake a second eradication attempt to eradicate rats and mice. This proceeded with a ground-based operation in 2002, using brodifacoum poison in bait stations on a 40 m grid. Monitoring indicated that rats were killed quickly, but mice persisted for several weeks around the livestock farm where alternative food sources were available (G. Climo, pers. comm., 2002). Both species were eradicated successfully within two months.

A black rat eradication was attempted on North Island in 2003 with an aerial baiting operation using three aerial applications of brodifacoum. In March 2004 black rats were still present (G. Climo, pers. comm., 2004; Rocamora & Henriette, 2015). Cats were eradicated successfully at this time with a combination of poisoning with Compound 1080 and trapping. A second attempt to remove rats was made in 2005 with four aerial applications and a grid of bait stations on the whole plateau and in the vicinity of housing (Climo & Rocamora, 2006). In response to a rat being captured four days after the third application a fourth application was conducted (Climo & Rocamora, 2006) which ultimately resulted in the eradication of rats.

Not only mammals have proved to pose problems for endemic island species: introduced Indian myna birds (Acridotheres tristis) attack some native birds and compete for nest sites with Seychelles magpie-robin (Burt, et al., 2015; Feare, et al., 2017). An attempt to eradicate mynas on Frégate in 2000–2003 by shooting was unsuccessful (Millett, et al., 2005) but eradication succeeded using traps in 2011 (Canning, 2011a). Eradication on Denis Island using an avicide (Starlicide) and shooting commenced in 2000 but was unsuccessful. A subsequent attempt used trapping with follow-up shooting, which succeeded in 2015 (Feare, et al., 2017). On North Island, in 2006, an attempt to eradicate mynas with Starlicide was unsuccessful due to difficulties importing a rifle to start the shooting phase when poisoning had reduced the population to fewer than 100 birds; shooting was finally conducted in 2008-2009 but the population had recovered and was too numerous to be effective (Rocamora & Henriette, 2015). It was reattempted with a decoy trapping campaign from May 2016 to March 2017, followed by shooting. This reduced the population to three individuals by June 2018 with the eradication attempt ongoing (Havemann, pers. obs., 2018).

Overall experiences on Denis, North and Frégate indicate that sustained trapping programmes using small decoy traps located in areas frequented by foraging mynas, followed by shooting with an experienced hunter, is effective. Shooting as a standalone measure and using avicides appear to create aversion and have not worked well. Disruption or cessation of culling results in a population recovery (Millett, et al., 2005; Feare, et al., 2017).

BIOSECURITY

Biosecurity controls have been implemented on each of the three islands since undertaking rodent eradication. North Island has rigorous biosecurity with pre-departure inspections of all cargo on Mahé, inspections on arrival, the processing of cargo and baggage through a pest containment room, and fumigation and permanent bait stations locate close to landing areas, human habitation and beaches (North Island, 2015). Frégate Island has a rodent abatement protocol which includes cargo inspection and controls as well as permanent rat bait stations (Rocamora, 2015). There is also a rodent-proof fence around the harbour, made of steel mesh set in to the ground and topped with a smooth metal strip. However, maintenance of the structure has remained a challenge, especially where the ends of the fence meet the water and are influenced by wave action (J. Millett, pers. obs., 2018). Denis Island has a rodent prevention protocol (GIF, 2015). The protocol is focussed on rodent control with measures including baiting on boats, baiting arrival points and contingency measures to respond to an incursion: Denis Island still brings cargo to the island using a beach-landing barge, which increases reintroduction risk.

On all three islands, visiting vessels need to be in possession of a rat-free certificate which is obtained after a thorough check for rats on board prior to departure from Mahé. All of the protocols have been implemented voluntarily and devote greater effort to inspection and containment of rodents on the islands and less on loading controls at departure. Although all plans concentrate on rodent prevention, they are likely to be effective at reducing wider biosecurity risks.

FOREST REHABILITATION

Endemic birds rely on forest (Vega, 2005; Njoroge, 2002). Most other native vertebrates and invertebrates are also forest dwelling species; some have been able to adapt to gardens and plantations. Invertebrate densities and diversity on foliage tended to be higher for native trees, yielding greater food availability for species such as the Seychelles warbler and Seychelles paradise-flycatcher (Komdeur, 1991; Komdeur, 1992; Richardson, 2001; Hill, 2002). Accordingly, rehabilitation of native forest has been a prerequisite to restoring endemic bird populations. The original vegetation on Frégate, Denis and North Islands is uncertain but evidence from remnant species and vegetation of similar, less modified islands suggests that the original contained *Pisonia grandis* and other native coastal trees including *Thespesia populnea*, *Heritiera littoralis* and *Calophyllum inophyllum* (Hill, 2002). The objective of rehabilitation has been to create habitat for native species, not to recreate pre-human forest.

North Island

Vegetation rehabilitation started in 2001 with the removal of invasive plant species such as *Lantana camara*, planting of native species on the coastal plateaux (including *Terminalia catappa*, *Barringtonia asiatica*, *Heritiera littoralis*) and attempts to rehabilitate vegetation on the hills by planting *Pyrostria bibracteata, Dodonaea viscosa* and other robust native shrubs. By 2017, approximately 60 ha of the coastal plateau was a native-dominated forest with *T. catappa* and *C. inophyllum* being the most abundant species. The establishment of native species on the hills has been slower and more labour intensive with <2 ha restored. The current area of native-dominated woodland is approximately 30% of the island's total surface area.

Denis

In 2001, approximately 20 ha of coconut plantation that was naturally reverting to native forest dominated by *T. catappa*, was cleared of coconuts and planted with native tree species (Hill, 2002). In 2007–2008, 12.5 ha were rehabilitated with the aim of creating habitat for Seychelles paradise-flycatchers (Bristol, et al., 2009). The rehabilitation involved removing coconut, *Nephrolepis biserrata* fern and other introduced weeds and replanting with tree species including *Terminalia catappa*, *C. inophyllum, Thespesia populnea, Cordia subcordata, B. asiatica, Ficus lutea, Guettarda speciosa, Hernandia nymphaeifolia, H. littoralis, Ochrosia oppositifolia, Pandanus balfourii, P. grandis*, *Ficus reflexa, Hibiscus tiliaceus* and *Morinda citrifolia.* In 2013–14, a further 2.5 ha area was cleared of coconut and *Casuarina equisetifolia* and replanted with *C. inophyllum* and *Mimusops sechellarum* and ca. 18 ha of *T. catappa* woodland were weeded. The current area of native-dominated woodland is approximately 40 ha (Bristol, 2014), comprising 29% of the island's total surface area.

Frégate

A small amount of native tree planting was undertaken in the 1990s to benefit Seychelles magpie-robins and, in 1998, the hotel development used mostly native tree species for landscaping. A wilt disease caused by *Fusarium oxysporum* (Boa & Kirendall, 2004) killed all the Sandragon trees on Frégate in the early 2000s. Most of the sandragon forest was on the hills and these areas were replanted with native species, mostly *Ficus reflexa*, *F. lutea*, *Premna serratifolia* and *Tabernaemontana coffeoides*. Some further coastal areas were replanted with *T. catappa* and *Guettarda speciosa*, which has resulted in approximately 30 ha of native-dominated forest, comprising 15% of the island's total surface area. In addition, quite a lot of non-native forest was under-planted with native species but, unfortunately, the habitat rehabilitation is not well documented.

ENDANGERED SPECIES RECOVERY AND INTRODUCTIONS

The eradication of vertebrate predators on three islands with a total area of 560 ha, and associated improvement in forest habitat for native birds, has contributed to the recovery of several endangered bird species by increases in existing populations or by reintroducing populations (Table 3).

North Island

In 2007, 25 Seychelles white-eyes were introduced to North Island from Conception (Rocamora & Henriette-Payet, 2008). The population established and in 2017 was estimated at between 127 and 140 birds using direct census of groups with colour-ringed and unringed birds (Pietersen, 2017).

Denis Island

Four bird species have been introduced; 47 Seychelles fodies were translocated from Frégate in February 2004 (Bristol, 2005), and the current population is estimated at 600 individuals (van de Crommenacker, pers. obs.,

Table 3 Species conservation outcomes – an estimate of the number of endangered birds on rehabilitated private islands.

Species	Frégate Island	North Island	Denis Island	Other populations		Percentage of Seychelles population on Frégate, Denis & North Islands.

Data: Birdlife International, 2017 except: [a] Bristol & Gamatis, 2017; [b] Pietersen, 2017; [c] van de Crommenacker, pers. obs., 2017; [d] Lopera-Doblas, et al., 2015; [e] Gala, 2017; [f] Vega, 2005 ; [g] Rocamora & Henriette, 2015; [h] Rocamora, pers. obs., 2017.

2016) using a grid point count with 58 counting points located every 150 m. Fifty-eight Seychelles warblers were introduced from Cousin in 2004, and the most recent population estimate is 400 individuals (Lopera-Doblas, et al., 2015; van de Crommenacker, pers. obs., 2016). Twenty Seychelles magpie-robins were introduced in June 2008, 16 from Frégate and four from Cousin (Burt, et al., 2016), and the population in June 2017 was 76 individuals, estimated by monitoring colour ringed birds (Bristol & Gamatis, 2017). Twenty-three Seychelles paradise-flycatchers were introduced from La Digue in November 2008 and the population in June 2017 was 84 individuals, surveyed in a direct count Bristol & Gamatis, 2017).

Frégate Island

The population of Seychelles magpie-robin prior to conservation efforts was very small, with as few as 39 in 2000 (Burt, et al., 2016). Habitat for this territorial species was limiting (López-Sepulcre, et al., 2010). Increased habitat area and quality allowed the population to rise to 137 by 2015 (Burt, et al., 2016) and approximately 145 in 2017. This was estimated by an ongoing programme to colour-ring as many birds as possible to allow identification in the field. Then, by searching the whole island for presence of birds and their nest locations, group associations and behaviour, a territory map was constructed along with a status list with the identity of all birds within each territory (van de Crommenacker, pers. obs., 2017). The Seychelles fody population was estimated to have a population of 1,182 using mark and re-sight methods (Vega, 2005).

Frégate was considered suitable to reintroduce Seychelles white-eyes because of the abundant fruiting trees, including the non-native cinnamon (*Cinnamon vernum*). Reintroduction was undertaken between 2001 and 2003, with 37 birds from Conception (Henriette & Rocamora, 2011). The most recent estimate is at least 200 individuals, based on point counts (van de Crommenacker, pers. obs., 2017). The habitat suitability for Seychelles warbler was investigated (Hammers & Richardson, 2011) and found to be suitable. Accordingly, 59 individuals were translocated from Cousin in 2011 (Wright, et al., 2014); the population was estimated to be at least 209 individuals in 2017 (Gala, 2017).

Other species appear to have benefitted from island rehabilitation, including the endemic beetle *Polposipes herculeanus* which showed a dramatic decline between 1995 and 2000, probably due to rat predation, but appears to have subsequently recovered (Lucking & Lucking, 1997; Canning, 2011b).

FACTORS THAT INFLUENCED ISLAND REHABILITATION

The Seychelles endemic birds' crisis in the 1970s and 1980s resulted in interventions by international organisations including the Royal Society for Protection of Birds (RSPB), International Council for Bird Preservation (ICBP), BirdLife International, and the Royal Society for Nature Conservation (RSNC), initially by direct funding and deployment of staff and later through the establishment and support of the local NGOs Nature Seychelles and Island Conservation Society (ICS). The investment, at its height, contributed several hundred thousand British pounds each year, and facilitated the involvement of technical expertise from New Zealand in an advisory role. The potential benefits of rodent eradication for tourism, farming and nature inspired island owners to finance eradications. At the same time a proactive approach was taken by the Seychelles government which wanted to promote eradication programmes and donor funding was available. International funding to help finance eradications and reintroduction operations was obtained by NGOs and Government through Global Environment Facility, Dutch Trust Fund and Fonds Français pour l'Environnement Mondial, among others.

As such, an enabling policy context (where a national biodiversity plan was in place and being implemented), international support, private sector interest, motivators with a "can do" approach, and finance all came together to facilitate change. At the time, the risk of failure in tropical rodent eradications was not estimated (Keitt, et al., 2015), and was therefore not perceived as a constraint.

The results of island rehabilitation, in particular rodent eradications, have not only been sustained but enhanced by hotel businesses who value it as part of their tourism product. Each island has a conservation manager and a small team of conservation staff and volunteers who implement biodiversity monitoring, biosecurity, habitat rehabilitation and education and awareness activities, including activities for hotel guests. These businesses have been able to access funds to support conservation management including directing Corporate Social Responsibility Tax (CSRT) to conservation programmes, donations from clients and paying volunteers. Each island has used independent approaches and methods to sustain this work, and cooperation improved when North Island, Denis Island and Frégate Island began working in partnership with the Green Islands Foundation (GIF), which was established in 2005 with the objective of improving cooperation and conservation work on islands. GIF has been able to assist with coordinating conservation programmes, apply for funds and manage projects on behalf of island conservation programmes and, importantly, act as a representative and advocate at national meetings related to the environment.

Limitations to biodiversity conservation on private islands

Recent years have seen a cessation of rodent eradications and species reintroductions, with no rodent eradications undertaken since 2010 (Rocamora & Henriette, 2015). International partners progressively reduced support to the Seychelles before ceasing funding, mainly due to the reduced threat to endemic birds and Seychelles being no longer considered a low-income country. National policy still supports island rehabilitation and species conservation (Nevill, et al., 2014), but specific actions are not being proactively promoted. Major donors' priorities have shifted and the national project portfolio is dominated by climate change adaptation and energy (Programme Coordination Unit, 2017). In principle, funding is available for island rehabilitation, but it is not being requested by the government.

Very few native animal species that are not birds have been introduced to Frégate, Denis or North Islands. Moreover, predator-free North Island's potential to support populations of endangered species has not yet been realised. One of the reasons is that habitat rehabilitation requires a number of years to produce a canopy-forming forest that is suitable for endemic birds and the forest has only recently become suitable for species such as Seychelles black paradise flycatcher (Bristol, 2017). Moreover, consensus building for species reintroduction takes time and may be influenced by views that are not necessarily evidence-based or pro-conservation.

There are several inner and outer islands with conservation potential for rehabilitation that have not been subject to eradication of invasive predators. For example, the inner island Félicité has potential for rehabilitation (Hill, 2002) and is currently suitable for the reintroduction of Seychelles paradise flycatchers, a species tolerant of rats, (Bristol, 2017) and potentially more endemic species if cats and rodents were eradicated. Several outer islands already have hotels that support conservation programmes run by ICS and four islands are proposed as protected areas (UNDP, 2016). Rodent and cat eradications, if feasible, are likely to be beneficial for seabird populations and other biodiversity and well as tourism (Millett, et al., 2016).

Globally, many island-based businesses have nature orientated tourism, and many islands have undertaken rat eradications. However, comparable examples, whereby tourism businesses have undertaken, often with the support of local NGOs, invasive species eradication, habitat rehabilitation and endangered species reintroductions have not been observed in other island regions such as the Pacific or Caribbean. There may be reasons for this: for example, islands may have complex traditional ownership, species that are conservation priorities may not be suited to smaller islands or eco-tourism may be less valued by tourism sectors in other regions.

CONCLUSION AND RECOMMENDATIONS

The contribution of private islands to national conservation objectives is substantial, with 560 ha of predator-free land on three islands supporting nine populations of five species of globally threatened birds. The self-financing private sector, the enabling role of the Seychelles government and the contribution played by NGOs in facilitation, information exchange and advocacy are important. Whilst the priorities and contributions of international networks and some NGOs have focussed on other areas of work, others, notably GIF and ICS, are still attempting to increase networking and cooperation between these and other islands.

Lessons and recommendations for future work are:

1. Local NGOs should work more closely together and with business to improve knowledge exchange, build capacity, and enhance rehabilitation programmes;
2. Opportunities for the restoration of species on predator-free islands should be taken to the full, notably on North Island;
3. Develop a shared biosecurity facility on Mahé to reduce the risk of invasive species reintroduction;
4. Promote mammal eradications and habitat rehabilitation on suitable inner islands including Félicité, the proposed protected areas in the outer islands of the Seychelles;
5. Government should translate national policies including the NBSAP into implementation plans for species and sites;
6. The allocation of resources for island rehabilitation should be advocated by the government of Seychelles to international donors for large-scale national projects;
7. The approach adopted by Frégate, North and Denis Islands should be promoted as good practice internationally by organisations that facilitate collaboration and information sharing between small island states.

Eradication of invasive animals and other island restoration practices in Seychelles: achievements, challenges and scaling up perspectives

G. Rocamora

Scientific Director & Chair, Island Biodiversity & Conservation Centre, University of Seychelles, Anse Royale Campus, Box 1348, Victoria, Seychelles. <IBC@unisey.ac.sc>.

Abstract In recent decades Seychelles has accumulated extensive experience in the management of invasive species and other island restoration practices. Non-government organisations (NGOs), governmental, parastatal and private stakeholders have conducted successful programmes to control and eradicate invasive animals and plants, particularly on small islands of high biodiversity value. Biosecurity protocols have been implemented to prevent (re)infestations. With at least 50 vertebrate populations (33 mammal, 16 bird and one reptile) from 14 different species successfully eradicated, Seychelles is the third country in the world after Australia and the USA for invasive vertebrate eradications from tropical islands, and the seventh when considering all countries. Twenty-four islands have benefited from invasive vertebrate eradications and other ecosystem restoration processes to create refuges for native biodiversity. About 470 ha of woodland have been rehabilitated through replanting and recovery of native vegetation, and at least 36 successful island translocations of native birds and reptiles have been conducted. This includes 16 conservation introductions or reintroductions of six endemic land birds (all but one threatened), two of a terrapin species and 18 of Aldabra giant tortoises. Recovery of native species and natural recolonisations have occurred on islands where invasive predators have been removed. As a result, four globally threatened endemic land birds have been down-listed in the IUCN Red List and dozens of other native species including seabirds, land birds, reptiles, invertebrates and plants have also benefited. Future challenges include increasing the proportion of the country's land area free of rats and cats from 3.9% to potentially 15.4%, mainly in the outer islands, and 50% in the long term if Aldabra and Cosmoledo are considered. Factors limiting future eradications and translocations are discussed. Alternative conservation approaches such as 'mainland-islands' are recommended for large islands, and the development of partnerships with nature-based tourism is encouraged to help fund further restoration.

Keywords: ecosystem recovery, habitat rehabilitation, invasive birds, invasive mammals, reintroductions, species recovery, species translocations, vegetation restoration

INTRODUCTION

The Republic of Seychelles comprises 115 main islands totalling 445 km^2 of land area within a marine Exclusive Economic Zone of 1,374,000 km^2. These are classified into the 'inner islands' archipelago, of granitic substrate (ca. 45), and the remote, coralline 'outer islands' (c.70) to the south and south-east, that include the Amirantes, Providence-Farquhar and Aldabra groups (Fig 1). Aldabra atoll, a nature reserve and World Heritage Site, represents about one third of the country area.

In recent decades, the restoration of small islands has been an effective conservation tool in Seychelles to create sanctuaries for native biodiversity (Rocamora, 1997; Nevill, 2001; Shah, 2001; Merton, et al., 2002; Shah, 2006; Asconit & ICS, 2010; Rocamora, 2010a; Samways, et al., 2010b; Nevill, 2011). This has been achieved by eradicating or controlling invasive alien predators and competitors. Native habitats have been restored by eliminating invasive alien plants and replanting native vegetation. Globally threatened species of endemic birds and other native wildlife have been translocated to these rehabilitated islands, contributing to their subsequent recovery (Kömdeur & Pels, 2005; Richardson, et al., 2006; Rocamora & Henriette-Payet, 2008; Shah, 2008). This paper updates the inventory of island restoration achievements in Seychelles documented in Rocamora (2015) and discusses future perspectives and challenges. It considers only actions for nature conservation purposes and excludes eradications of invasive species for agricultural (two declared; National Biosecurity Agency, pers. comm. 2017) or public health purposes. Names of islands are the ones normally used by the islanders as listed in the Constitution of Seychelles, with the exception of 'Ile du Nord' also referred to as 'North Island'.

MATERIALS AND METHODS

Rocamora (2015) used information from publications (Beaver & Mougal, 2009; Nevill, 2009), internal reports and newsletters, and unpublished information from personal knowledge, to construct a database recording all attempts made in Seychelles to eradicate vertebrate populations. For each eradication attempt the database records: island name, area, animal species, year(s), methods used, and the final outcome of the overall eradication programme but not to the immediate result of each method employed. This information was checked in 2014 and made consistent with the Database of Island Invasive Species Eradications (DIISE) managed by Island Conservation, to allow comparison of Seychelles' performance in eradication with that of other countries (DIISE, 2017). This information base was updated in 2017. No new eradication attempts have taken place since 2014. One operation formerly classified as control was re-classified as 'eradication' as the target species, the crested-tree lizard (*Calotes versicolor*), was eradicated. The status of the five operations that were ongoing in 2015, and finalised by 2017, was updated.

Rocamora (2015) also gathered information on the area of natural habitat rehabilitated (from reports, or estimates by island owners, managers or conservation staff) as a result of removing invasive plants and propagating and planting native vegetation. He also documented translocations of native species that occurred in Seychelles, i.e. reintroductions to islands where the species was formerly present, 'conservation introductions' to islands outside a species' known historical range (IUCN, 2013), and historical introductions or reintroductions of Aldabra giant tortoises (*Aldabrachelys gigantea*). For each translocation he recorded: species, island, year, type of translocation (reintroduction, conservation introduction), and outcome. He then analysed how island restoration practice has developed in Seychelles, together with nature-

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 588–599. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

based tourism, and how this has benefited the conservation of native biodiversity.

RESULTS

Eradication of introduced predators and competitors: the first step to ecosystem recovery

By September 2017, 68 attempts to eradicate invasive animals had been made on 24 islands. Three of these operations are still in progress (Table 1).

Most island eradications conducted in Seychelles have targeted mammals (44 attempts, 68%) and birds (22 attempts, 29%) on 22 islands of at least 10 ha, plus two mammal eradications on two islets smaller than 1 ha. In five of the 65 completed eradications, species that were not the main target (feral cats and barn owls) also disappeared following the removal of rats and on three occasions island populations of feral goats and chickens died out following control. Of the remaining 55 eradication attempts completed (excluding the two small islets), 40 (72.7%) succeeded and 15 (27.3%) had a failed outcome (i.e. survival or recolonisation before the island could be certified pest-free; see DIISE, 2017). When including the rat eradications on two islets (< 1ha), success rate is 73.7% and failure 26.3% (n=57).

By the end of 2017, 50 alien vertebrate (33 mammal, 16 bird and one reptile) populations had been eradicated from islands in Seychelles. One operation targeting common myna (*Acridotheres tristis*) on Ile du Nord is almost finished and one (the ring-necked parakeet, *Psittacula krameri*, on Mahé) is in the final phase of monitoring. Fig. 2 lists the 14 species of vertebrates eradicated from islands in Seychelles (plus one yet to be confirmed) and gives the outcomes of eradication attempts. Success rates of eradication attempts vary: 33% for house mouse, 56% for common myna, 57% for feral goat, 75% for black rat (*Rattus rattus*) and brown rat (*R. norvegicus*) (excluding the two islets), and 100% for other species.

Domestic pigs (*Sus scrofa*) and cows (*Bos taurus*) were also removed from Cousine and Ile du Nord. These were small numbers: some of the animals were not completely wild and may have still depended on supplementary food from humans, so they were easy to catch, and it is unclear if some of them were reproducing in the wild (Samways, et al., 2010a; Bruce Simpson/North Island Ltd; pers. comm.; Victorin Laboudallon, pers. comm. 2015). Feral cats (*Felis catus*) died out on Picard after the 1970s, with no control or eradication programme involved. These pig, cow and cat cases are not included in the calculations as eradications, but we did include the reported eradication of goats on Aride by shooting before 1920 (Warman & Todd, 1984), the removal of feral goats from the Aldabra atoll islands of Polymnie and Ile Esprit in the 1970s in response to localised control (Nancy Bunbury/SIF, pers. comm.), and the extinction of feral chickens on Desnoeufs in 2007 by local staff for consumption (Roland Nolin, pers. comm.).

The numbers of eradication attempts and success rates have varied over time (Table 2): 73% (over 11 attempts) before 1995, 64% (over 28 attempts) during 1995–2004, and after 2004 up to 89% (over 18 attempts finalised by 2017).

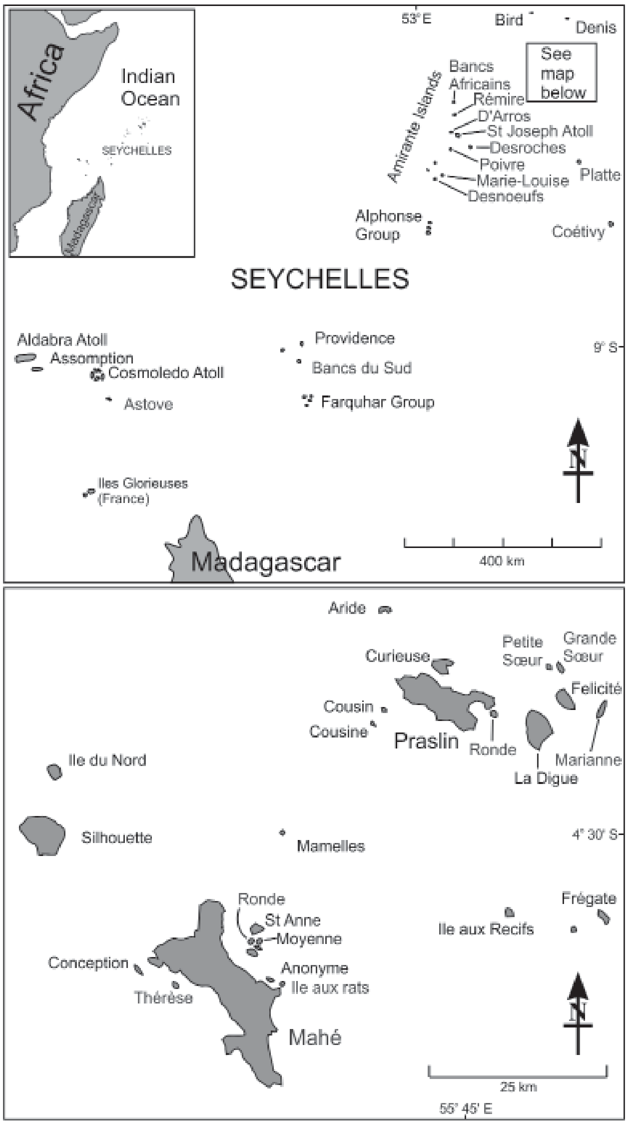

Fig. 1 Islands of the Republic of Seychelles.

Removal of invasive alien plants and replanting native vegetation

Control of invasive plants and habitat rehabilitation has been important for restoring ecosystems and protecting native biodiversity (Table 3). Significant areas (over 60 ha) have been rehabilitated since the 1990s on Praslin (National Park) and Mahé (Morne Seychellois National Park). Most invasive plant control and native species replanting activities have taken place on small and medium sized granitic islands, as part of programmes to restore

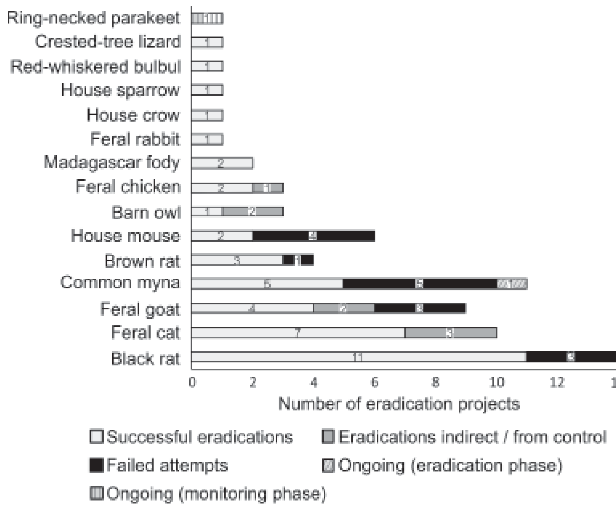

Fig. 2 Number of eradication attempts (n = 68), and success outcomes for the 15 species of invasive vertebrates targeted in Seychelles. Species are listed in increasing order of successful attempts. Success or failure refers to the final outcome of the operations (see text).

Table 1. Attempts to eradicate invasive alien animals from islands in Seychelles. Total number of attempts = 68 (65 completed; 3 in progress). Successful attempts (in **bold**) = 50 (42 direct; + 5 indirect eradications induced by rat removal and 3 from control, in brackets). Success or failure refers to the outcome of the operation. 'Failed' attempts involved animals that either survived or immediately reinvaded after a technically successful eradication phase. Only the active removal of individuals that had established a substantial wild breeding population is considered a genuine eradication attempt. Removal of small numbers of wild or semi-feral domestic animals (cattle, pigs, chickens), or populations of the same that died out naturally are not included here. * = eradications almost finished or in monitoring phase, to be confirmed in 2018. Occ. inc. = occasional incursions. Species and islands are listed in chronological order of their first eradication.

abandoned coconut plantations and lowland coastal forests previously dominated by invasive species.

Habitat rehabilitation was initiated on Aride and Cousin in the 1970s (Warman & Todd, 1984; Kömdeur & Pels, 2005), and since the mid-1990s has been implemented on Frégate, Ile du Nord, Denis, Curieuse, Cousine and Félicité as well as to a minor extent on other granitic islands. Very little vegetation restoration has taken place in the outer islands. On D'Arros, some 11 ha of former coconut plantations have progressively been replaced by plantations of native trees since 2009 (von Brandis, 2012; von Brandis, pers. comm. 2015). On Alphonse and Desroches, since 2006 and 2009 respectively, small areas have been cleared of exotics and replanted. At Aldabra, rehabilitation activities to control sisal (*Agave sisalana*) have taken place since the 1970s on Picard, Polymnie and Ile Michel and, since 2013, to eradicate it (van Dinther, et al., 2015).

In Seychelles, control and clearing of exotic plants has mostly been done physically, using machetes and chainsaws for woody plants, pulling by hand for creepers, and sometimes using heavy machinery, as on Frégate or Ile du Nord. Chemical treatments have rarely been used to eradicate invasive plants, although some trials have been conducted on several islands (Kaiser-Bunbury, et al., 2015). Elimination of coconut trees inland of the beach crest has been done on most of the rehabilitated islands that had, in the past, been exploited as coconut plantations. These have been replaced by forests dominated by native and endemic species, through natural regrowth or replanting.

Although precise figures are not available for all islands, we estimate that at least 220 ha have been actively cleared of alien invasives, replanted with native trees and maintained. This reaches 300 ha when including areas partially restored and ca. 470 ha when including natural recovery of native woodland. Rehabilitated vegetation now covers 17% (405/2,480 ha) of middle-sized and small inner islands, but only a tiny proportion (c.1%) of the country area.

Nurseries were established by successive ministries and associated public authorities responsible for the environment on Mahé and Praslin. On private islands such as Frégate (early 1990s), Ile du Nord (early 2000s) and Félicité (early 2010s), nurseries dedicated to propagating Seychelles native plants and trees have been created. These have successfully multiplied most of the 85 endemic plants of Seychelles and have produced tens of thousands of saplings that have been used in island rehabilitation. Based on the areas rehabilitated at the average density of 1,000 plants/ha normally used in Seychelles (Kueffer & Vos, 2004), we estimate that a minimum of 220,000 native trees have been planted in Seychelles over the last 50 years.

Species translocations to rehabilitated islands

Species translocations to predator-free islands with suitable habitats also contribute to the process of island restoration. Table 4 lists 20 documented translocations of eight rare and threatened species and one common species that have taken place to date on ten rehabilitated islands. This includes six species of Seychelles endemic land birds, one species of reptile and one very rare insect. Ninety percent of these translocations were successful (including nine reintroductions and 10 conservation introductions of rare and threatened species). In addition, a common land bird was successfully transferred to Bird Island (Ile aux Vaches). The two translocations which failed were of Seychelles leaf-insects, *Phyllum bioculatum*, to Conception and of Seychelles white-eyes, *Zosterops*

Translocations of Aldabra giant tortoises (IUCN Red List category ‘Vulnerable’) have been accounted for separately as many are ancient and/or poorly documented (dates uncertain; possible failures not accounted for). After the giant tortoises naturally present on most of the granitic islands had been overexploited and driven to extinction (Fauvel, 1909), 18 successful translocations of Aldabra giant tortoises have taken place. Eight granitic islands have been repopulated since 1850, including Frégate, Curieuse and Cousin where they were reintroduced before 1950, Moyenne (probably in the 1970s), and Ile du Nord, Cousine, Grande Sœur and Silhouette that were last repopulated during the period 1993–2012 (Gerlach, et al., 2013). Aldabra giant tortoises have also been introduced or reintroduced to 10 coralline islands (Bird, Denis, D’Arros, Desroches, Rémire, Alphonse, Farquhar, Providence, Assomption, Cosmoledo) during the past 25–50 years, although some of these populations are small and of uncertain long-term viability (Gerlach, et al., 2013). Four of these translocations were to rat and cat free islands (Cousin, Cousine, Frégate and Bird). The reintroduction of giant tortoises to Aride in 1933–34 is not counted, as the animals were removed in 1951 and brought to Cousin (Warman & Todd, 1984); however, some are planned to be reintroduced from Frégate Island in 2018.

Including the reintroductions of giant tortoises, the total number of successful species translocations between islands in Seychelles is 36.

DISCUSSION

With 50 island populations of invasive vertebrates (of 14 species) eradicated from islands, Seychelles stands as a world leader. In 2014, it was ranking third after Australia and the USA for tropical islands, and seventh when all islands are considered (DIISE, 2017; Rocamora, 2015). Despite more eradication attempts during the period 1995–2004, a lower success rate (64%) was recorded compared to the following decade (89%). This may be a result of improving project selection, field implementation, and post-eradication biosecurity measures to prevent reinvasions.

Global conservation impacts of Seychelles island restoration

Population translocations to islands that have benefited from predator eradications and habitat rehabilitation have improved the conservation status of endemic species threatened with global extinction in Seychelles (Henriette, 2011; Nevill, 2011; Russell, et al., 2016). Island restoration has allowed 17 successful reintroductions or conservation introductions of eight rare and threatened species and the down-listing of four globally threatened birds on the IUCN Red List: the Seychelles warbler (*Acrocephalus sechellensis*) from Critically Endangered to Near Threatened; the Seychelles magpie-robin (*Copsychus sechellarum*) and Seychelles white-eye (*Zosterops modestus*) from Critically Endangered to Endangered and Vulnerable respectively; and the Seychelles fody (*Foudia sechellarum*) from Vulnerable to Near Threatened. The Seychelles black paradise flycatcher (*Terpsiphone corvina*), which was transferred to Denis Island, is still considered Critically Endangered. The Aldabra giant tortoise (Vulnerable) has also benefited from 18 successful translocations (Gerlach, et al., 2013).

Ecosystem recovery

The recovery of native fauna and flora on rehabilitated islands where introduced predators and competitors have been eradicated has already been observed on many islands around the world (Mulder, et al., 2011; Veitch, et al., 2011; Russell & Holmes, 2015). This is also occurring in Seychelles, where monitoring of birds, reptiles, invertebrates and plants has been undertaken and casual observations collected (Rocamora & Henriette, 2015). After the eradication of introduced predators and competitors, some species that had become inconspicuous started to reappear (e.g. giant millipedes *Sechelleptus sechellarum* and endemic snails *Stylodonta unidendata* on Conception; Galman, 2011). Five species of seabirds (*Ardenna pacifica, Gygis alba, Anous tenuirostris, Phaethon lepturus* and *Sula dactylatra*) have (re)established nine new breeding populations on seven rehabilitated islands. Populations that already existed have increased, as observed on most other islands where invasive mammals have been eradicated around the world (Brooke, et al., 2017). Reptiles and land birds have typically shown increasing or stable trends and some (e.g. Seychelles blue pigeon *Alectroenas pulcherrima*, common moorhen *Gallinula chloropus*) have recolonised islands, whereas invertebrates showed mixed responses, including strong decreases for some groups. This is probably linked to the increase in native land birds, reptiles and large invertebrates that had previously been preyed upon by rats and cats (Galman, 2011). As part of a global study to demonstrate the impact of mammal eradications on native wildlife (Jones, et al., 2016), 67 populations of 26 native vertebrates (13 land birds, eight seabirds, five reptiles) were identified as having benefited from these operations in Seychelles (Rocamora & Henriette, 2015). This illustrates how important it is to undertake ecosystem monitoring before and after eradications to measure and understand the ecological changes that occur on islands under rehabilitation.

The reintroduction of giant tortoises, which dominated the terrestrial ecosystems of Seychelles for millions of years, is an essential step in the island restoration process. These animals fill an important (but still poorly known) role in the ecosystem by dispersing and promoting the germination of seeds, fertilising native plants, and influencing soil invertebrate communities through their dung. These mega-herbivores are used as ecological analogues to replace extinct tortoises and help restore island ecosystems in Mauritius and Rodrigues (Griffiths, et al., 2010; Hansen, et al., 2010; Griffiths, 2014). The (re)introduction of Seychelles white-eyes (Rocamora & Henriette-Payet, 2008), which disseminate many native berry-producing trees, also contributes to the restoration process. Future challenges include a more integrated 'ecosystem approach', aiming at rehabilitating entire habitats and communities (including invertebrates), rather than focusing only on 'flagship' threatened species (Asconit & ICS, 2010; Kaiser-Bunbury, et al., 2010; Galman, 2011).

Seabirds play a critical role in ecosystem recovery as they boost soil nutrients thereby assisting the development of the ground microfauna (Mulder, et al., 2011). Seabird recolonisation can be slow, although decoys and sound recordings to attract passing adults can speed this process (Jones & Kress, 2012). In Seychelles, this has only been done for the sooty tern (*Onychoprion fuscatus*) on Denis Island, with little success (Feare, et al., 2015). Seabird translocations may also be tried in future in Seychelles; this technique has been employed successfully in the Pacific (Kappes & Jones, 2014) and is being trialled in Mauritius (Carl Jones & Nik Cole, pers. comm., 2016).

Scaling up eradication projects and increasing the rat and cat free area of Seychelles to create more biodiversity refuges

Since the 1970s, ecosystem restoration has taken place on 25 small and medium sized islands of Seychelles (i.e. < 2,000 ha; see Fig. 2). As a result, island refuges for native biodiversity and particularly for rare species threatened with extinction have multiplied. This process was started on NGO-owned islands in the 1970s, then followed on government and privately-owned islands, the public trust Seychelles Island Foundation and more recently on government islands managed by the parastatal Island Development Company and associated partners (private hotel/villa owners and the Island Conservation Society).

With about 30 small and medium-sized islands free of rats and cats (see Table 5), Seychelles probably has proportionally more territory (3.9%) free of invasive predatory mammals than most island countries. Rats and cats have been removed from 11 islands larger than 10 ha. Between 1996 and 2011, the number of islands of ≥10 ha free of rats has increased from four (Aride, Cousin, Cousine, Ile aux Récifs) to 12, and the total rat-free area of Seychelles has more than tripled from 581 ha to 1,757 ha (Fig. 3).

Nevertheless, there is scope for more eradications to benefit both wildlife and humans. This would require scaling up the size of islands tackled for eradications. Rats

and cats could be removed from another 22 islands with currently available techniques (Table 6). This includes five more granitic (inner) islands, plus three small islands in the Ste Anne group which would require a permanent grid of rat bait stations owing to their proximity to other infested islands.

The outer islands have greater restoration potential, with 14 islands where rats (and cats) could be eradicated. However, reinvasion may be difficult to prevent through strict biosecurity on three of the larger islands (Coëtivy, Assomption, Desroches) depending on future developments envisaged. The maximum potential area that could be cleared of rats and cats is currently ca. 7,000 ha or 15.4% of the total area of the country (see Fig. 3 for inner and outer islands totals). Clearing rats and cats from these additional 19–22 islands would open huge possibilities for ecosystem rehabilitation and population recovery of many species (land birds, seabirds, reptiles, amphibians, invertebrates and plants). The eradication of rats from Aldabra and Cosmoledo (Menai Island) atolls, which have large extensions of mangroves, is not considered currently feasible. However, this may change if new techniques become available in future, in which case up to half (49.7%) of the country area could be made rat and cat free in the long term.

Eradication operations should now be extended to invertebrates such as invasive ants, moths or snails that also have a high negative impact on native biodiversity.

However, the ability to apply permanent biosecurity protocols will be critical for these islands to retain their pest free status. In the low-lying coralline outer islands, options for translocation of native species may be limited by sea-level rise in future decades.

Developing partnerships associating nature-based tourism to fund ecosystem restoration

Seychelles provides some examples of collaborations between private island owners, parastatals, government agencies and NGOs to achieve successful control or eradication of invasive species and to develop ecosystem rehabilitation programmes (Asconit & ICS, 2010; Government of Seychelles, 2011; Kueffer, et al., 2013). By creating synergies, such partnerships can speed-up the long-term process of ecosystem rehabilitation, and can help meet the financial, technical and ecological challenges of these complex operations (Rocamora, 2010a). Many islands are engaged in tourism activities that can help

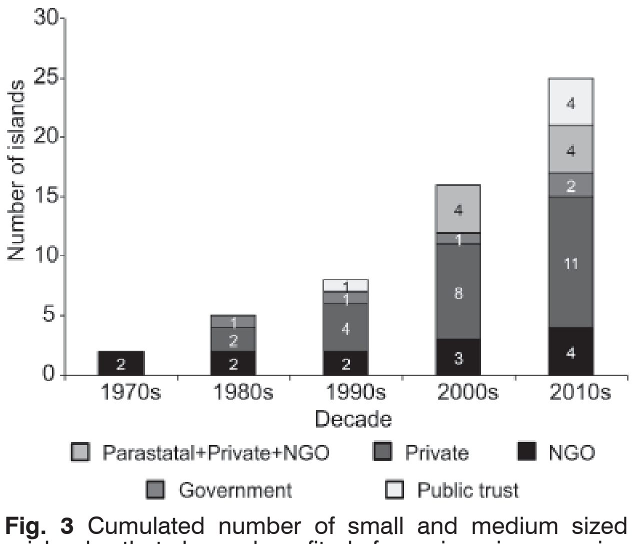

Fig. 3 Cumulated number of small and medium sized islands that have benefited from invasive species management and other forms of ecological restoration in Seychelles since the 1970s, and type of management.

conservation funding (Rocamora & Payet 2002; Nevill, 2004; Skerrett, 2010). The successful record of Seychelles in invasive species management and ecological restoration of many small islands is attributable, at least in part, to the fact that these operations can make economic sense for private owners or investors wishing to generate revenue through ecotourism operations. High densities of rats are incompatible with tourism, and eradication and biosecurity procedures are more cost-effective than long-term pest control. The progressive rehabilitation of an island ecosystem to recreate a wildlife sanctuary with its original fauna can be marketed as an attraction (Rocamora, 2010b; Samways, et al., 2010a). The development of partnerships associating sustainable nature-based tourism with funding ecosystem restoration must be strongly encouraged.

Perspectives and challenges in invasive species management and restoration

The creation of island refuges where invasive species management enables the (re)introduction of species that cannot survive in the presence of invasive predators has proven to be extremely effective in improving the conservation status of various species, including endemic birds of Seychelles that had come very close to global extinction. However, several factors limit the further development of this strategy.

Availability of additional islands suitable for restoration and preservation

Although Seychelles still has considerable potential to increase its area free of alien predatory mammals, the number of islands where such operations can be conducted is limited. In the inner islands, there are currently five to eight islands left which could be made, and kept, free of rats and cats. Most of these have actual or planned development projects or do not presently fulfil the required strict biosecurity conditions to prevent reinvasion.

Challenges to eradicate rats from larger islands in a humid, tropical climate

Techniques currently available to eradicate rats are more successful in temperate and sub-Antarctic climates than in tropical environments, particularly humid ones (Russell & Holmes, 2015). Here, rains (that can seriously affect the attractiveness and palatability of rat pellets) and abundant natural food (which reduces the likelihood that rats will eat the bait) can be present for much of the year (Varnham, 2010; Keitt, et al., 2015). Whereas rats (*Rattus rattus* and *R. norvegicus)* have been eradicated from islands of over 10,000 ha outside of the tropics, the largest tropical eradication of black rats to date is Cayo Centro, Chinchorro Bank (539 ha, Mexico) and for brown rats Frégate Island (219 ha, Seychelles) (DIISE, 2017).

Mangroves are also a limiting factor and the main obstacle to a large-scale rat eradication on Aldabra atoll (15,380 ha; c.1,300 ha of mangroves). Although small areas of mangroves can be dealt with by placing bait stations or tying rodenticide blocks to trees (Samaniego-Herrera, et al., 2015; Samaniego-Herrera, et al., 2017), using 'collars' or 'bolas' (Harper, et al., 2015; Rocamora & Henriette, 2015), efficient methods to eradicate rats from large tropical islands are not yet sufficiently well developed (Russell & Holmes, 2015).

Rat eradications may prove challenging on large islands with high densities of coconut trees, where nuts provide abundant food for rats both in the trees and on the ground, (Climo & Rocamora, 2006). This requires bait to be available at high densities and for a long-time period. Unpredictable rainfall and the year-round high primary productivity of Seychelles ecosystems add further challenges to conducting rat eradications. Abundance of bait-eating crabs can also cause problems (Griffiths, et al., 2011; Wegmann, et al., 2011; Keitt, et al., 2015) but this has not so far been a major problem in Seychelles.

Suitable habitats on restored islands non-existent or too limited for some species

Some rare and threatened species require very specific habitats that may not be found on small to medium sized islands. Examples include the Critically Endangered Seychelles sheath-tailed bat (*Coleura seychellensis*) and the Vulnerable Seychelles swiftlet (*Aerodramus elaphrus*), both of which occur only on the larger granitic islands, breeding in caves and feeding on flying insects. Such limitations also apply to endemic plants and animals (reptiles, amphibians, invertebrates) found exclusively at altitudes above 300–400 m on Mahé and Silhouette where much of the terrestrial diversity of Seychelles is concentrated (Senterre, et al., 2013). Most of these species would probably not survive on the low-lying small islands, where climatic conditions differ from the more humid and colder high altitudes. Some species may also require large expanses of specific habitats that could not be made available on small islands, such as the Vulnerable Seychelles black parrot (*Coracopsis barklii*), which requires extents of palm-dominated forests (Rocamora & Laboudallon, 2013).

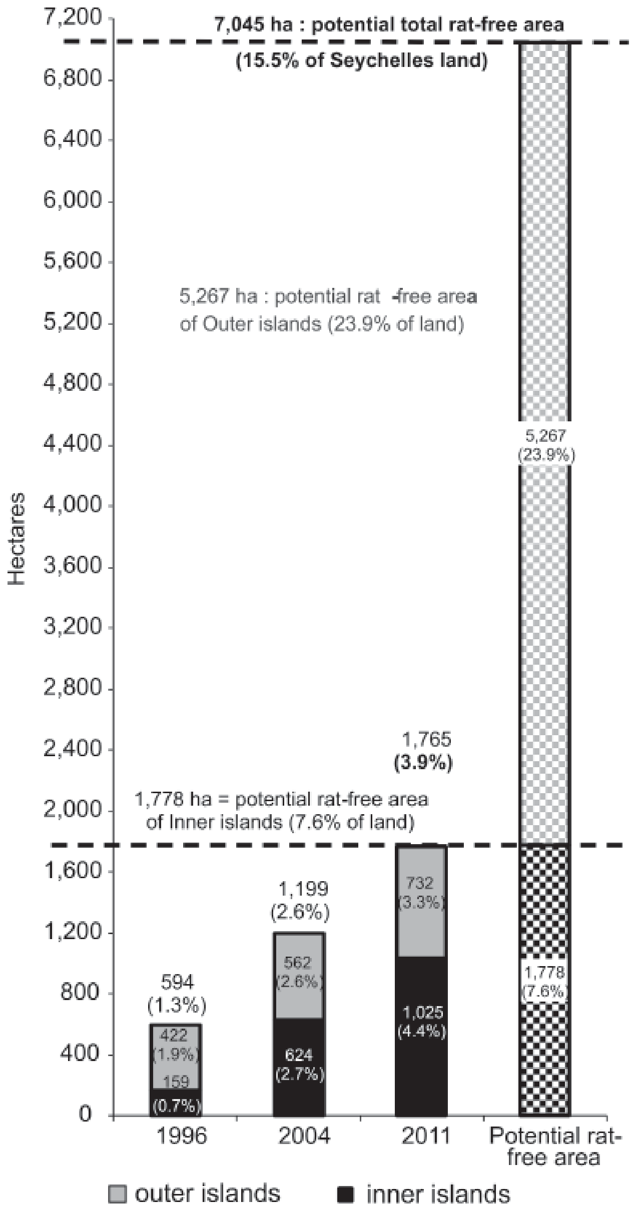

Fig. 4 Time progression of the rat and cat free area in the inner islands, the outer islands and the whole of Seychelles (reported in hectares and as % of the land surface). The total land surface that could potentially be freed of rats and cats with currently available techniques is also indicated.

Increased interspecific interactions on small islands with multiple (re)introductions

The number of species that can coexist on a given island is limited by the quality and diversity of habitats available on the island (MacArthur & Wilson,1967), which is influenced by island area and characteristics. The survival of any small newly (re)introduced population will depend on interactions with the species already there (Blondel, 1979). This factor may partly account for the failed translocation of Seychelles leaf insects to Conception Island, many of which were preyed on shortly after their release (Galman, 2011). On Cousine Island (26 ha), the 23 Seychelles white-eyes translocated in 2008 established a small breeding population, but predation of nests and fledglings and high adult mortality did not allow this population to grow despite considerable efforts. Young fledglings had to be caged and fed through the mesh by adults as they were repeatedly preyed on by another introduced species, the Seychelles magpie-robin (Rocamora, 2013). Such problems were not observed after the introduction of white-eyes to two larger islands, Ile du Nord (201 ha), and Frégate (219 ha) where a large population of Seychelles magpie-robins was present. This suggests a limit to the number of (re) introduced species that a small island can host. In other words, it will become more difficult to 'squeeze in' new species into small rehabilitated islands as their ecosystems become increasingly saturated.

The need for alternative conservation approaches on large islands

In Seychelles, the availability of many small islands suitable for rehabilitation, and the presence of private island owners willing to develop ecotourism has favoured the *in situ* approach. In other countries, such as Mauritius or New Zealand, more intensive and costly *ex situ* techniques, which require the additional step of readapting the captive reared animals into the wild, have also been used (Jones & Merton, 2012). In view of the limitations of the 'small island restoration' model, ecosystem restoration programmes may be developed on the large islands of Seychelles through the creation of "mainland islands" where invasive species are controlled or excluded to enable native species to thrive, as in New Zealand, Australia and Hawaii (Innes & Saunders, 2011). Predator control and habitat rehabilitation programmes are being developed at large scales in Mauritius and La Réunion for the conservation of threatened land birds (Vikash Tatayah & Marc Salamolard, pers. comm., 2016). Similar operations could be conducted in selected priority sites on the largest granitic islands of Seychelles. Innovative management techniques such as predator-proof fences, self-resetting traps, more effective or target-specific bait, etc. will be key to success. The only Seychelles example to date is permanent rat control using grids of bait-stations at the main breeding areas of the Endangered Seychelles white-eye on Mahé (25–40 ha) since 2006 (Rocamora & Henriette, 2015). More such projects could bring some of the rarest birds of Seychelles, now restricted to remote small island sanctuaries, back to the main islands where they once lived. By providing better access to these species and native wildlife in general, such 'mainland islands' would benefit environmental education programmes for the public and school children. This in turn would increase awareness of, and hopefully support for, pest management programmes.

CONCLUSION

Seychelles' achievements with invasive species management and other island restoration practices are remarkable. This includes a minimum of 50 island eradications of invasive vertebrate populations, the rehabilitation of ca. 470 ha of natural habitats, and at least 36 successful island translocations of native species. The rehabilitation of small and medium sized islands has made possible the down-listing of four globally threatened land birds in the IUCN Red List and the recovery of many other native animals and plants.

Scaling up the size of islands for eradications is now required in Seychelles. Factors limiting rat eradication on larger islands include high densities of coconut trees and the presence of mangroves, especially on Aldabra atoll. Invasive predators such as rat and cats could be eradicated from 19–22 more islands with existing techniques, mainly in the outer (coralline) islands. As a result, the proportion of the country's land area free of rats and cats would increase from 3.9% to 15.4%, but new techniques will be needed to remove rats from Aldabra and bring this proportion to 50%. Making half of Seychelles rat and cat free by 2030–2050 could be a commitment made by Seychelles government and the main stakeholders involved as part of the Honolulu Challenge on Invasive Alien Species, launched at the 2016 IUCN Word Conservation Congress in Hawaii.

Eradication operations need to be extended to invertebrates such as invasive ants, moths or snails that also have a high negative impact on native biodiversity. Apart from the availability of islands free of invasive predators, limiting factors to further translocations of rare and threatened species include lack of suitable habitats and increased interspecific interactions on small islands with multiple (re)introductions. Because of global warming and sea-level rise, the long-term relevance of island restoration and species translocations to outer low-lying coralline islands is questioned.

Local partnerships and financial support from nature-based tourism have been key to past successes. We recommend for these to be enhanced and alternative conservation approaches such as 'mainland-islands' be developed on large islands. Most importantly, biosecurity protocols will be critical to prevent (re)invasion of invasive species, as lack of vigilance and poor biosecurity could undo so much of what has already been achieved.

ACKNOWLEDGEMENTS

I wish to thank J.P. Siblet (MNHN), J.Y. Kernel (Biotope), and A. Grieserjohns (Project Coordinating Unit UNDP-GEF-Government of Seychelles) for authorising the publication of updated figures and modified short text sections initially published in Rocamora & Henriette (2015), the English of which had been reviewed by Jeanne Mortimer (IBC centre of UniSey) Two anonymous referees reviewed the manuscript and provided much appreciated fruitful comments and improvements.

Abstract Invasive alien species represent one of the greatest threats to native plants and animals on islands. Rats (*Rattus* spp.) have invaded most of the world's oceanic islands, causing lasting or irreversible damage to ecosystems and biodiversity. To counter this threat, techniques to eradicate invasive rats from islands have been developed and applied across the globe. Eradication of alien rats from large or complex island ecosystems has only been successful with the use of bait containing a rodenticide. While effective at eradicating rats from islands, rodenticide can persist in the ecosystem longer than the time required to eradicate the target rat population and can potentially harm non-target species. However, the persistence of rodenticides in ecosystems following rat eradication campaigns is poorly understood, though predictions can be made based on the chemical properties of the rodenticide and the environment it is applied in. Brodifacoum, a relatively persistent second-generation anticoagulant, was used to successfully eradicate rats from Palmyra Atoll. With this study, we evaluated the persistence of brodifacoum residues in terrestrial and marine species at Palmyra Atoll (Northern Line Islands) three years after rat eradication. We collected 44 pooled samples containing 121 individuals of the following: mullet (*Moolgarda engeli*), cockroaches (*Periplaneta* sp.), geckos (*Lepidodactylus lugubris*), hermit crabs (*Coenobita perlatus*), and fiddler crabs (*Uca tetragonon*). Despite detection of brodifacoum residue in all five of the species sampled in this study 60 days after the application of bait to Palmyra Atoll in 2011, brodifacoum residue was not found in any of the pooled samples collected three years after bait application. Our study demonstrates how brodifacoum residues are unlikely to persist in the marine and terrestrial food web, in a wet tropical environment, three years after rat eradication.

Keywords: aerial rodenticide broadcast, best practice, brodifacoum anticoagulant rodenticide, land crabs, *Rattus rattus*, risk assessment, tropical island

INTRODUCTION

Invasive alien species represent a key threat to native plants and animals on islands (Tershy, et al., 2015). In particular, invasive rodents are known to have widespread negative impacts following introduction to islands (Towns, et al., 2006), and rodents have been introduced to most of the world's island groups (Atkinson, 1985). In prior decades, techniques to eradicate invasive rodents from islands have been developed and applied across the globe, most using anticoagulant rodenticides (Howald, et al., 2007). Demonstrable conservation benefits are common following successful eradication (Jones, et al., 2016; Brooke, et al., 2017).

To date, rat (*Rattus* spp.) eradications on tropical islands experience a lower success rate than those in temperate regions (Russell & Holmes, 2015). Lack of seasonality and warm temperatures in tropical latitudes can provide year-round breeding opportunities and a consistent abundance of alternative food sources that rodents may choose instead of the offered bait. Tropical regions also host land crab populations which readily compete with rats for bait (Wegmann, et al., 2011; Holmes, et al., 2015). In 2011, Palmyra was the site of a successful eradication of *R. rattus* (US Fish and Wildlife Service, 2011). The planning and implementation of the rat eradication required novel techniques, including direct baiting of the tree canopy, and two aerial broadcast applications, each at rates of 75 and 85 kg/ha, of bait containing brodifacoum (0.0025%) (Wegmann, et al., 2012). Ecotoxicology monitoring undertaken during and after the project detected residual brodifacoum in soil, water and biota (Pitt, et al., 2015). Sampling ceased 60 days after the bait application before undetectable levels of brodifacoum were reached (Pitt, et al., 2015). Resources to continue the monitoring were not secured until three years after the bait application for rat eradication, providing the opportunity to investigate longer-term persistence of brodifacoum within the Palmyra food web.

METHODS

Study site and animals

Palmyra Atoll (5°53' N, 162°05' W) is located at the northern end of the Line Islands in the Central Pacific Ocean. Palmyra is a wet atoll containing approximately 235 ha of emergent land primarily covered in thick rainforest. The atoll is an incorporated, unorganised territory of the United States that is managed in partnership by The Nature Conservancy (TNC) and the US Fish and Wildlife Service (USFWS). TNC's preserve includes Cooper/Menge (94.3 ha) and Barren (4.6 ha) islands. Most of the remaining emergent land is owned and managed by USFWS as Palmyra Atoll National Wildlife Refuge, which includes all marine habitats to 12 nm offshore.

Palmyra's islets support a regional flora that is typical of Central Pacific wet forests (Wester, 1985). Heavily influenced by the Intertropical Convergence Zone, Palmyra receives an average of 450 cm of rain each year. Palmyra is a refuge for 11 species of seabirds and is home to a robust community of land crabs comprised of nine species. Black rats (*Rattus rattus*) were inadvertently brought to Palmyra during WWII. In 2011, Palmyra's rat population was eradicated through two strategic applications of compressed-grain bait containing the second-generation anticoagulant rodenticide, brodifacoum, at 0.0025% (25 ppm) (Wegmann, et al., 2012). Pitt et al. (2015) collected and analysed fifty-one animal samples representing 15 species of birds, fish, reptiles, and invertebrates for brodifacoum residue out to 60 days after the initial bait application.

Environmental monitoring methodology

We followed the sampling methods outlined in Pitt et al. (2015) to assess brodifacoum residue concentrations three years after bait application in cockroaches

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 600–603. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

(*Periplaneta* sp.), fiddler crabs (*Uca tetragonon*), hermit crabs (*Coenobita perlatus*), and geckos (*Lepidodactylus lugubris*). Limited time and resource restrictions did not allow sampling of black-spot sergeant fish (*Abudefduf sordidus*) or ants, as undertaken in 2011; however, we harvested mullet (*Moolgarda engeli*)), which were opportunistically collected as carcasses in 2011 following the eradication and their tissues were found to contain brodifacoum (Pitt, et al., 2015). All biological samples were collected at Palmyra Atoll between 4 and 19 June 2014. Biological samples were frozen immediately after collection.

Sampling site selection (Fig. 1) was determined by ease of access to the target species. All emergent land at Palmyra has relatively similar characteristics and vegetation and was treated with the same baiting prescription during the 2011 eradication campaign. We therefore assumed that site location would not be an influential factor in brodifacoum residue concentrations three years after bait was applied. Biological samples were collected at least 500 m from The Nature Conservancy's research station where rodenticide bait is maintained in bait stations for biosecurity when planes and ships arrive.

All biological samples were collected with gloved-hands and segregated in sterile sample bags. Captured hermit crabs were placed in a freezer (-4 C) for 24 hours and then removed from their gastropod shells and stored in sterile sample bags. Mullet were collected by dip-nets and fence-nets from several shoreline locations around Palmyra's central lagoon. Geckos and cockroaches were captured at night from the leaves of *Scaevola taccada* shrubs, and fiddler crabs were collected from lagoon flats at low tide. American Veterinarian Medical Association guidelines for euthanasia were followed with all collections. All samples were pooled (Table 1) to increase probability of detecting brodifacoum within the funding limits of this project and to ensure minimum amounts of sample material were provided for analysis (e.g. cockroach samples required two individuals to achieve the 2 g minimum for brodifacoum residue analysis). Samples were shipped frozen to US Department of Agriculture's National Wildlife Research Center (NWRC) in Fort Collins, Colorado, for brodifacoum residue analysis. Samples were prepared and analysed according to methods established by USDA NWRC for detection of brodifacoum in animal tissue, and these methods, as well as the laboratory conducting the analyses, were the same as those used in Pitt et al. (2015). Same-species pooled carcasses' samples were homogenised for analysis.

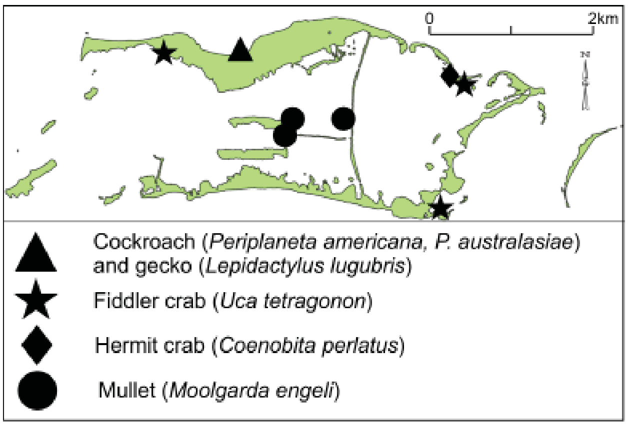

Fig. 1 Locations of sample collections that were used to investigate persistence of residual brodifacoum three years after the implementation of the 2011 eradication of rats from Palmyra Atoll.

Brodifacoum residue analysis methodology

The whole bodies of geckos and fish were homogenised. Cockroaches (whole bodies), as well as fiddler crabs and hermit crabs were homogenised in a liquid nitrogen freezer mill and 0.25 g of homogenate was placed into 25 ml glass tubes for further extraction and analysis following methods of Pitt, et al. (2015). Aliquots (0.5 g) of each homogenised gecko and fish sample were placed in MARS vessels for microwave extraction (Pitt, et al., 2015). Samples were clarified by centrifugation prior to HPLC analysis.

Brodifacoum analyses were performed with Agilent 1100 and 1200 HPLC systems (Pitt, et al., 2015). Brodifacoum concentrations were determined from the peak area ratio of brodifacoum to surrogate in each extracted sample and were compared to the average peak area ratio from replicate injections of a working standard. Samples with analytical concentrations above the linear range were re-diluted into the linear region.

RESULTS

We collected 44 pooled samples containing 121 total individuals (Table 1). Brodifacoum residues were not detected (detection levels reported in Table 1) in any of the pooled samples of mullet, geckos, cockroaches, hermit crabs, or fiddler crabs.

DISCUSSION

Ecotoxicology monitoring is uncommon for rodent eradication projects using rodenticides, but future projects are dependent on the collective knowledge gained from toxicological monitoring efforts. The Palmyra rat eradication used substantially higher rodenticide application rates compared to other rodenticide-based rodent eradication projects on islands and provided a unique opportunity to follow residue persistence in the environment over time. Brodifacoum residues were detected in soil, water and biota up to 60 days after the first aerial broadcast application (Pitt, et al., 2015) but were no longer detectable in the range of biota studied three years later, indicating rodenticides break down in this ecosystem over time. Resource availability did not allow complete repetition of the 2011 sampling, thus we chose to sample animals with known residue concentrations, as this had the most biologically useful outcome for management.

The use of second generation anticoagulant rodenticides can pose significant risks to non-target species (Howald, et al., 2007), particularly birds and mammals. However, knowledge gaps exist, particularly for taxa less sensitive to rodenticides, such as reptiles and invertebrates (Hoare & Hare, 2006). The distribution and longevity of rodenticide residue within a food web will be a function of rodenticide properties and how it is applied, environmental

Table 1 Biological samples analysed in 2014 for brodifacoum residue analysis following the 2011 eradication of rats from Palmyra Atoll. "Pooled" represents the number of individuals contained in each sample; "MLOD" is the mean level of brodifacoum detection.

Organism	Samples analysed	Pooled	MLOD (µg/g)
Mullet	9	2–3	0.013
Gecko	5	5	0.011
Cockroach	15	1–2	0.011
Hermit crab	5	3	0.0057
Fiddler crab	10	3	0.0057

compartments it ultimately resides within (e.g. soil, animals), open pathways to transfer residue (e.g. scavenger consumption of poisoned carcasses), and exposure to environmental conditions (e.g. temperature, precipitation, ultraviolet radiation, and fungi) that impact its persistence. Ultimately, the breakdown of rodenticides is believed to be accelerated in soil rich in organic matter with healthy populations of microbiological organisms. Different island ecosystems can be expected to have different timescales of residue longevity, and we expect our results will transfer most closely to other wet tropical atolls and low islands, rather than dry and/or temperate island environments.

Rodenticides are known to temporarily infiltrate the food web when undertaking rat eradications as happened with the Palmyra rat eradication. Brodifacoum residues were found in ocean water, soil, and marine and terrestrial biota within 60 days of the initial baiting, indicating diverse food web integration (Pitt, et al., 2015). Other studies document brodifacoum residues in various compartments of the food web after brodifacoum bait was applied to eradicate rats from islands (e.g. Dowding, et al., 1999; Masuda, et al., 2014; Masuda, et al., 2015; Pitt, et al., 2015; Siers, et al., 2015; Rueda, et al., 2016; Shiels, et al., 2017). Although few studies include long-term (>1 year) sampling for residues after brodifacoum application, there are three recent studies that report residues in animals two years (Rueda, et al., 2016), three years (Siers, et al., 2015), and four years (Shiels, et al., 2017) post-application. Brodifacoum persisted in lava lizards (*Microlophus duncanensis*) in the Galápagos Islands for 2.1 years (Rueda, et al., 2016), where liver residue levels were <0.200 μg/g (mean level of detection [MLOD] = 0.010 μg/g). On Wake Island in the Pacific Ocean, three years after rat eradication (Siers, et al., 2015), two out of 69 fish samples had detectable levels of brodifacoum in their livers, with concentrations 0.0038 μg/g and 0.0086 μg/g (MLOD = 0.0035 μg/g); the two fish were caught within an intermittently land-locked pond. Finally, on Desecheo Island, Puerto Rico, detectable levels of brodifacoum were found in seven animal samples (three endemic lizards, two black rats, one forest bird, and one cockroach sample [18 individuals]) four years after bait application (Shiels, et al., 2017). The range of brodifacoum residues in these seven samples was 0.027-0.134 μg/g (MLOD = 0.0054-0.012 μg/g, depending on species. Desecheo, Wake, and the Galápagos islands receive less rainfall than Palmyra (e.g. Desecheo = 1,020 mm/yr, Wake = 906 mm/yr; Pinzon, Galápagos = <1,100 mm/yr; Palmyra = 3,500 mm/yr), and this may contribute to the lack of detectable levels of brodifacoum in the Palmyra food web three years after bait application. We hypothesise that warmer and wetter environments, and soils with more diverse microbiological communities support microbiological processes breaking down residues faster. This remains an important research avenue, including decomposition experiments in a laboratory setting.

Undertaking eradications of invasive species from islands should only proceed where expected benefits outweigh expected costs (Broome, et al., 2014), including consideration of the environmental impacts of the method used (Empson & Miskelly, 1999). Potential non-target impacts were anticipated as part of the environmental impact assessment for the Palmyra rat eradication, but the decision to proceed was based on negative impacts ceasing shortly after the bait application and positive benefits accruing over a longer time-span (US Fish and Wildlife Service, 2011). Immediately following bait application, brodifacoum residues were detected within multiple levels of the food web, and were attributed to mortality of birds, fish, and crabs (Pitt, et al.., 2015). Our results show undetectable levels of residue three years later, suggesting this short-term impact is no longer present. Longer-term changes to native species populations following the removal of rat impacts are emerging, including increased seedling recruitment of several native tree species and the non-native coconut palm (*Cocos nucifera*), the elimination of a non-native mammal-biting mosquito population (*Aedes albopictus*), as well as the discovery of two new-to-Palmyra land crab species (*Geograpsus grayi* and *Ocypode cordimanus*). These short and long-term changes are consistent with management expectations, and the rat eradication has proven to be a baseline restoration activity to advance natural resource management goals.

ACKNOWLEDGEMENTS

The authors thank Coral Wolf (Island Conservation), Eric VanderWerf (Pacific Rim Conservation), Stacie Hathaway (US Geological Survey), and Marie Hellen (Simon Frasier University) for assistance with sample collection. We also thank the staff of The Nature Conservancy's Palmyra Program for operational support. This study was funded by a grant from the Packard Foundation. The field activities and sample collections were authorised under permit number 12533-14033 by the Palmyra Atoll National Wildlife Refuge, U.S. Fish and Wildlife Service, Department of the Interior.

'Island' eradication within large landscapes: the remove and protect model

P. Bell, H. Nathan and N. Mulgan

Zero Invasive Predators Ltd, 39 Waiapu Road, Karori, Wellington 6012, New Zealand <phil@zip.org.nz>.

Abstract New Zealand has been the world leader in the eradication of invasive mammalian predators from offshore islands. Today, the focus for invasive predator management is shifting to larger landscapes; big inhabited islands or the mainland itself. The most cost-effective approach in the long term will be to eradicate the predators from those areas, ensuring permanent freedom for vulnerable and threatened native biodiversity to recover or be reintroduced. Island eradication technologies cannot always be employed on the mainland (e.g. aerial brodifacoum), so a new approach is required. Zero Invasive Predators Ltd (ZIP) is a not-for-profit research and development entity, established in New Zealand through public, private, and philanthropic funding, to pioneer a novel predator management model for landscape-scale application – a model known as 'Remove and Protect'. ZIP is developing the tools and technologies to both enable the complete removal of rats, possums, and stoats from large areas of mainland New Zealand, and then protect those areas from reinvasion. Among the innovations being tested is the 'virtual barrier', essentially converting large peninsulas into islands without the use of traditional predator fencing (which is expensive and impractical in some terrain); and a 'minimal infrastructure' detection system for automated early warning of any predator incursions. We review the transformative predator management model ZIP is developing and how it could help to pave the way towards large-scale predator-free landscapes.

Keywords: detection, invasive predators, mainland, *Rattus*, response, *Trichosurus vulpecula*, virtual barrier, 1080

INTRODUCTION / CONTEXT

New Zealand is a global biodiversity hotspot (Myers, et al., 2000), yet more than 3,000 native taxa are threatened or at risk of extinction (Hitchmough, 2013). It is generally agreed that there are three mammalian predator species that cause most of the ecological damage in New Zealand: possums (*Trichosurus vulpecula*), ship rats (*Rattus rattus*), and stoats (*Mustela erminea*) (Brown, et al., 2015). From here on, the term 'predators' refers to these three species plus Norway rats (*Rattus norvegicus*). The house mouse (*Mus musculus*) is specifically excluded as a predator in the context of this paper and is not a target species for ZIP. Aside from the estimated 25 million native birds they kill each year (Russell, et al., 2015), predators cost New Zealand hundreds of millions of dollars annually, both in terms of revenue lost and in control costs (Clout, 2011), and they impact the country's primary production base through the transmission of diseases such as bovine tuberculosis (Coleman & Caley, 2000).

New Zealand has an impressive track record in the eradication of invasive mammalian predators from offshore islands for the protection of native biodiversity. Since the first successful eradication in 1964 (Towns & Broome, 2003), 134 islands have been completely freed from invasive mammals (Parkes, et al., 2017a). Although costs vary widely from island to island, the initial eradication cost is in the order of NZ$300/ha (Parkes et al., 2017b); and the ongoing biosecurity surveillance costs of these islands typically ranges from NZ$17 to NZ$160/ha per annum (New Zealand Department of Conservation (DOC) unpublished data, 2017). These costs *exclude* incursion response. For example, the stoat incursion response on Kapiti Island in 2010–2011 cost approximately NZ$600,000 (NZ$305/ha) (King, et al., 2014). These predator-free islands are considered to be the 'jewels' of the conservation crown; however, they represent only 58,921 ha, or <0.01% of the land area of New Zealand (Parkes, et al., 2017a).

For most of the New Zealand mainland, where restricting the reinvasion of predators is currently not possible, the management model used is the ongoing suppression of predator populations. Currently the main tool used by the major predator management agencies (DOC, TB Free New Zealand, Regional Councils) for large scale (up to 100,000 ha) predator control is repeated pulsing of aerially applied sodium fluoroacetate (1080) toxin, typically every three to five years (Brown, et al., 2015; Elliott & Kemp, 2016). The current annualised cost of this is approximately NZ$10/ha (Brown, et al., 2015). The benefits of this technique are of limited duration without ongoing sustained control, because not all individuals are removed from the treatment area, and immigration is uncontrolled so predator populations are able to recover (Griffiths & Barron, 2016).

The alternative, ground-based predator control methods rely on either a knockdown of the resident predator population, followed by ongoing suppression to low levels, or seasonal control to realise biodiversity benefits (e.g. for the native bird breeding period). This work is relatively labour intensive (via trapping or toxins in bait stations) and is presently undertaken over areas of up to 50,000 ha (e.g. Murchison mountains stoat trapping; Hegg, et al., 2013). The current annualised cost of this work is in the order of NZ$25 to NZ$60/ha depending on the scale and intensity of the control efforts and target predator species (Brown, et al., 2015).

Predator exclusion fencing, a physical mesh fence with a solid steel capping, is also used to recreate eradication-like conditions on the mainland (colloquially, New Zealand's North and South Islands) by providing a physical barrier to halt reinvasion (Burns, et al., 2012). Predator fencing is scale-limited by terrain and cost, with the cost of recently constructed fences ranging from NZ$253–NZ$461/linear metre (Curnow & Kerr, 2017), with ongoing maintenance costs estimated to be 4% of capital costs per annum for the life of the fence (Norbury, et al., 2014), and eradication costs additional. Debate continues on the ecological, social and financial return on investment for predator fencing (Scofield, et al., 2011; Scofield & Cullen, 2012; Innes, et al., 2012; Norbury, et al., 2014).

To dramatically improve the status of New Zealand's biodiversity, a step change is required in the ability to manage predators, and the cost of doing so. The New Zealand Government has declared the goal of a predator-free New Zealand by 2050 (Cabinet, 2016). In order to

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 604–610. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

achieve this ambitious goal, the country will need to heed the call of The Royal Society of New Zealand (2014), for urgent action to develop novel approaches and to improve existing tools to protect the country's environment and economy.

Remove and protect model

One novel approach being investigated is the 'remove and protect' model, entailing complete removal of predators from an area and then protection against reinvasion. In essence, this creates permanent 'island' eradications within large landscapes of the New Zealand mainland. A research and development entity, Zero Invasive Predators Ltd (ZIP; founded in 2015), has been established with the purpose of developing the 'toolbox' to enable this model.

The remove and protect model involves three streams of research and development:

Initial removal of target predators

The most common and most successful technique for island eradication has been the aerial application of the toxin brodifacoum (Howald, et al., 2007; Parkes, et al., 2011). However, the use of this technology in New Zealand is governed by a Code of Practice (Epro Ltd. 2006) that limits its current use to offshore islands and stock-free areas of the mainland behind predator fences – preventing its immediate application in the remove and protect model. As a result, eradicating predators on the New Zealand mainland will likely require new techniques to be developed or novel refinement of the application of existing tools – refer to Case Study 1 for one such example.

Defending a line to protect against reinvasion

Implementing a campaign of the scale of predator-free New Zealand by 2050 (Cabinet, 2016) will require the ability to divide the country up into manageable land parcels for progressive removal operations. Predator fencing has allowed small areas to be treated as 'islands' on the mainland but has limited application because of rugged terrain and/or social acceptance (Clapperton & Day, 2001; Burns, et al., 2012). Dividing up the country will require additional approaches; the creation of a virtual barrier is one such approach – refer to Case Study 2.

Detecting and removing invaders before they significantly impact on the predator-free area

Traditionally, in the island eradication context, biosecurity surveillance consists of intensive networks of passive devices to find individual invaders (Russell, et al., 2008). In order to ensure the remove and protect model is scalable, and to protect any significant predator-free investment, there is a need to develop a minimal infrastructure detection system that can facilitate timely incursion response before significant ecological damage is incurred – refer to Case Study 3 for detection concepts being explored.

Changing the cost model

Eradication is the most cost-effective methodology for predator management (Pascal, et al., 2008), so long as long-term biosecurity costs are manageable, as the upfront costs of removal only need to be found once. However, on the mainland, where reinvasion into management sites is typically not controllable, the most cost-efficient technique at present is to aim for predator suppression over as large a land area as affordable, in the knowledge that it will need to be repeated *ad infinitum* to maintain the gains achieved. In New Zealand, where a relatively modest budget for predator control (given the scale of the issue at hand) is largely static year-on-year, the cyclical pattern of suppression means that only a limited land area can be managed and that cannot expand without increased investment.

The remove and protect model seeks to change that cost structure. By treating blocks of land like island eradications, i.e. removing all predators and managing reinvasion to zero, those gains can be secured, and the predator management programme can be expanded to treat new land areas. Due to the greater expected biodiversity outcomes derived from complete predator absence in the long term (Ismar, et al., 2014; Towns, et al., 2016), i.e. a larger ecological return on investment, the initial management costs can be greater than those currently afforded for suppression, especially as they are a one off cost. However, for this cost structure to be feasible, the remove and protect model must achieve similar cost profiles to those of island or fenced sanctuary eradications in both the removal and maintenance phases. The initial targets ZIP is currently working to are: initial predator removal costs of NZ$100/ha (cf. NZ$300/ha for island eradications; Parkes, 2017b); NZ$200/m for installation of a virtual barrier (cf. NZ$253−NZ$461/m for predator fencing; Curnow & Kerr, 2017); and NZ$50/ha/annum for detection and response (cf., for example, NZ$160/ha per annum for biosecurity surveillance on Ulva Island; DOC unpublished data, 2017). All costs exclude Goods and Services Tax (GST).

A focussed approach: Zero Invasive Predators Ltd (ZIP)

The opportunity to establish a public-philanthropic partnership presented itself when the NEXT Foundation approached DOC to invest in 'transformative change' for conservation. In what is a first for DOC, the decision was made to 'spin out' of Government and establish ZIP as a limited liability company (with NEXT Foundation as the sole shareholder). Founded in 2015, the intention was that ZIP would be tightly focussed on the core challenge of developing a new model for predator management; the equivalent of taking a specialist research and development unit and sheltering it from the rest of a business until the problem is 'solved'. It was further considered that freedom from Government would provide the best environment in which to remain agile and innovative.

While ZIP has a business structure, it does not have commercial motives. Any self-generated Intellectual Property is held for New Zealand, effectively making it openly available to those in New Zealand who want to use or build upon it. The founding constitution confirms this 'not for profit' stance, with any products to be sold at the most accessible price point in New Zealand (while reserving the right to profit from international sales), with any profit to be reinvested in conservation, rather than returned as a dividend to shareholders. ZIP is also recognised as a Registered Charity by the Charities Commission (the governing body in NZ). This charitable status has aided in securing further philanthropic investment (beyond NEXT Foundation) as donations, which are tax deductible in New Zealand.

Some of the high-level goals of ZIP, such as removal of possums and a reduced reliance on cyclic toxin applications, have also attracted support from New Zealand dairy companies, who share those intentions (F. Eggleton, Fonterra Co-operative Group, pers. comm). This support includes non-shareholding investment in the research and development programme, thereby further enhancing the unique public-philanthropic-private investment positioning of ZIP.

Operating culture – try, sense, respond

Ecological systems are usually complex and therefore the development approach of ZIP is to 'try, sense, and respond'. Potential solutions are suggested, techniques and tools are rapid-prototyped and placed in the field as soon as possible, impacts are measured, and prototypes are refined as soon as required. The 'try, sense, respond' approach allows rapid learning about real world constraints, which in turn informs the next iteration of development and testing.

This operating style aims to recognise failure quickly, to expose what we don't know, and to maximise the return on effort and resources. Supporting this 'fast fail' approach, field trials of prototypes typically begin at small scale, i.e. less than five units, in the expectation that limitations will be exposed and the prototype redesigned. Once the prototype shows sufficient promise, the trial is scaled-up in stages, going from, for example, 50 to 100 units, then many hundreds of units, etc. to test if the statistical performance holds as the scale increases. Alternatively, if the prototype fails catastrophically at the small scale, and no practicable alternatives are found, the trial is shut down to minimise loss of investment.

This operating culture is strengthened by a diverse, highly-skilled team, purpose-built for research and development. Scientists and engineers co-design field trials and technologies, field rangers actively test prototypes, with timely data analysis by a specialist modeller. Input from all aspects of the team feeds into each step of the development process, enabling rapid evolution of the project. All team members spend time at the field site(s) to remain grounded in the challenge.

Development in the field

ZIP, under permission from DOC (the land manager), has established a 391 ha forested site at Bottle Rock Peninsula, Queen Charlotte Sound, Marlborough (41°06'30" S, 174°14'06" E) dedicated to field trialling the remove and protect system, and its component prototype parts. Remove and protect is well suited to peninsulas as they are easier to defend, with only one major exposed front (with the sea 'protecting' the remainder). Interception efforts can then be concentrated within a relatively small zone to protect a much larger area.

Bottle Rock Peninsula was selected as it offered the ideal initial size for rats and possums, and was a favourable shape (2 km narrow neck with a bulbous peninsula). Importantly, this peninsula is not a site of high biodiversity priority for DOC (unpublished data, 2015), therefore it is able to be manipulated without risk to vulnerable native species. However, it does enable a 'real world' assessment of new or modified technologies. [NB: the majority of the field trials carried out at Bottle Rock to date have excluded stoats on account of their home range size, mobility, and our current lack of sensitive detection devices rendering robust stoat research impracticable.]

Evaluation of the performance of the remove and defend model at Bottle Rock Peninsula uses a 'systems design' approach (Cabrera, et al., 2008), assessing the whole, as opposed to a reductionist approach which seeks to understand the role of the individual elements to explain the utility of the system. The goal is to prove the system works, not just some parts of it, hence multiple tools need to be tested simultaneously in the defence system. Individual considerations are secondary and are investigated by 'switching off' components to specifically test their relative impact on the system's performance.

REMOVE AND PROTECT CASE STUDIES

Case study 1: Removal – '1080 to Zero'

It is expected that an aerially applied tool will be required for the initial removal of predators at large-scale implementation sites. Some of the early work developing techniques for island eradications investigated sodium fluoroacetate (1080) as an option (McFadden & Towns, 1991; Moors, 1985). However, it was subsequently discounted because of its acute toxicity and the perception that some individuals of the target populations could detect it in the bait and avoid it (McFadden & Towns, 1991). There has been significant improvement since that work, namely prefeeding to increase toxicant uptake (Nugent, et al., 2011) and manufacturing quality control (Nugent, et al., 2010; Nugent, et al., 2012). Extensive use in suppression operations has refined aerial 1080 use, but those operations still do not remove all target individuals (Elliott & Kemp, 2016).

ZIP sought to test whether dual aerial 1080 operations, each using different bait (to overcome learnt aversion; Ross, et al., 2000) and coupled with multiple prefeed applications, could completely remove rats and possums. Success was deemed to be functional extinction. The thresholds for achieving functional extinction were set at ≤1 possum per 400 ha (OSPRI, 2014); and ≤1 rat per 100 ha (Innes, et al., 2011).

The trial was carried out on a 1,600 ha area (39°15'30" S, 174°07'45" E) on the north-eastern slope of Mt Taranaki. A 400 ha core, set back with a 1 km buffer to minimise reinvasion compromising the results (Griffiths & Barron, 2016), was intensively monitored for surviving rats and possums after treatment with toxin. The trial excluded stoats due to the scale being insufficient to account for stoat home range size and mobility (Murphy & Dowding, 1994; Murphy & Dowding, 1995).

Prior to commencing the trial, monitoring (using peanut-butter filled chew cards, self-manufactured using corflute supplied by Pest Control Research and Pic's peanut butter – Picot Productions Ltd) was deployed three times for between two and 10 nights using between 36 and 55 cards each time. The cards were placed every 50 metres on 2–3 randomly selected lines (of between 1.6 and 2 km in length) within the 400 ha core. The purpose of this monitoring was not to measure a relative abundance, but merely to confirm presence of target animals. 98% of total cards deployed were chewed by rats, 6% of total cards deployed were chewed by possums.

The first phase of baiting consisted of multiple prefeed baiting of non-toxic RS5, 6 g, cinnamon-masked cereal pellets (manufactured by Orillion, formerly Animal Control Products) applied by helicopter-slung bait-spreading bucket – at (on-ground application rates of) 4 kg/ha; 2 kg/ha (20 days later); 1 kg/ha (21 days later); 1 kg/ha (47 days later). Application of (on-ground rate) 4 kg/ha of RS5, 6 g, 0.15% 1080, cinnamon-masked cereal pellets (Orillion) followed 21 days later. Bait was flown with a 50% swath overlap, as per island eradication best practice (Broome, et al., 2014), to ensure no gaps in bait coverage. Baiting was intended to be completed in winter, when 1080 has been shown to be most effective (Veltman & Pinder, 2001; Gillies, et al., 2003); but adverse weather resulted in the toxin being applied on 1 December 2016.

In an effort to detect survivors, 835 chew cards were deployed on a 50 m × 100 m grid throughout the 400 ha core four nights after the toxin application, and checked every eight days, for a total of 42 days. In addition, 421 pre-weathered tracking tunnels installed on a 100 m × 100 m grid were baited 17 days into the detection period and maintained live until the same 42-day period post-toxin application had passed. Furthermore, 80 motion-activated cameras (Little Acorn, LTL5200 and LTL5300) were deployed in a 100 m × 100 m grid in the north-eastern corner of the ZIP block for the final 17 nights of the detection period to validate the performance of the other detection devices.

Functional extinction of possums was considered to be achieved, with only one possum detection (chew card) recorded across 36,430 detection nights across all applicable detection devices (chew cards and cameras). The same was not achieved for rats, with 42 detections (two chew cards; 25 tracking tunnels; 15 camera detections) recorded over 46,755 detection nights.

In light of the numbers of surviving rats, we attempted to individually test them for any learnt bait aversion (rather than undertake the second phase of toxic aerial baiting). Research by Morgan (2004) suggested that cereal pellets cannot overcome aversion if created by cereal pellets in the first place; however, that study did not include prefeeding. Morgan, in the same work, states that 'learnt food safety' (i.e. learnt through prefeeding) is a very strong behaviour once established. Ross et al. (2000) achieved 30% mortality in captive 1080 bait-shy possums when 'postfed' with cereal (compared with 0% of non-postfed possums). We sought to determine whether it is possible, in the wild, to overcome any bait aversion in the surviving rats through prefeeding with the different bait, even if it is cereal.

The 1,600 ha trial area was prefeed-baited twice, using non-toxic Wanganui #7, 6g, double orange-masked cereal pellets (Orillion) from a helicopter-slung bait-spreading bucket, seven days apart (58 and 65 days after the first toxin application). McGregor live-capture traps were set in areas of known detections and baited with a single Wanganui #7 0.15% 1080 6g double orange-masked cereal pellet (Orillion). Traps were baited in such a way that the rat had to interfere with the pellet to trigger the trap. Traps were in place for 270 trap nights across various detection sites.

Thirteen rats were caught that were deemed to be survivors based on the weight:age profile (Bentley & Taylor, 1965); animals that were very likely to have been present when the initial toxin application was carried out. Of those, six were found dead in the trap (following consumption of a lethal dose of the bait), while an additional two were alive but showed clear signs of toxicosis with bait consumed (with death expected). The remaining five animals were all alive and were subsequently euthanised. While those rats found alive suggest some level of aversion, the trap itself may have contributed to the aversion once triggered, or alternatively they may have received a sub-lethal dose and did not return to the bait. It is expected that some rats did not encounter the live capture traps or chose to avoid them (and the bait within).

If the second aerial toxic baiting had been carried out, the total cost of the novel prescription (including all prefeed and toxic baiting applications) is estimated at approximately NZ$90/ha, excluding costs associated with gaining regulatory approvals. There is potential for this cost to reduce further with economies of scale and reduced prefeed applications.

ZIP retested the hypothesis in a trial on the West Coast of the South Island during the second half of 2017. After the first phase of baiting (two prefeed applications, and one toxin application using Wanganui #7 0.15% 1080 6g double orange-masked cereal pellet (Orillion)), zero rats and possums were detected over 83,410 detection nights across 55 days post-toxin application (unpublished data). The trial was deemed a success, and ended here.

Case study 2: Protect – the 'virtual barrier'

The virtual barrier is a system that aims to exclude 99% of rats, and 95% of possums that attempt to enter a protected area. The virtual barrier being tested across the 2 km neck at Bottle Rock Peninsula consists of multiple defence lines, 100 m apart, comprising kill (for rats) and live capture (for possums) traps only, with no toxins currently deployed in the system. Devices are placed at high intensity along each defence line, one every 10 m, based on the assumption that this spacing would 'guarantee' no animals could breach the barrier without encountering a device, i.e. if the target animal is on the ground it is never more than five metres from a device as it passes through a line. Whether they choose to interact with that device is another matter entirely!

Possums

The most effective virtual barrier for possums tested to date consisted of four lines of leg hold traps (PCR #1, Pest Control Research) running across the peninsula and a 400 m long line of leg hold traps running along the central, prominent ridge through the barrier. The leg hold traps are set in a custom-made platform raised 1.2 metres above the ground (to avoid non-target captures of weka, *Gallirallus australis*, a ground dwelling endemic rail). The traps are visually lured with a plain white corflute card (Connovation Ltd) nailed to the tree approximately 30 cm above the platform. Each platform has a wooden ramp attached, at 60° to the horizontal. In addition to preventing weka access, alternating trials by ZIP have shown that ramps improve trap effectiveness by 18% (95% C.I. [2.5%, 29%]) compared with non-ramped traps.

Traditionally, live-capture leg hold traps must be physically inspected by the trapper every day in order to comply with New Zealand animal welfare legislation. ZIP has developed an automated, remote reporting system that uses a magnetically switched trap transmitter to advise that a trap has been sprung, via a 433 MHz 'daisy chain' and the Iridium satellite network. To date (May 2017), the remote reporting system has been in service for more than 580,000 trap nights and has remotely reported over 500 possum captures – there has not been a single false negative in this time. In conjunction, the NZ Ministry for Primary Industries has developed industry guidelines to allow the automated reporting of live-capture traps, while conforming to animal welfare standards as required by law (MPI, 2016). This innovation has reduced the labour cost of servicing the traps by 95%, with only sprung traps needing to be checked by the trapper.

During the period from 26 November 2016 to 17 May 2017, the virtual barrier caught 127 possums, with at least 11 possums breaching the barrier; i.e. 8% 'leakage' (95% confidence interval, [4%, 14%]). Leakage was determined from the number of possums killed in the protected area (beyond the barrier), using leg hold traps, set up as per the barrier, but placed on a one per 50 ha density, divided by the total number that attempted to breach the barrier (number killed in the barrier plus number killed beyond it). In addition, a detection network of 554 chew cards (self-filled as described in the removal case study), serviced every three weeks, confirms the ongoing absence or presence of possums in the protected area. On average, approximately 18 possums/month attempted to cross the 2 km wide barrier, with 1.5 possums/month succeeding. Improvements to the system have been identified, and therefore future versions of the barrier are expected to approach the target of ≤ 5% leakage.

Ship rats

The current virtual rat barrier at Bottle Rock consists of six lines of 'Tun200s' (two DOC200 single action stainless steel kill traps (CMI Springs), in custom built 'run-through tunnel' wooden trap box). The wooden tunnels have a 72 mm diameter entrance hole and 265 mm long tunnel leading to the kill plates from both ends, to avoid non-target captures of weka which cannot fit inside the entrance hole nor stretch out to reach the traps themselves (currently <1 kill every 35,000 trap nights).

From 26 June to 26 October 2015, the virtual barrier caught 160 ship rats, with at least nine rats breaching the barrier; i.e. 5% leakage (95% confidence interval, [2.5%, 10%]). Leakage was estimated as described for possums in the previous section (e.g. number of rats killed on 100 m x 60 m grid of single-set DOC150 kill traps (CMI Springs) in 'standard' wooden boxes, placed throughout the peninsula beyond the barrier), in conjunction with the detection network of chew cards (as described above for possums) confirming the absence or presence of rats in the protected area. On average, approximately 40 ship rats/month attempted to cross the 2 km wide barrier, with two rats per month succeeding. All Tun200 traps were lured with peanut butter (Goodnature Ltd) during this period. We found no evidence to suggest that the effectiveness of identically lured, multiple lines of Tun200 traps declined with repeated presentation (effectiveness 40%, 95% C.I [33%, 46%], for all Tun200 lines treated as samples from the same population, that is irrespective of the line placement).

A variety of alternative food lures have subsequently been trialled including Nutella (Ferrero Australia Pty Ltd), Colby cheese (Mainland Ltd), milk chocolate (J.H. Whittaker and Sons Ltd), and peanut butter (Goodnature Ltd, and Pic's - Picot Productions Ltd). These lures performed similarly and intercepted on average 36% (95% C.I. [33%, 39%]) of rats, as measured by the percentage of rats that breached each line.

Costs of the barrier

Including the cost of track cutting and installation, the current capital cost of a multiple line, ship rat and possum virtual barrier at Bottle Rock Peninsula is approximately NZ$250/m (excl. GST). This cost is for a 20-year life, and includes device replacement, remote reporting system, and an automated lure dispenser (in development to further reduce labour costs).

The annual operating cost is approximately NZ$20/m (8% of capital cost).

Case study 3: Detection – a 'minimal infrastructure' system

Ship rats

Considerable effort has gone into understanding the exploratory behaviour of invading rats in predator-free spaces, with substantial individual variation identified in the roaming behaviour (Russell, et al., 2005; Russell, et al., 2008; Russell, et al., 2010; Innes, et al., 2011). Not unexpectedly, the majority of this work has been focussed on the individual, as current biosecurity detection systems are tailored towards intensively targeting the individual invader.

ZIP is conceptualising an alternative approach that looks beyond the individual, and rather focusses on the emergent population (if it happens). So long as the incursion events are infrequent, if the invading rat is alone and non-pregnant, then the scale of their individual impact is expected to be small and impacts only begin to have significance once a new population emerges (Norbury, et al., 2015; Elliott & Kemp, 2016). This is the point of intervention ZIP proposes to target.

Targeting the first generation (Generation One) of a pregnant female provides up to 11 individuals, 10 juveniles plus mother (Innes, 2005) to trigger detection devices, rather than the sole invader, greatly increasing the chances of interaction. Furthermore, the anticipated dispersal footprint of Generation One is likely to lend itself to a minimal infrastructure network spacing (perhaps one detection device every 20 ha, based on emerging data from ZIP trials such as that below). This network could be further tailored to be predominantly coastal and waterway biased, to maximise the probability of encounter. In addition, we estimate that we could have up to 100 days to detect and remove the first generation of invaders, before those juveniles reach sexual maturity and begin breeding themselves (based on reproductive biology; Innes, 2005). Conversely, this approach will require bigger treatment areas to remove the entire emerging population. The response could well be aerially based, rather than the ground-based responses traditionally deployed for island incursions.

A ZIP field trial is currently underway (during the drafting of this paper) at the confluence of the Jackson and Arawhata Rivers, South Westland (44°03'00" S, 168°43'32" E) whereby a mother ship rat and her offspring have been released into an area of very low rat abundance to observe their dispersal footprint. Early indications, based on the distance between release point and subsequent trap capture points, are that some individual offspring dispersed at least 650 m from the natal den location by the time they were 86 days old.

If the concept works, the capital cost of installing this system today would be NZ$20/ha. The annual surveillance cost would be NZ$4/ha (using an automated reporting kill trap as the 'sentinel' detection device), with an annual response cost of NZ$5/ha (assuming a leakage rate of 0.5%).

Possums

Possums, once isolated, roam over considerable ranges, in the order of 50–100 ha (Sweetapple & Nugent, 2009; OSPRI, 2014), presumably looking for other possums. If possum incursions are infrequent, their slow breeding rates (Cowan, 2005) and curiosity (Carey et al., 1997) suggest that delayed detection and response may be all that is necessary to prevent possum re-establishment.

ZIP is currently trialling a minimal 'lethal detection' network for possums at Bottle Rock Peninsula. Six leg-hold traps, deployed as in the virtual barrier (excluding ramp) but spaced at approximately one per 50 ha, have been established beyond the virtual barrier. In the 12 months since its deployment, this network has prevented possum reestablishment; with 17 possums caught to June 2017 (and no sustained detections on the 'background' chew card network, as described in case study 2). The capital cost of installing this system today would be NZ$10/ha, with a current operating cost of detection and response of approximately NZ$5/ha/annum.

Automated reporting system

To support these minimal infrastructure detection networks, development of an automated system for near real-time updates on the status of remove and protect sites is continuing. ZIP has already developed the ability to use daisy chain communication for short range data transmission, e.g. trap lines in a barrier setting. However, a landscape scale network will require a different transmission technology – one that can transmit reliably over large distances, in rugged or forested terrain (Jones, et al., 2015). Recent advances in the international telecommunications industry are seeing the emergence of low powered, long range radio technology (LoRa). A small number of sensitive receiving stations allows the use of many battery-powered transmitters across a landscape. LoRa, used in combination with satellite-based communications, is likely to be the platform technology on which to build an incursion notification system for these remote networks.

CONCLUSION

The New Zealand Government has announced the goal of being predator-free by 2050. Momentum is building on this goal, with the Predator Free 2050 Ltd company established with a board of directors to guide strategic investment into projects of significance (Anon., 2016). While New Zealand has an internationally enviable track record in island eradications and developed the predator fenced sanctuary approach, these methodologies cannot be scaled on the mainland.

It is widely acknowledged that new technologies, along with a shift in operating model and cost structure, will be required to completely eradicate predators from the mainland. Such a shift from the suppression paradigm could utilise the remove and protect model, where peninsulas are able to be converted into 'islands' for eradication operations. Zero Invasive Predators (ZIP), a not-for-profit research and development company founded in 2015, is helping to develop the techniques required to enable this model on the mainland.

Further trials are underway to use a novel prescription of dual aerial 1080 operations to drive initial removal at a cost of less than NZ$100/ha (with no more than two prefeed applications per toxin application). In-forest capability exists now to intercept over 95% of all rats and possums using a virtual barrier at a capital cost of approximately NZ$250/m and an annual operating cost of less than NZ$40/m. The initial testing of a minimal infrastructure detection system shows promising signs of success. Large social strides are still required to make predator-free New Zealand a reality, but the first tentative technical steps are being taken now.

ACKNOWLEDGEMENTS

The authors, and wider ZIP team, would like to thank all of our investors for their support (financial and otherwise). Thank you to the DOC Sounds team for their support of the work being undertaken at Bottle Rock Peninsula. The DOC Taranaki team were monumental in helping with the '1080 to Zero' and 'Generation One' trials on the Mounga – thank you. The Generation One rat release trial was approved by the Lincoln University Animal Ethics Committee and conducted under approval #2016-09. Thanks to James Russell for guidance on the structure and concept behind this paper. Al Bramley and Charlotte Bell (and two anonymous reviewers) provided many useful comments on earlier versions of this manuscript, which greatly improved this paper.

Multi island, multi invasive species eradication in French Polynesia demonstrates economies of scale

R. Griffiths[1], S. Cranwell[2], D. Derand[2], T. Ghestemme[3], D. Will[4], J. Zito[4], T. Hall[4], M. Pott[4] and G. Coulston[5]

[1]Island Conservation, Warkworth, New Zealand. <rgriffiths@islandconservation.org>. [2]BirdLife International, Pacific Secretariat, Fiji. [3]Société d'Ornithologie de Polynésie, Tahiti, French Polynesia. [4]Island Conservation, Santa Cruz, CA, USA. [5]Good Wood Aotearoa Ltd, Whangarei, New Zealand.

Abstract Eradication of invasive vertebrates on islands has proven to be one of the most effective returns on investment for biodiversity conservation. To recover populations of the critically endangered Polynesian ground dove (*Gallicolumba erythroptera*), the endangered white-throated storm-petrel (*Nesofregetta fuliginosa*), the endangered Tuamotu sandpiper (*Prosobonia cancellata*) as well as other native plant and animal species, a project was undertaken to eradicate five species of invasive alien vertebrates: Pacific rat (*Rattus exulans*), ship rat (*R. rattus*), feral cat (*Felis catus*), rabbit (*Oryctolagus cuniculus*) and goat (*Capra hircus*), on six islands spanning 320 km of open ocean in the Tuamotu and Gambier Archipelagos of French Polynesia. Using a ship to deliver supplies and equipment, a helicopter for offloading and bait application, and ground teams for follow up trapping and hunting, invasive vertebrates were successfully removed from five of the six islands. Pacific rats survived at one site. The project was planned and executed by a partnership consisting of international and local conservation NGO's, working together with local communities. Combining the different eradication operations into one expedition added complexity to project planning and implementation and increased the risk of the operation failing on any one island but generated greater returns on investment allowing six islands to be targeted at significantly less cost than if each island had been completed individually. An extensive and thorough planning effort, effective relationships with local stakeholders and communities, a good operational strategy and a partnership of stakeholders that each brought complementary capacities to the project contributed to its success.

Keywords: cat, conservation, goat, rabbit, rat, restoration, threatened species recovery

INTRODUCTION

The removal of alien species from islands, especially invasive vertebrates, offers one of the best returns on investment for the protection of indigenous biodiversity (Donlan & Wilcox, 2008; Genovesi, 2011). There is now a growing list of island species no longer regarded as endangered because a key invasive species threat has been lifted (Russell, et al., 2016). The San Nicolas island night lizard (*Xantusia riversiana*) (Rice & Clark, 2016), the Seychelles magpie robin (*Copsychus sechellarum*) (Burt, et al., 2016) and the northern tuatara (*Sphenodon punctatus*) (Towns, et al., 2016) are just three examples of the many species whose threat status has been downgraded to a more secure category as a consequence (IUCN, 2010).

Eradication projects can be expensive (Simberloff, 2002). The remote nature of many islands and the necessity to target every individual within a population requires extensive planning effort, meticulous execution (Cromarty, et al., 2002) and resourcing that often exceeds the means of a single organisation. For many island nations, eradication projects are simply unaffordable and for some projects, the cost may exceed the annual environmental expenditure of an entire country.

French Polynesia is an overseas collectivity (political unit) of the French Republic. It is composed of 118 geographically dispersed islands and atolls scattered over an expanse of more than 5,030,000 km^2 in the South Pacific Ocean. Like many other tropical island archipelagos, French Polynesia is biologically rich and its remoteness has led its flora and fauna to be characterised by high levels of endemism (Gillespie, et al., 2008; Meyer & Butaud, 2009). Sixty three percent of its plants and 72% of its birds are found nowhere else (Gillespie, et al., 2008; Meyer & Butaud, 2009). As witnessed elsewhere, French Polynesia has been severely affected by habitat loss and invasive species. Nineteen of its bird species have become extinct since the 16th century and of the 25 surviving endemic birds, 18 are listed as threatened and five as critically endangered (Zarzoso-Lacoste, 2013).

Invasive vertebrates are widely considered the most significant threat to French Polynesia's avifauna (Zarzoso-Lacoste, 2013). Interventions, to remove invasive vertebrates, could be made to improve security for many species. However, investment within the collectivity for the management of invasive alien species remains small and a national invasive species strategy has not yet been developed. The collectivity does not appear to have the financial mechanisms to undertake vertebrate eradications and outside financial support will be required if species extinctions are to be avoided.

In 2015, four species of invasive alien vertebrates, Pacific rat (*Rattus exulans*), ship rat (*R. rattus*), feral cat (*Felis catus*) and rabbit (*Oryctolagus cuniculus*), were successfully removed from five of six islands spanning 320 km of open ocean in the Tuamotu and Gambier Archipelagos of French Polynesia. The project failed to remove rats from one project site and completion of goat (*Capra hircus*) eradication from another was delayed until 2017.

Here we describe the methods used to remove invasive vertebrates from the project sites and the logistics associated with the project. We explain how cost efficiencies were gained by combining operations and targeting multiple islands and define how the project partnership was instrumental to the project's success.

METHODS

Site description

Six islands in the south-east of French Polynesia were targeted for the removal of invasive vertebrates (Fig. 1). These included the two atolls of Vahanga and Tenania (Tenarunga) that, together with Tenararo and Matureivavao, make up the Acteon Island Group. Vahanga and Tenararo are identified as a Key Biodiversity Area (Atherton, 2007) and as an Important Bird Area (Raust & Sanford, 2007). Tenararo is one of four islands in French Polynesia never

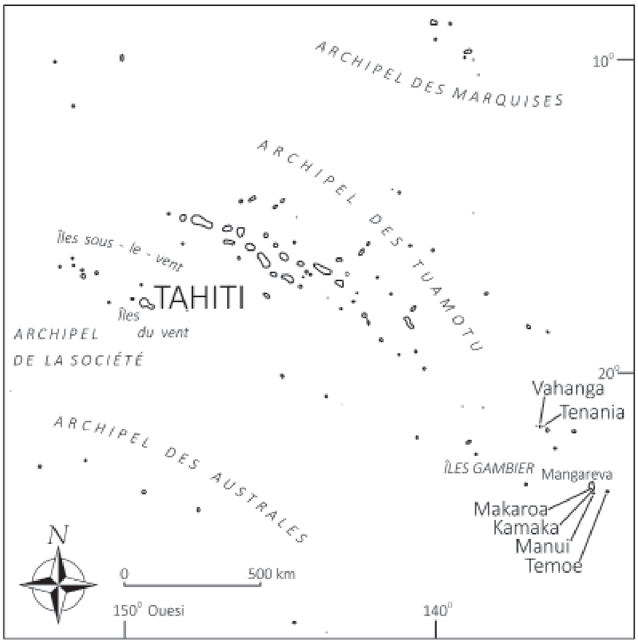

Fig. 1 Location of the six project sites within French Polynesia.

to have had invasive vertebrates and the atoll remains a stronghold for the critically endangered Polynesian ground dove and the endangered Tuamotu sandpiper as well as other native species (Blanvillain, et al., 2002). The operation also included Makaroa, Kamaka and Manui, three of the higher elevation islands that form Mangareva atoll complex and Temoe atoll, which lies to the south of Mangareva. Makaroa, Kamaka and Manui, together with the pest-free Motu Teiku, are classified as an IBA (Raust & Sanford, 2007). The endangered white-throated storm petrel breeds on both Manui and Motu Teiku.

All three of the atolls included in the operation were planted with coconut (*Cocos nucifera*) and used historically for copra production although only Tenania continues to be used for this purpose. Consequently, although areas of indigenous vegetation remain, *C. nucifera* dominates many of the forested parts of the atolls. Makaroa, Kamaka and Manui have also been extensively modified by burning, and the introduction of herbivores such as goats and rabbits. At the time of the project, little ground cover existed on Makaroa and large areas of Kamaka and Manui were covered in the invasive molasses grass (*Melinus minutiflora*). Of the six targeted sites, only the islet of Kamaka in the Gambier group is permanently inhabited. The atoll of Tenania in the Acteon group is occupied for part of the year for copra harvesting and Temoe is regularly visited by local fisherman. Table 1 summarises the general characteristics of the six sites.

Project feasibility and planning

Planning for rat eradication on Vahanga began in 2006 after a previous attempt undertaken in 2000–2001 was confirmed as having failed (Pierce, et al., 2006). Research was completed on the atoll to quantify the impact of terrestrial crabs on rodent bait availability, assess bait uptake by rats and quantify the effort required to hand broadcast bait across Vahanga (Griffiths, et al., 2011). Following this, an operational plan for rat eradication on the island was prepared (Broome, et al., 2011), but lack of funding delayed the project's implementation. A feasibility assessment for the removal of rats from Kamaka and Makaroa, completed in 2008 (Faulquier, 2008), stipulated the need for a helicopter due to the steep topography of these sites.

Following several high profile rat eradication failures on tropical islands, a global review of eradication methods was undertaken in 2013 to increase success rates (Russell & Holmes, 2015). New best practice guidelines were published, recommending higher bait application rates and longer periods of bait availability (Keitt, et al., 2015). The new guidelines meant it would be extremely challenging logistically to complete a ground-based operation for Vahanga and the use of a helicopter was recommended.

Funding for rat eradication on Vahanga was eventually obtained in 2014. However, due to the costs associated with transporting a helicopter to the south-east corner of French Polynesia and the relatively low cost of including additional sites and invasive species, a decision was made by project partners to target five additional, high conservation value islands in the area. This decision was facilitated by broadening the project partnership and securing additional funding. An operational plan was devised that prescribed the aerial application of rodent bait containing brodifacoum to target rats followed by trapping and hunting to target cats, rabbits and goats across the six project sites (Derand, et al., 2015).

The target bait application rate for rat eradication was derived using the methods described by Pott et al. (2015) to interpret bait availability data collected by Griffiths et al. (2011). The proposed application rate, coupled with reported island sizes and areas derived from available satellite imagery and a 15% contingency for lost or damaged bait, were then used to estimate the total amount of bait required. Immediately before the project's implementation, higher resolution satellite imagery acquired from the Millennium Coral Reef Mapping Project (Andréfouët, et al., 2005)

Table 1 Characteristics of the six sites targeted for invasive vertebrate removal.

Island	Area (ha)	Elevation (m)	Location	Native threatened species expected to benefit	Targeted invasives
Vahanga	380	5	Acteon	Pacific ground-dove, Tuamotu sandpiper, atoll fruit-dove (*Ptilinopus coralensis*), Murphy's petrel (*Pterodroma ultima*), bristle-thighed curlew (*Numenius tahitiensis*), green turtle (*Chelonia mydas*)	*Rattus exulans*
Tenania	425	5	Acteon	Pacific Ground-dove, Tuamotu sandpiper, bristle-thighed curlew, green turtle	*R. exulans, R. rattus, Felis catus*
Kamaka	58	166	Gambier	Polynesian storm petrel, Murphy's petrel	*R. exulans*
Makaroa	22	136	Gambier	Polynesian storm petrel	*R. exulans, Capra hircus*
Manui	8	54	Gambier	Polynesian storm petrel, Murphy's petrel	*Oryctolagus cuniculus*
Temoe	431	5	Gambier	Murphy's petrel	*R. exulans*

and EVS-Islands digital earth imagery showed that initial estimates of island areas had been overestimated, in some cases by as much as 22%. Consequently, this made more bait available for distribution at each site than had been planned.

Project implementation

Staging

Ninety-two tonnes of rodent bait, 30,000 l of Jet A1 helicopter fuel, three bait-spreading buckets, and equipment and supplies necessary for the project were shipped from the port of Papeete to the project sites by the coastal freighter 'Nuku Hau'. Rodent bait was transported in 22.7 kg paper-walled sacks stacked inside Ox Boxes (waxed cardboard pods) (hereafter referred to as pods) and the fuel in 200 l drums. A single-engine Squirrel AS350 B2 supplied by Tahiti Helicopters was flown from Papeete by 'island hopping' between four intermediate islands (a total distance of 1500 km) before converging with the Nuku Hau at Vahanga to commence the offloading process.

Immediately prior to unloading, the island's coastal boundaries were flown to confirm the size of the area to be treated and revalidate the amount of bait and fuel to be unloaded at each site. All equipment and supplies were first offloaded from the Nuku Hau to a small barge which was then unloaded by helicopter in separate sling loads. Bait and fuel, sufficient for each atoll, were staged on Vahanga, Tenania, and Temoe with unloading taking between 4–6 hours for each atoll. Supplies for the three closely grouped Gambier Islets were staged in less than four hours on Kamaka. To minimise flying between island groups, two bait spreading buckets were offloaded in the Acteon Group, one for use on Vahanga and the other for Tenania. One bucket and a range of spare parts were stationed in the Gambier Islands for use on both Temoe and the Gambier Islets.

Project team members, 24 in total, were also deployed at this time. Team members were stationed on Vahanga (6), Tenania (5), Temoe (3) and Kamaka (1). The project manager, GIS analyst, baiting team (3), pilots (2) and helicopter mechanic travelled by helicopter between the islands to complete bait applications and one person, stationed in Mangareva, provided logistical support. In between bait applications, the project manager, GIS analyst and members of the baiting team deployed to different islands to provide support for monitoring, trapping and hunting.

On Tenania, large piles of broken coconut husks containing coconut flesh were found across the atoll. These byproducts of the recent copra harvest represented a signficant alternative food source for rats and a risk to the project's likelihood of success. To reduce risk, members of the project team systematically burned piles of coconuts. This laborious activity greatly reduced the amount of coconut available to rats but did not eliminate it.

Bait application

After staging was complete, bait application took place sequentially beginning on Temoe followed by the Gambier Islets, Vahanga and finally Tenania. Each of the three atolls took more than one day to complete due to the amount of bait applied and the requirement to break the circular atolls into multiple blocks. Dividing the operational area into blocks maximised the length of flight lines that could be flown thereby simplifying the operation for the pilot. Adjacent baiting swaths were overlapped by 50% to reduce the risk of gaps in coverage (e.g. Fig. 2). In addition to parallel flight lines across each island's interior, a swath with a deflector bucket (which spreads bait in one direction only) was completed along the edge of both coastal and lagoon vegetation. Additional bait was applied by helicopter over areas considered to be higher risk, such as areas of human habitation or sites known to support the highest crab densities. At the same time as bait was applied by helicopter, rodent bait was placed in small dishes within all buildings still in use and scattered by hand underneath buildings and inside all derelict or abandoned structures.

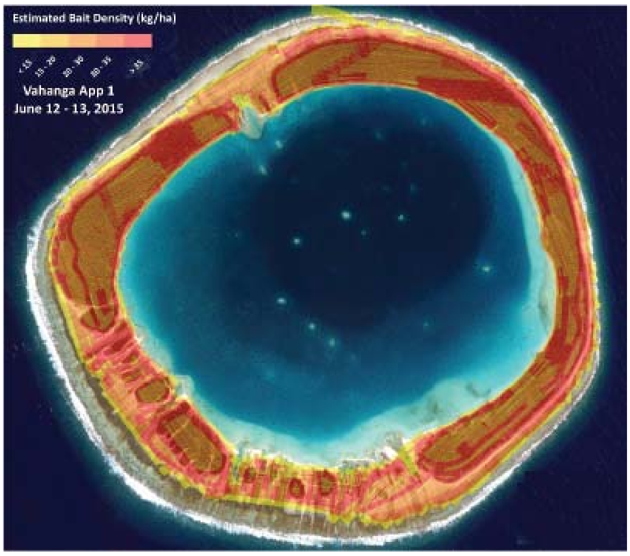

Fig. 2 First bait application completed on Vahanga.

Following an 18 day interval, a second application of bait was completed at the project sites in the same sequence. The length of the interval was dictated by a desire to ensure that all individuals (including juveniles) within the targeted rat populations were exposed to bait, as discussed in Keitt, et al. (2015), and also by the resource limitations of the project partnership. Operational specifications for the second bait application were the same, except for the exclusion from bait application of barren storm-washed coral habitat across all three atolls. Bait availability monitoring and anecdotal observations suggested negligible disappearance of bait from these atolls and thus no advantage in re-treating these areas. This action was also seen as a means of reducing risk to non-target species such as Tuamotu sandpiper (*Prosobonia cancellata*). Operational areas treated were thus smaller in the second application for Vahanga, Tenania and Temoe (Table 2). Dates of bait application and the application rates achieved are provided in Table 2. No significant delays because of sustained rainfall or excessive winds were encountered.

Loading of bait spreading buckets was undertaken from platforms constructed from an 18 mm thick plywood sheet set atop two pods. A second plywood sheet was placed on the ground in front of these pods to ensure a level footing for the spreader bucket. The helicopter was fitted with a VHF radio for ground to air communications with the bait loading team.

The pod and pallet containment system withstood crushing (some pods were stacked up to seven high in the hold of the Nuku Hau), being dipped in saltwater (as they were airlifted onto the islands), tropical temperatures and periods of heavy rain. Water was found inside the internal plastic bag (used to protect sacks of bait) in just four pods and of these pods only the bags at the bottom of the pod were affected. Only four of the 4,065 bags (<0.1%) of bait shipped were considered unfit for application. Water ingress into pods was primarily a result of damage incurred to the cardboard during shipping and unloading, coupled

Table 2 Bait application summary.

with water pooling on the lid of the pod. Intact pods showed no sign of water ingress despite water pooling.

Rabbits

Based on the results of other projects (e.g. Griffiths, et al., 2014), most rabbits were expected to consume rodent bait and succumb to poisoning on Manui. This proved to be the case, with just four survivors found and one of these appeared to be close to death at the time it was shot. Two staff began follow-up work targeting surviving rabbits, nine days after the first application of bait, to eliminate survivors before the team departed French Polynesia.

All accessible areas of the island offering apparently suitable habitat were searched for sign and surviving rabbits during the day and at night, using powerful head lamps (see Fig. 3). Some inaccessible parts of the island such as cliff faces were searched with spotlights at night, but comprehensive searching of these areas was not possible. To manage search effort and spatial data, the island was divided into zones. Generally, the same zone was searched during the day and then again at night. Areas where fresh sign was found, or a live rabbit sighted were searched more intensively. Search effort was logged using handheld GPS and a map used to identify areas that had not yet been visited. Waypoints were recorded for any fresh sign found and live rabbits sighted.

Two trail cameras were established on the island from 26 April 2015 and seven added from 10 June. Three cameras were kept at the same locations throughout the operation while the remaining four were moved to locations where fresh sign was found or where rabbit presence was suspected. Old rabbit sign (faeces and chewed vegetation) was found in most parts of the island except within the molasses grass sward and the coastal littoral zone. Ten freshly dead rabbits (presumed poisoned) were found. Carcasses were found in three discrete locations and were generally associated with areas of concentrated old sign.

Fresh rabbit sign was found in three discrete locations during the period of follow up searching. In each case the discovery of fresh sign led to the location of freshly dead or surviving rabbits within the same area. One adult female was found during the day on 19 June and shot. This individual superficially appeared to be in good condition but was presumed to be in the last stages of anticoagulant

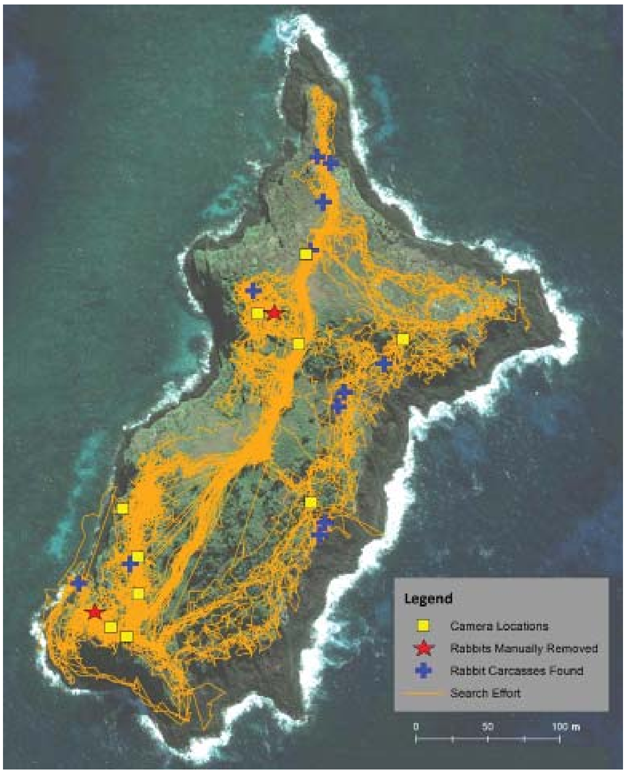

Fig. 3 Search effort and location of surviving rabbits on Manui 10 June to 3 July 2015.

poisoning as it did not move when approached and, although not evident in the gut, the lower intestine was full of blood.

Two young rabbits (a male and female) were found together while spotlighting and shot.. These individuals appeared healthy and a necropsy indicated no evidence of bait ingestion or anticoagulant poisoning. The last surviving rabbit was shot 100 m further north also after finding fresh sign. This individual, an adult female, was in excellent condition and showed no sign of bait ingestion or anticoagulant poisoning. Following removal of this individual, no further fresh sign or images on cameras were found during five more days of search effort.

Cats

Cat trapping on Tenania began on 6 June prior to the 1st bait application and continued until 4 July when the team departed. A total of 564 trap nights (sum of the number of active traps for each trap night) were achieved. Trapping was conducted primarily with leg hold traps, No. 2 Bridger padded, and No. 1.5 Oneida/Victor unpadded leg hold traps set in a combination of cubby, trail and bucket sets. Traps were baited with either canned or fresh fish, lured with a commercial lure or left un-baited in the case of some trail sets. Every 2–3 days, traps that had sprung were triggered and reset. Trap locations were changed as necessary when sign (tracks, scat, and visual observation) was encountered in the field and camera data collected.

Traps were raised (i.e. positioned on top of sand filled buckets) or left unlured to minimise crab interference. However, traps were often triggered by what remaining sign indicated was crabs, mostly *Coenobita perlatus*. Spotlight surveys were undertaken but only one cat detected using this method and this method was not pursued. A total of 10 remote trail cameras were installed on 5 June and data collected daily, in most cases, to inform trap placement. Monitoring with cameras continued until 4 July. Camera data were also used to verify the identity of captured cats. Ten distinct individual cats were detected with trail cameras and, of these, nine were caught: five female and four male. All were mature adults and one female was pregnant with three foetuses at the time of capture. Feral cat captures were made exclusively with leg-hold traps; three were caught in cubby sets, five in trail sets and one in a bucket set. The last cat captured displayed signs of internal haemorrhaging, likely due to secondary exposure to brodifacoum. The last feral cat detected by trail camera on 29 June was not captured, despite concentrated trapping in the vicinity of detection, and is assumed to have succumbed to secondary poisoning. An individual with distinct black and white fur patterns, seen during the first spotlight survey, was also never observed again despite follow-up surveys.

All cats captured appeared to be in excellent body condition. When the captured cats' stomach contents were examined, the only prey remains observed were rodents. Interestingly, the stomachs of two cats captured contained coconut flesh. Rat remains encapsulating the observed coconut within one individual, indicated rats to be the source; however, the other had its stomach completely full of coconut.

Goats

Despite local reports to the contrary, eight goats were still present on Makaroa in 2015 at the time of the project's implementation. One of these (a young female) was shot, but further hunting effort was abandoned due to insufficient capacity, a lack of suitable firearms and the remaining goats being extremely wary due to having been hunted recently. Two experienced hunters returned in 2017, each with a .308 calibre rifle and thermal imaging equipment. Eighteen goats were removed during the first four days and no more were seen in the subsequent six days of intensive search effort (Table 3). It is unknown whether goats ate rodent bait, but its application to remove rats had no apparent impact on the population, and the presence of goats did not impact the success of the rat eradication.

Non-target species mitigation

The proposed application of rodent bait posed a potential risk to non-target native species such as the Polynesian ground dove and the Tuamotu sandpiper. Tuamotu sandpiper were considered at high risk based on observations made on Tahanea Atoll during a rat eradication in 2011 (Pott, et al., 2014). Concerns were also held for Polynesian ground dove although other projects had targeted rats in the presence of conspecifics without apparent losses (Griffiths, 2014). Both species were recorded in very low numbers at just one of the project sites (Vahanga) and, because of their conservation status, mitigation was undertaken.

Prior to bait application, efforts were made to catch all Polynesian ground dove on Vahanga and translocate them to Tenararo. Of the five to six birds observed, two were captured and transferred. The others evaded capture and were monitored over the course of the project's implementation, along with two individuals sighted on Tenania. Transferred birds had two of the outermost primaries of each wing removed to lessen the chances of them flying back to Vahanga.

Efforts were also made to capture and transfer Tuamotu sandpiper. More birds were found on Vahanga than had been anticipated and five of the six birds present were caught. One escaped, but four were translocated to Tenararo with outermost primaries plucked on both wings (1–3 per wing, depending on bird condition) to prevent their return to Vahanga.

Table 3 Monitoring completed to confirm eradication success at the six project sites.

Island	Invasive species	Monitoring effort				Outcome
		Corrected trap nights	Spotlighting (hrs)	Sign searches (hrs)	Trail cameras (hrs)	
Vahanga	Pacific rat	345	16	112	0	Successful
Tenania (Tenarunga)	Pacific rat, ship rat, cat	213	17	112	420	Successful
Temoe	Pacific rat	455	25	128	0	Successful
Kamaka	Pacific rat	612	-	-	0	Failed
Makaroa	Pacific rat, goat	210	8	188	440	Successful
Manui	Rabbit		20	232	1,230	Successful

These interventions were partially effective for both species with 90% of captured birds resighted in 2017 (R. Pierce pers. comm.). Ground dove that remained on Vahanga and Tenania were resighted throughout the period of implementation, suggesting any risks to this species were low. Sightings of an uncaptured Tuamotu sandpiper displaying symptoms of poisoning were made on Vahanga. This individual was not seen again highlighting the vulnerability of this species.

ERADICATION SUCCESS

Trapping, spotlight searches and searches for sign of invasive vertebrate presence, conducted in April and May 2017 nearly two years after the project was implemented, confirmed the project was successful at removing invasive vertebrates at five of the six sites. No rats were found on Vahanga, Tenania, Temoe or Makaroa. No cats were found on Tenania or rabbits on Manui and goats were finally removed from Makaroa. The monitoring effort expended for each site to confirm eradication success is provided in Table 3. Despite Kamaka being inhabited, rats were not detected until monitoring was instigated nearly 12 months after the project was implemented. Rats are now widespread on the island. Analysis of DNA confirmed that some rats survived the operation.

OUTCOMES

In removing invasive species from five islands, the project increased the total number of islands free of invasive vertebrates within French Polynesia from four to nine and created an additional 1,426 ha of secure habitat, effectively tripling the area available for Polynesian ground dove and Tuamotu sandpiper recovery. Early signs of recovery were observed in 2017 with more individuals of Polynesian ground dove seen on both Vahanga and Tenania in 2017 and Tuamotu sandpiper recorded on Tenania for the first time. Recovery of native vegetation was observed on both Manui and Makaroa. Longer term monitoring is required to confirm trends.

With the removal of rats, the risk of rodent-borne leptospirosis has been eliminated from Tenania and the quality and quantity of copra produced appears to have increased, although the increase in income generated for the local community has yet to be quantified. Local skills to undertake future eradication projects were developed and support from policy-makers, funders and the public for future rodent eradications on other atolls/islands generated.

PROJECT COST

The operational cost of the project was estimated based on expenditure records kept by project partners. The total cost of the project, from when concerted planning began in 2014 to completion of the operation in 2015, was €1.4M with the largest costs being the helicopter, shipping, rodent bait and personnel. The cost efficiency of the project gained by targeted all six islands was assessed by comparing the total cost of the project with estimates completed separately for eradicating invasive mammals independently at each site (Table 4). Costs such as helicopter, shipping and staff travel would all have added significantly to cost if each island had been completed as a standalone project. Postponement of goat eradication on Makaroa increased costs for this component of the project but only by a relatively small margin as the cost of goat eradication was small (<€20,000).

DISCUSSION

Implementing the project described in this paper was challenging due to the remote nature of the islands, the number of sites, the range of invasive species targeted, and the lack of infrastructure and resources available within French Polynesia. Overcoming these challenges required an extensive and thorough planning effort. An added benefit of the time taken for project planning was the clear identification of roles and responsibilities for each project partner. Each of the project partners provided capabilities that could not readily have been supplied by the other partners.

An operational strategy, informed by a contemporary review of rat eradications on tropical islands (Keitt, et al., 2015) contributed to project success although, as noted, rats survived on Kamaka despite the application of best practice guidelines. Reasons why rats survived on Kamaka are unknown but an investigation to determine causal factors is currently underway. The project also benefited from generally favourable weather through the implementation phase. In hindsight, sufficient time, effort and resources were put in place to ensure successful cat and rabbit removal from Tenania and Manui. However, more time spent on each of these islands would have increased the level of confidence held by departing teams that surviving individuals had been removed. Local reports that goats were no longer present on Makaroa proved incorrect and eradication of this species had to be postponed.

The cost efficiencies gained in this project through removing invasive species from multiple islands are evident. Completing each of the islands as a standalone project would have increased the total cost of removing invasive species from the six sites by a factor of three. Resources for conservation are scarce and similar approaches will need to be considered for many projects to make them economically viable. The proposed removal of rats and cats from five uninhabited islands in the Marquesas archipelago is one such example. The high costs of shipping and helicopters would rule out doing any one of the islands as a standalone project.

Interventions to mitigate the impacts of the operation to non-target species were largely effective (Pierce, et al., 2015) and the level of mortality sustained will be outweighed by the anticipated benefits to populations following the removal of rats from Vahanga. Although it is too early to measure the full impact of this conservation intervention, Polynesian ground dove and Tuamotu sandpiper should increase in abundance on both Vahanga and Tenania, eventually forming self-sustaining populations. The number of populations of Polynesian ground dove will increase from three to five and for

Table 4 Projected standalone project costs and the actual costs incurred for removing invasive vertebrates from the six project sites.

Island	Projected cost	Actual cost[1]
Vahanga	€1.1M	€0.3M
Tenania	€1.1M	€0.3M
Temoe	€1.1M	€0.3M
Kamaka	€0.4M	€0.15M
Makaroa	€0.5M	€0.2M
Manui	€0.4M	€0.15M
Total	€4.6M	€1.4M

[1] Costs such as flying the helicopter from Tahiti were divided equally between project sites.

Tuamotu sandpiper from six to eight. Polynesian storm petrel (*Nesofregetta fuliginosa*) along with other sea birds are expected to recolonise Makaroa increasing the number of breeding sites for this species from at least six to seven. Translocations of these species and others are also now possible.

Completion of the project provided greater security from extinction for a number of plant and animal species but most importantly for bird species listed as critically endangered or endangered by the IUCN (IUCN, 2010), Polynesian ground dove, white-throated storm petrel and Tuamotu sandpiper. The project also delivered socio-economic benefits to local communities through increased production from a coconut plantation on Tenania and greater resilience for harvested seabird populations on Temoe. In doing so, the project provides a precedent for further action within French Polynesia to protect endemic biodiversity and livelihoods.

ACKNOWLEDGEMENTS

This project received financial support from the European Union ENTRP, the David and Lucile Packard Foundation, the British Birdwatching Fair, the Mohamed bin Zayed Species Conservation Fund, and National Geographic Society. Sponsorships were received from Bell Laboratories and the T-Gear Trust of Canada. The project also received in-kind support from the New Zealand Department of Conservation, Pacific Invasives Initiative and the Government of French Polynesia. We are indebted to these funders and organisations for making this project possible and to the many individuals who worked on or supported the project.

Trialling gene drives to control invasive species: what, where and how?

T. Harvey-Samuel[1], K.J. Campbell[2], M. Edgington[1] and L. Alphey[1]

[1]The Pirbright Institute, Ash Road, Woking, GU24 0NF, UK. <tim.harvey-samuel@pirbright.ac.uk>. [2]Island Conservation, 2100 Delaware Ave, Santa Cruz, CA, 95060, USA.

Abstract The control of invasive species would be enhanced through the addition of novel, more effective and sustainable pest management methods. One control option yet to be trialled in the field is to deploy transgene-based 'Gene Drives': technologies which force the inheritance of a genetic construct through the gene pool of a wild population, suppressing it or replacing it with a less harmful form. There is considerable interest in applying gene drives to currently intractable invasives across a broad taxonomic range. However, not all species will make efficient or safe targets for these technologies. Additionally, the safety and efficacy of these systems will vary according to where they are deployed, the specific molecular design chosen, and how these factors interact with the ecology of the target pest. Given the transformative but also controversial nature of gene drives, it is imperative that their first field trials are able to successfully demonstrate that they can be used safely and efficiently. Here, we discuss how to maximise the probability of this outcome through considering three important questions: *What* types of invasive species should we use to trial gene drives? *Where* should we be trialling them? and *How* should these trials be conducted? In particular, we focus on the ecological, genetic and geographic features of small, isolated islands which make them ideal locations for these initial trials. A case study of an island invasive that is deemed highly appropriate for gene drive intervention, and for which gene drive development is currently underway (*Mus musculus*), is used to further explore these concepts.

Keywords: biodiversity conservation, CRISPR, *Culex quinquefasciatus*, gene drive, island invasive, *Mus musculus*, population eradication, restoration

INTRODUCTION

Molecular advancements have made feasible a new range of Genetic Pest Management (GPM) strategies – the transgene-based gene drives (Sinkins & Gould, 2006). These technologies aim to introduce DNA sequences (the gene drive transgene) into the genome of a wild pest population through the release of genetically engineered individuals which go on to mate with conspecifics in the field. Once introduced, the inheritance of the gene drive is forced – driven – through the target population gene pool along with its control phenotype. This driving effect can be achieved, for example, by biasing inheritance of the transgene above normal mendelian levels, or through placing an evolutionary advantage on inheritance of the transgene at the population level. Proposed control phenotypes aim either to reduce/eradicate a pest population – "population suppression" strategies – or to leave a population intact but modify it so that it is less harmful (e.g. by spreading a transgene which makes a mosquito population less able to transmit a particular disease) – "population replacement" strategies (Alphey, 2014). Within population suppression, current proposals aim to spread either a sex ratio bias (usually in favour of males) or a genetic load, e.g. female sterility (Deredec, et al., 2008).

Theoretically, gene drives could be engineered that are capable of spreading to every member of an interbreeding population from one or several relatively small initial releases (Deredec, et al., 2008). This autonomous nature is appealing for invasive species control, where programmes often extend into remote/inaccessible areas and less than total eradication may be viewed as failure. Indeed, there is increasing interest in applying gene drives to currently intractable invasive species that threaten biodiversity (Alphey, 2002; Gould, 2008; Esvelt, et al., 2014; Simberloff, 2014; Thresher, et al., 2014; Campbell, et al., 2015; NASEM, 2016; Harvey-Samuel, et al., 2017; Piaggio, et al., 2017). However, two primary concerns arise from their proposed use. Firstly, that a gene drive transgene could unintentionally spread beyond a target geographic area (e.g. from an invasive population into the native range of the invader) or into a non-target species through hybridisation/horizontal-gene transfer – here collectively termed 'transgene escape'. Secondly, that their persistence, once released, could cause unintended ecological effects that are difficult to reverse (Sutherland, et al., 2014; Webber, et al., 2015; NASEM, 2016).

Previous field testing of gene drives is limited to non-transgenic population replacement utilising artificial infections of *Aedes aegypti* mosquitoes with the intracellular bacterium *Wolbachia* (Hoffmann, et al., 2011; Schmidt, et al., 2017). *Wolbachia* technologies are considered non-transgenic as they do not, deliberately, involve the introduction of DNA sequences into the target pest genome. Proposed application of transgene-based gene drives to invasive species differs from *Wolbachia* in that the systems available are, potentially, significantly more powerful and flexible and their taxonomic scope is broader, encompassing groups as divergent as plants, mammals, fish and molluscs, in addition to insects (Gould, 2008; Hodgins, et al., 2009; Thresher, et al., 2014; Campbell, et al., 2015; Sytsma, et al., 2015; Webber, et al., 2015). The first open-field trials of transgene-based gene drive technologies will thus represent a precedent-setting milestone. As recommended by the USA National Academy of Sciences (NASEM, 2016) , these trials will seek to examine whether the efficacy (e.g. its ability to invade a target population and induce a desired control phenotype therein) and safety (e.g. our ability to constrain its spread to the target population using molecular or experimental designs) of a gene drive system conform with theoretical expectations, themselves informed by preliminary laboratory experiments and mathematical modelling (Benedict, et al., 2008; Brown, et al., 2014). As such, open-field trials can be considered extensions of initial highly biocontained laboratory experiments where artificial biocontainment (Akbari, et al., 2015) is 'relaxed' because aspects of efficacy and safety have previously been demonstrated. Both these aspects – efficacy and safety – are important in order to convince a potentially sceptical public that they may have confidence in the wider use of these technologies.

Here we summarise the primary considerations involved in conducting the precedent-setting open-field trials of transgene-based gene drives (henceforth 'gene

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 618–627. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

drives') in invasive species through posing three questions (1) What types of invasives are appropriate targets for these trials? (2) Where should the trials of these systems be located? (3) How should these trials be conducted? These questions are considered with the aim of exploring how these technologies could be trialled against invasive species as efficaciously as possible, whilst minimising the risk of transgene escape. In order to increase the value of this discussion these points are addressed in a general, rather than taxon-specific manner. Additionally, we explore their implications for a specific invader currently being targeted for control using gene drives – the house mouse, *Mus musculus* (See case study: GBIRd and Table 1). We bring this forward with the purpose of encouraging dialogue and improving criteria for such trials.

WHAT CHARACTERISTICS ARE IMPORTANT WHEN CHOOSING A TARGET ORGANISM?

General characteristics of a gene drive target

Minimum *requirements* for gene drive development are that the target pest is sexually reproductive, is amenable to laboratory rearing/germ-line transgenesis and is genetically well characterised.

As barriers to gene-flow within a population will decrease the efficiency of a gene drive's spread (see: The importance of dispersal), target species should preferably be obligately sexually reproductive (Alphey, et al., 2010) and incapable of self-fertilisation, which may simultaneously reduce the potential for gene drive resistance evolution (Bull, 2016). As such, it is unlikely these systems will be broadly applicable to invasive plants, of which many propagate vegetatively or through self-fertilisation (Kolar & Lodge, 2001; Rambuda & Johnson, 2004). Regarding transgenesis, the ease with which the germ-line cells can be manipulated will influence the speed that new transgene designs can be tested. Insect transgenesis has predominantly been through microinjection of pre-blastoderm embryos which requires that the fertilised egg is accessible. Transformation of species which are viviparous (e.g. the tsetse fly) or whose embryos are laid in inaccessible protective structures (e.g. pods or cases) may prove more challenging (Bourtzis, et al., 2016). Finally, as gene drives require the expression of various genetic components in highly temporal or spatially explicit patterns, often to target precise genomic loci, a good knowledge of the genetics of a target, e.g. a high-quality genome/transcriptome sequence and an understanding of the molecular-genetic basis of sex determination, is imperative.

Desirable characteristics are not absolutely necessary for gene drive development but, in practice, species whose biology diverged significantly from these characteristics would be deemed as inappropriate targets for these technologies.

Chief amongst desirable characteristics is a short generation time. This will minimise the time taken for strain development, and for these vertically transmitted systems to spread through and control a target population. Similarly, species with complex mating systems (e.g. the synchronised and ephemeral mating events of termites or ants) or where subsets of the population can remain dormant and inaccessible (e.g. long-term seed banks) effectively

Table 1 Idealised ecological selection criteria proposed as an initial filter for potential trial islands for potential gene drive constructed mice trials within Australia, New Zealand, USA. Additional steps will be required prior to any potential field trial, including engagement with stakeholders (e.g. land managers, local communities) and regulators to determine final approval.

Criteria	Rationale
1 Island is biosecure Desktop assessment indicates: a. Closed to public or infrequent/controlled visitation b. Remote enough (>1 km from other land masses) to avoid unassisted immigration or emigration	● Mice typically invade remote islands through human mediated transport, not through swimming (Russell & Clout, 2005). ● *M. musculus* are known to have swum up to 500 m between land masses (Harris, et al., 2012). ● Closed population required for proof-of-concept ● After desktop assessment. If the island passes other filters and is tentatively selected, conduct a biosecurity risk assessment. Island biosecurity plans for individual islands or island groups should be developed and implemented if island is selected (Fritts, 2007; Russell, et al., 2008; AAS, 2017)
2. No significant challenges exist to treatment using traditional methods to eradicate mice, e.g.: a. Uninhabited (besides research station or similar) b. No livestock c. No native rodents d. No non-target species of concern e. Regulatory environment allows the use of brodifacoum bait products and no rodenticide resistance alleles present f. Island size <300 ha g. Single land manager	● Provides a means to terminate experiments (i.e. exit strategy) using traditional methods without known complicating factors.
3. *M. musculus* are the only rodent present *or* could be introduced.	● Mouse behaviour is known to change significantly in the presence of rats (Harper & Cabrera, 2010). ● There may be man-made or other islands that are suitable that don't currently have *M. musculus* present.
4. Reasonably economical and feasible to visit the island year-round.	● Some islands are cost prohibitive to visit. ● Seasonal conditions may impact safe access to the island.

extend the generation time and may limit transgene introgression into or through a wild population (Alphey, et al., 2010). Furthermore, it is critical that there is a good knowledge of the ecology (e.g. mating systems, population dynamics and community interactions) of the target and in the case of vectors, the ecology and epidemiology of the pathogen and disease. The importance of this knowledge when developing a GPM strategy – from choosing the most appropriate/effective system, to predicting the impact of a strategy on a target population and community – cannot be overstated (Yakob, et al., 2008; Bax & Thresher, 2009; Yakob & Bonsall, 2009; Bonsall, et al., 2010; Thresher, et al., 2013; Piaggio, et al., 2017). Finally, it is desirable that the target is the dominant and ideally, sole, cause of an impact. As these strategies are vertically transmitted, they are extremely species-specific, making scenarios where there are multiple contributors to an impact (e.g. the spread of avian pox in Hawaii, where there are both mechanical and vector-based disease transmission routes) less appropriate.

The importance of dispersal

Gene-flow between populations

In limiting transgene escape into non-target areas, two important and interacting considerations are the level of gene-flow between a target and non-target population and the invasion threshold of the gene drive deployed (Figs 1 and 2) (Marshall & Hay, 2012). The invasion threshold is the theoretical frequency a gene drive transgene must be present at in a population before it will begin to spread. Highly invasive gene drives spread from very low invasion thresholds (e.g. the introduction of a few individuals into a target population) while less invasive systems may require significant levels of introduction before they begin to spread (high invasion threshold). Transgene escape may be considered an issue if gene-flow occurs at a frequency which makes it probable that a gene drive will exceed its invasion threshold in a non-target population

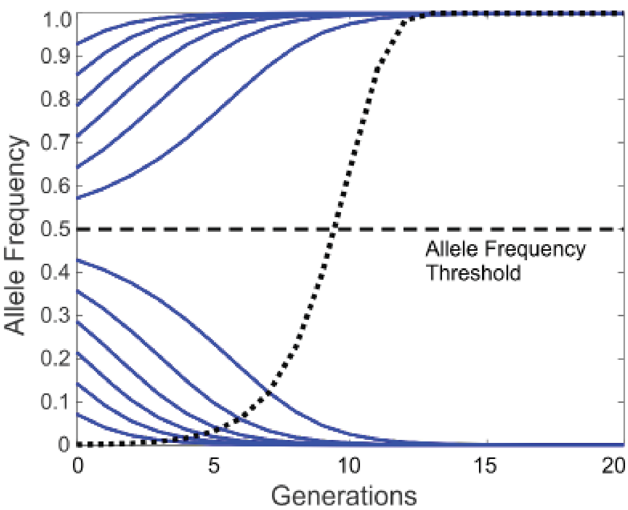

Fig. 1 Gene drives may be classified by their level of invasiveness, which is defined as the frequency they must reach in a target population before they begin to spread (the invasion threshold).Relatively non-invasive gene drives such as underdominance-based systems (Reeves, et al., 2014) (solid lines) require a high minimum allele frequency (dashed line) to be exceeded before they will begin to spread (50% of the population in this simulation). This differs from highly invasive (also known as "global") gene drives such as homing-based systems (Deredec, et al., 2008; Unckless, et al., 2015) (dotted) that will theoretically spread throughout a population even from a very low initial allele frequency, at least in the absence of resistant alleles.

within the time-frame of a trial (Akbari, et al., 2013). An 'acceptable' level of gene-flow between target and non-target populations will therefore be significantly higher for less invasive gene drives (Fig. 2). As the choice of gene drive may be constrained by the desired outcome (less invasive systems are generally more suited to replacement rather than suppression), it may not always be possible to choose less invasive designs to prevent transgene escape in species which are capable of long-distance gene-flow. A more flexible option is to trial gene drives in species which show limited ability to disperse and where human-mediated dispersal pathways can be managed. As previously noted (NASEM, 2016), important considerations here are the distance, frequency and life-stage of dispersal. Generally, species which disperse as juveniles/adults will show lower rates of gene-flow between populations than those which disperse as fertilised embryos (seeds or spores) or gametes (e.g. wind-borne pollen) (NASEM, 2016). Furthermore, dispersal via gametes may be more likely to result in interspecific hybrids, potentially increasing the risk of transgene escape into non-target species (NASEM, 2016). Consideration of these dispersal issues may make terrestrial animals more attractive targets than plants or marine species. As social interactions can strongly influence adult/juvenile dispersal events, it is important to consider how the predicted outcome of a particular gene drive may interact with these species-specific behavioural cues. For example, mate-limitation or increased inbreeding at low population densities or highly skewed sex ratios (both expected outcomes of proposed suppression gene drive designs) could in some species/scenarios result in increased levels of dispersal (Clobert, et al., 2012; Matthysen, 2012) and potentially also transgene escape.

Prior knowledge of the dispersal behaviour of an invasive population is therefore a prerequisite to safely deploying a gene drive. Fortunately, for many important invaders details of their dispersal mechanisms, invasion rates and levels of gene-flow within their invaded range already exist – in addition to other useful details such as the observed variance in their population size. Potential target species and populations could be short-listed based on the existence of this historical information, which could then be used to inform models predicting the potential for transgene escape during the expected time-frame of a trial.

Gene-flow within a population

Reaction-diffusion models have shown that dispersal rates will affect the speed that a gene drive travels through a target population (Beaghton, et al., 2016). Under more realistic scenarios, barriers to gene-flow within a population may have a more qualitative effect on whether a gene drive will spread or persist (North, et al., 2013). This concern could be reduced by avoiding targets whose populations show strong local spatial structuring, e.g. those which engage in high levels of sib-sib mating (Hamilton, 1967). However, even less extreme levels of spatial structuring resulting from limited life-time dispersal can significantly affect the ability of a gene drive to spread through and collapse a target population (Huang, et al., 2011; Eckhoff, et al., 2017). In particular, species whose population dynamics are significantly affected by seasonality may provide more fragmented landscapes for a gene drive to attempt to traverse. Models comparing gene drive dynamics in spatially explicit and homogenous mosquito populations suggest that increased structuring of a target population decreases the parameter space under which the target population is successfully eradicated (Eckhoff, et al., 2017). In these models, sub-populations became explicit annually in response to lowered population densities during the dry season. If sub-populations became explicit prior to arrival of the spreading transgene, these areas could act as a source for wild-type reinvasion into areas where the drive had eradicated the pest the previous season. Although limited within-population dispersal can be overcome through increasing the 'patchiness' or number of transgenic releases (Huang, et al., 2011; Eckhoff, et al., 2017), this tactic partially negates the primary advantage of employing gene drives. In choosing a target it is thus critical to have evaluated whether, given their population spatial-structure and the gene drive chosen, the release effort required to efficiently eradicate or replace a population is low enough to justify intervention with this technology.

Relatedness to important pests

Development and trialling of gene drives against invasives will proceed most efficiently if target species impact multiple values (e.g. human or animal health, agriculture, conservation). If these 'dual-target' species can be identified then the financial burden of developing gene drive strategies could be shared amongst different funding agencies, efficient designs/components shared between different researchers and the benefits of, and motivation for gene drive deployment shared amongst varied stakeholders. If a target invasive did not impact multiple values, gene drive development would still benefit if they were closely related to species in which GPM technology had previously been investigated, due to the transferability of many underlying molecular designs and components (Harvey-Samuel, et al., 2017). Examples of dual-target species are the mosquito (*Culex quinquefasciatus*) – a vector for multiple human diseases (Eldridge, 2005) and an invasive vector of avian malaria in Hawaii (LaPointe, et al., 2012) – and rodents including the house mouse (*Mus musculus*) and rats (e.g. *Rattus exulans, R. norvegicus and R. rattus*) which collectively are serious economic pests of agriculture (Aplin, et al., 2003; Pimentel, et al., 2005), impact infrastructure, are hosts for human, domestic animal and wildlife disease (Banks & Hughes, 2012), and amongst the most damaging invasives of island ecosystems (Angel, et al., 2009; Harper & Bunbury, 2015). Encouragingly, germ-line transgenesis and genome sequences already exist for *C. quinquefasciatus* (Allen, et al., 2001; Arensburger, et al., 2010), *M. musculus* (Waterston, et al., 2002; Ivics, et al., 2014) and *R. norvegicus* (Gibbs, et al., 2004; Ivics, et al., 2014). Moreover, all these species are invasive in isolated, uninhabited areas where there are no closely related species: desirable characteristics for a gene drive trial location (see next section).

WHERE SHOULD TRIALS BE CONDUCTED?

In order to maximise containment and efficacy, small, isolated islands are ideal locations for the first trials of gene drives (WHO/TDR, 2014).

Advantages of island locations to trial safety

Limiting intraspecific transgene escape

Gene-flow from an invasive population to conspecifics in its native range will decrease with increasing inter-population distance, the ecological inhospitality of the intervening area and the size of the invasive 'source' population. Locating trials on small, isolated islands can therefore act as an ecological containment strategy (WHO/TDR, 2014; NASEM, 2016), reducing the risk of intraspecific transgene escape. The effectiveness of this containment will depend on the proximity of a trial island to the native range of an invader, its natural and human-

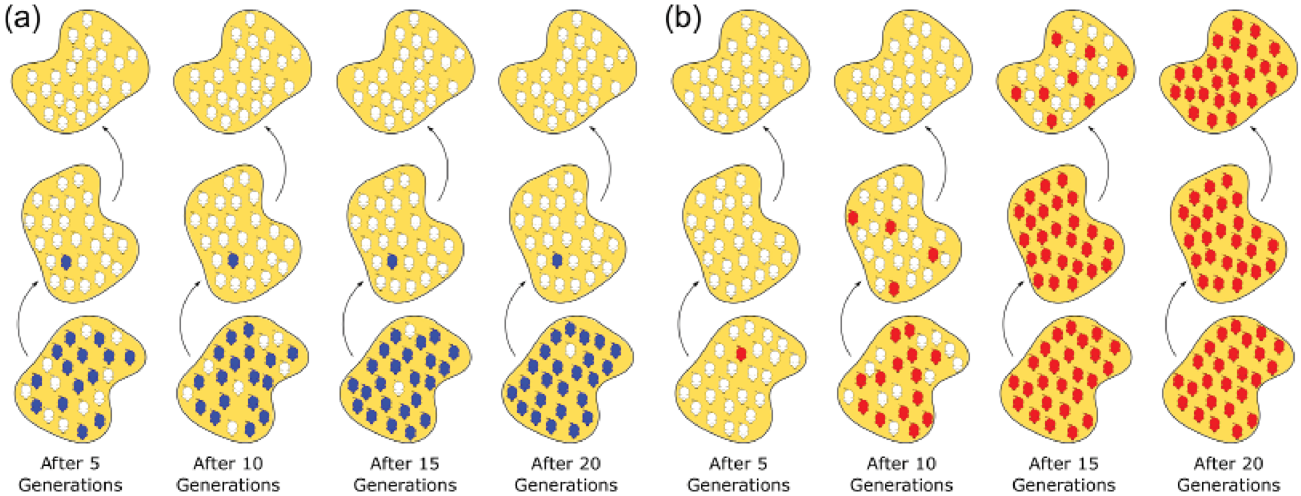

Fig. 2 The invasiveness of gene drive systems affects their containment ability once deployed in the field. Relatively non-invasive systems require large initial introductions before the gene drive will begin to spread and therefore migration alone is unlikely to exceed their invasion threshold. Highly invasive gene drives, on the other hand, can spread from only a few initial colonists and are predicted to spread through all linked populations. This is illustrated above using a three deme population genetics mathematical models. In each case we assume that a target (bottom) island and a nearby neighbour (middle) exchange 2% of their respective populations by migration in each generation while the nearby neighbour and a more remote (top) island exchange just 1%. It is assumed that no direct migration occurs between the target and remote islands due to the distance between them. Resulting transgene frequencies for each island at various times after the transgenic release are represented diagrammatically by a series of 25 mice (each representing a transgene frequency of 4%). White and shaded mice respectively represent wild-type and underdominance/homing drive transgenic allele frequencies, rounded to the nearest 4% (i.e. to the nearest whole mouse). Panel (a) shows results for a frequency dependent, single locus haploinsufficient underdominance-based system (Reeves, et al., 2014). This is a relatively non-invasive system with a high invasion threshold of 50% (See Fig. 1, solid lines). Here it is assumed that wild-type and transgene homozygotes suffer no fitness cost while 50% of heterozygous offspring are non-viable. For an initial transgene frequency of 55% it can be seen that the system spreads throughout the target population but does not reach significant levels in the neighbouring populations. Panel (b) shows results from a homing-based gene drive (Deredec, et al., 2008; Unckless, et al., 2015) which imparts no fitness cost on individuals and converts heterozygotes to homozygotes with 100% efficiency, introduced with an initial transgene frequency of 0.1%. The population genetics of this gene drive are shown in Fig. 1, (dotted line). Even this low initial frequency allows this highly invasive gene drive to spread throughout the target, and in time, the neighbouring populations also.

mediated dispersal ability and the invasiveness of the gene drive being trialled. A set of case-studies illustrating the interplay between these factors is the open-field releases of artificial *Wolbachia* infections aimed at local replacement of *A. aegypti* mosquito populations in Australia. After deliberate establishment in relatively isolated trial *A. aegypti* populations (Hoffmann, et al., 2011), it was found that long-distance dispersal was taking *Wolbachia* infected mosquitos into areas beyond the trial site (up to 1.86 km away) but that migration rates were insufficient over this distance to overcome the relatively high invasion threshold of the *Wolbachia* system (>30%) which remained largely contained to the trial site (Hoffmann, et al., 2014). Conversely, in subsequent releases where the trial site formed part of a larger, continuous *A. aegypti* population, *Wolbachia* was capable of spreading, albeit slowly, to high frequency beyond release sites and into the wild target population (Schmidt, et al., 2017). Gene drives with lower invasion thresholds than *Wolbachia* will require significantly greater isolation and/or molecular safeguard designs to limit transgenes to target populations/areas (discussed in the **How** section). This concept is illustrated for transgene-based gene drives in Figs 1 and 2.

In the context of island trial locations, the potential for a gene drive to cover large geographic distances, potentially back to mainland populations, through 'island-hopping' should not be overlooked (Bellemain & Ricklefs, 2008). For suppression drive designs, this island-hopping would require the existence of viable populations extending back to a native range and for the drive to escape each invaded 'stepping-stone' population before that population was itself eliminated by the drive. However, for replacement drives these aspects would not be a pre-requisite.

Limiting interspecific transgene escape

Transgene escape between species could take place either through horizontal gene transfer (HGT – acquisition of genetic material from an organism other than a direct ancestor) or introgression following hybridisation. Signals of HGT in metazoans can be seen by sequence comparisons between species (e.g. Crisp, et al., 2015). However, even the most frequent of these HGT events are rare, seen in nature on timescales of millions of years (e.g. Ortiz, et al., 2015). Therefore, as discussed generally for mosquitoes (Besansky, 2015) and specifically for homing-drives (Burt, 2003), HGT of a gene drive is held to be unlikely to occur at a frequency which will make it a realistic concern.

Regular gene-flow between native and invasive species through introgressive hybridisation, however, is well documented (Mooney & Cleland, 2001). Here, island locations provide both benefits and disadvantages in terms of limiting transgene escape. A benefit is that, given a frequency of fertile hybridisation events, stochastic elimination of an escaped transgene prior to its spread in a non-target species is more likely in small, island populations than at continental scales. However, hybridisation between closely related invasive and native species may be higher in insular compared to continental communities (Rhymer & Simberloff, 1996), potentially allowing transgenes to introgress into native populations at increased rates on islands. The potential genetic homogeneity of an island invasive population and simplicity of island communities (reducing the number of hybridising congeners) may prove advantageous in designing sequence-specific molecular safeguards to limit this risk.

Advantages of island locations to trial efficacy

Geographic isolation

Trials of gene drives will seek to achieve a series of pre-defined scientific endpoints (Brown, et al., 2014; NASEM, 2016). These will include evidence that the transgene is able to spread efficiently in the wild population, as well as endpoints specific to individual designs (e.g. reduced population density or reduced number of fully-competent vectors for suppression and replacement strategies, respectively). As immigration of wild-type individuals into a target population effectively dilutes the frequency of the transgene, unanticipated immigration will cause drive rates to be estimated inaccurately; this has been a frequently-observed problem in trials of sterile insects for population suppression (Klassen & Curtis, 2005) and is assumed to have prevented fixation of artificial *Wolbachia* infected mosquitoes in open-field trials (Hoffmann, et al., 2014). A sufficiently isolated island trial site will reduce this concern through minimising wild-type immigration. What constitutes 'sufficient' geographic isolation could be considered in conjunction with estimating outward gene-flow from a proposed trial island, acknowledging that migration rates between populations may not be symmetrical (Kawecki, 2004) and may only occur during infrequent events (e.g. El Niño, hurricanes).

Small population size

For equivalent release numbers/resources, introductions can be made at a higher population allele frequency on small islands than at larger, continental scales. This is primarily advantageous in testing gene drives with high invasion thresholds. However, even for more invasive systems, test releases would likely take place at frequencies well above the estimated minimum to protect against stochastic loss of the transgene in initial generations. Increased introduction rates will also allow the transgene to reach fixation (or a stable internal equilibrium) more rapidly (Deredec, et al., 2008). Moreover, for population-suppression strategies, smaller target populations may mean that density-dependent processes such as Allee effects (Tobin, et al., 2011) and environmental stochasticity (Eckhoff, et al., 2017) can be leveraged to more rapidly drive populations to extinction.

Genetically distinct

Small, insular populations arising from recent single invasion events are likely to be relatively genetically homogenous (Dlugosch & Parker, 2008). Assuming that heritable resistance to gene drives is possible (Bull, 2015), but founder individuals did not carry resistance alleles, this would provide target populations initially entirely susceptible to a released drive. Furthermore, given a constant mutation rate, such a gene drive resistance allele is less likely to arise in smaller, isolated populations within the time-frame of a trial. Conversely, however, if founder individuals did display pre-existing resistance it may occur at high frequencies. Target island populations should be screened prior to a trial for the presence of pre-existing resistance mutations; a relatively simple task for sequence-specific homing-drives, but potentially less straightforward for other technologies.

Which islands?

Islands that are small and sufficiently isolated to provide effective ecological containment could provide ideal locations for trialling gene drives. However, there are a number of biological, geographic and social criteria which will, in general, make a location more or less suitable for trialling GPM strategies (Benedict, et al., 2008; Lavery, et al., 2008; Brown, et al., 2014) and which can be extended to identify particularly promising examples within this group.

Biological criteria

If sufficiently isolated, invasive populations will be allopatric from conspecifics in their native range but sympatric with native congenic populations with which they might hybridise. If it occurs at an appreciable frequency, interspecific gene-flow may therefore be considered the more likely of the two risks when trialling gene drives in these locations. The most effective solution would be to avoid locations where there are closely related native species. For example, targeting invasive rodents on off-shore islands in New Zealand (which has no native terrestrial mammals) would pose low/no risk of transgene escape into native species, whereas deployment of the same technology in areas with diverse endemic rodent fauna such as south-east Asian archipelagos (Amori, et al., 2008) would likely require extensive pre-trial risk assessment. A further point to consider is that hybridisation events may be unidirectional with regards to sex (Rhymer & Simberloff, 1996). Molecular designs such as Y-drive which are transmitted exclusively through the paternal line would not be introgressed into a native population if hybrids formed via crosses between native males and invasive females.

If sufficient safety measures are taken, gene drives are expected to act in an extremely species-specific manner and are thus highly suitable for deployment in ecologically sensitive locations. However, a precautionary approach would suggest that precedent-setting trials be conducted in locations devoid of endangered/threatened flora or fauna (Brown, et al., 2014). This is particularly relevant if broader spectrum conventional control methods are used to terminate the trial at a pre-defined endpoint (see Table 1).

Geographic criteria

Barriers to gene-flow will decrease the efficiency of a released gene drive. Islands with relatively simple geographies and a resulting homogenous invasive population, for example low-lying oceanic islands, will therefore be most amenable to initial trials of these technologies. Where multiple islands occur in close proximity, these areas could be used to test assumptions on the spread of a drive technology within/between populations depending on the dispersal of the target (e.g. coral atolls/archipelagos for short/longer distance dispersal, respectively).

Social criteria

Challenges associated with invasive species control in inhabited areas are well-documented (Oppel, et al., 2011; Glen, et al., 2013). The novel and controversial nature of gene drives means that these challenges are likely to be exacerbated during their first trials. Levels of regulatory/engagement costs, risk assessment and societal objection are all likely to be more favourable if initial trials take place in uninhabited areas which are not of great cultural value. At least as importantly, restricting traffic off an island during a trial will substantially reduce the likelihood of transgene escape via intraspecific gene-flow. Employing modified biosecurity measures currently employed during conventional eradication efforts (Russell, et al., 2008), this would be far more feasible for uninhabited areas.

Previous experience in choosing sites for self-limiting GPM mosquito trials suggest that two social criteria critical for site identification are the existence of a credible regulatory structure and an enthusiastic local participant (e.g. academic researcher or wildlife management agency) with expertise regarding the invasive being targeted (Brown, et al., 2014). The regulatory framework in operation is relevant at multiple stages during planning and implementing a gene drive trial, from granting importation permits for gene drive organisms (Brown, et al., 2014) to determining appropriate risk assessment (NASEM, 2016) and public engagement (Lavery, et al., 2008) activities and experimental design/biosecurity during and after a trial (Benedict, et al., 2008). A robust and defensible regulatory framework allows public confidence in approved trials and reduces the likelihood of a trial being halted prematurely due to previously unvoiced concerns (Brown, et al., 2014). As regulation of gene drive trials is expected to take place on a case-by-case basis (Oye, et al., 2014) a local participant with knowledge of the regional ecological, social, economic, political and cultural context of deployment is invaluable. Additionally, due to the relative complexity and large scale (both temporal and spatial) expected of a gene drive trial, access to experienced research teams provided by a local collaborator would likely be necessary.

How should trials be conducted?

Practical guidance on how to conduct field-trials of self-limiting GPM mosquitoes (e.g. aspects of experimental design, safety and efficiency endpoints) is available (Benedict, et al., 2008; Brown, et al., 2014) and has been extended to the case of gene drives (WHO/TDR, 2014; NASEM, 2016). We will not replicate this discussion, but instead focus on how molecular designs can be utilised to increase the safety of a gene drive trial.

Proactive approaches

Proactive designs aim to limit the probability of transgene escape in the first instance. 'Precision' CRISPR-Cas9 gene drives (Esvelt, et al., 2014), which have been demonstrated in yeast (DiCarlo, et al., 2015) target the Cas9 endonuclease to cut a fixed DNA sequence in the genome unique to the specific target population, with the gene drive transgene then copied across into the cut site. The occurrence of such unique targeting sites is more probable in isolated populations derived recently from small numbers of initial founders and therefore may be particularly useful against island invasives. Alternatively, a 'daisy-chain' drive design could be employed (Noble, et al., 2016). Here a CRISPR-Cas9 gene drive is divided into a linear series of sub-components where each component will only drive in the presence of the component directly beneath it in the series. Critically, the basal component in a daisy-chain cannot drive and will be subject to loss over time through purifying selection. These components are then integrated at independent loci in a release strain meaning that the system is constrained spatially and taxonomically (multiple, sequential, components must escape an island population in the same individual or be combined again through interbreeding in order to continue driving) and temporally (selection will erode each basal component of the daisy-chain in turn until it is flushed from the population). Daisy-chain drives are currently being investigated for the island invasives *C. quinquefasciatus* and *M. musculus*, however analysis so far is theoretical, with – to our knowledge – no prototype strains reported in any metazoan.

An alternative proactive approach is to place inherent fitness costs on a gene drive such that it will persist for a time in a target population, potentially suppressing it, but not increase in frequency. Proposed examples include utilising a gene drive to spread a dominant female-lethal transgene, as proposed for mosquitoes (RIDL-with-drive) (Thomas, et al., 2000), and the endogenous *t*-haplotype meiotic-drive system to spread the male-determining *Sry* gene in mice. Although these systems utilise independent technologies and gene targets, their effects are the same: the transgene doubles in frequency each generation but half those individuals inheriting it (females) are non-viable. If transgenic individuals suffer from reduced fitness, or the drive is less than 100% efficient at biasing its inheritance – both of which are likely in the field – these systems will decrease in frequency over time once deployed (Backus & Gross, 2016), reducing the risk of transgene escape from a trial site but also their efficiency as suppression systems.

Responsive approaches

Responsive designs are complete or partial genetic systems, likely themselves gene drives, designed to be deployed in the event of an escaped drive in order to curtail its spread and potentially remove it or its phenotypic effects from a non-target population. These can include for example a 'reversal-drive' designed to target, spread into and disrupt the DNA sequence of an escaped drive, or the 'immunisation-drive' designed to spread into a non-target population and recode the wild-type target locus, making it unrecognisable to an escaped drive (Esvelt, et al., 2014). These designs can be combined into a single 'immunising-reversal' drive and be made less invasive through using the daisy-chain architecture. A more complex 'restoration-drive' design integrates a relatively non-invasive underdominance system (Figs 1 and 2) into this daisy-chain 'immunising-reversal' drive to theoretically allow the entire system to be flushed from the non-target population once the escaped drive has been halted (Min, et al., 2017).

Although reversal drives have been demonstrated in lab yeast colonies (DiCarlo, et al., 2015) and a non-driving equivalent in *Drosophila* (Wu, et al., 2016) it is unclear how effective these and other responsive approaches would be in the field. There is also concern that, in the event of an escaped gene drive, there may be considerable pressure against rectifying the situation through the release of another gene drive. A more realistic, but not mutually exclusive, approach would be to integrate a high level of conventional control methods at all potential transgene escape points (e.g. connected docking areas/airstrips) during and for a period after a trial. It is clear that responsive approaches should not be relied upon as critical containment methods during a gene drive trial.

Case study: Genetic Biocontrol of Invasive Rodents (GBIRd)

The Genetic Biocontrol of Invasive Rodents (GBIRd) programme aims to develop multiple gene drive systems in mice (*Mus musculus*) for simultaneous evaluation of their safety and efficacy using biosafety standards beyond those required by existing law, while carefully assessing the social, cultural and policy acceptability of such an approach (Campbell et al., 2019). The programme's first stage culminates in the potential submission of an application to a regulatory agency for release of gene drive constructed mice with a spatial control mechanism on a small, biosecure island to test eradication of the wild, invasive mouse population (Campbell et al., 2019). This step-wise approach follows recommendations from USA and Australian National Academies of Sciences (NASEM, 2016; AAS, 2017). Ecological criteria for selecting an appropriate trial island for this application have been proposed (Campbell et al., 2019; Table 1). However, these criteria are just an initial filter and additional steps will be required prior to any potential field trial, including engagement with stakeholders (e.g. land managers, local communities) and regulators to determine final approval (Campbell et al., 2019).

Mus musculus are non-native in countries within the GBIRd partnership (Australia, New Zealand, USA). Mice are not consumed as a food item by people in these countries; negatively impact native species, stored foods, crops, and infrastructure and can carry zoonotic diseases that impact the health of people and their livestock (Stenseth, et al., 2003; Meerburg, et al., 2009; Capizzi, et al., 2014), likely increasing socio-political acceptability. Further, these countries have (or are expected to have) appropriate regulatory capacity and systems established to evaluate a GBIRd proposal, if one is submitted (Campbell et al., 2019). Idealised island selection criteria for potential trials within these countries are provided in Table 1.

CONCLUSION

Gene drives hold enormous potential for application against invasive species and there is increasing interest in adapting them to this purpose. As a transformative but controversial set of technologies, it is important that the first instances of their use in the field are successful, both in terms of efficacy and safety. As discussed, the likelihood of a successful trial can be increased by making appropriate decisions at multiple stages of a gene drive's development and deployment. Making these decisions requires input from a broad range of scientific disciplines (Gould, 2008; Piaggio, et al., 2017) involving, for example, conservationists identifying potential targets, ecologists advising on the biological appropriateness of these targets and efficiencies of different gene drive strategies, molecular biologists advising on the feasibility of building proposed designs, mathematical modellers devising the most efficient means of deploying these systems and, finally, managers who will ultimately advise on the logistic feasibility of deployment. Although described in a linear series, in practice this will require informed dialogue between all these parties from the outset – there is no point in developing a system that performs well in computer models or in the lab if it is ultimately deemed impractical to deploy in the field. With proof-of-principle suppression (Hammond, et al., 2016) and replacement (Gantz, et al., 2015) drives functional in anopheline mosquitoes, it is critical that these conversations begin now to ensure these technologies are applied as safely, efficiently and rapidly as possible to the control of invasive species.

Abstract Indicators for tracking conservation efforts at a global scale are rare but important tools for understanding trends and measuring progress towards global conservation targets. Eradication of invasive species from islands is an increasingly used conservation intervention in countries and territories around the world. With a goal of collating these efforts, the Database of Islands and Invasive Species Eradications (DIISE) holds records of the location, target species, year and outcome of invasive mammal and bird eradications on islands from around the world. The database is publicly available in Spanish and English, at <diiise.islandconservation.org>, and represents a partnership between the University of California at Santa Cruz, University of Auckland, IUCN Invasive Species Specialist Group, Landcare Research and Island Conservation. The database holds records for more than 1,200 eradication attempts. This database will continue to be added to and evolve as new opportunities for its application arise; thus, we expect these numbers to change over time as new events are added and knowledge about existing events improves. Updating the DIISE relies on contributions from experts and reporting from island restoration activities. Here we present database history, parameter definitions and database considerations. We also highlight additional studies the underlying data have contributed to, including evaluating the native species benefit from invasive mammal eradications on islands, and global indices to track progress towards the Convention of Biological Diversity Aichi target 9 (Invasive Alien Species), that explicitly requires an increased effort of eradication of priority invasive species.

Keywords: database, eradication, global, invasive, islands, mammal

INTRODUCTION

Eradication of invasive species from islands is an increasingly used conservation intervention in countries and territories around the world. Indicators for tracking conservation efforts at a global scale are rare but important tools for understanding trends, and measuring progress towards global conservation targets (McGeoch, et al., 2010). The number of eradications of invasive species on islands is one response indicator that contributes to measuring such progress. The number of eradications of invasive species on islands is a particularly good metric as these events tend to take place over discrete periods of time, occur in clearly defined spatial areas, and have a clear measure of success or failure (Niemeijer & de Groot, 2008).

With a goal of collating these efforts, the Database of Islands and Invasive Species Eradications (DIISE) holds records of, at a minimum, the location, target species, year and outcome of invasive mammal and bird eradications on islands around the world. Data within the database focus on terrestrial vertebrate species, primarily mammals and birds. Fish eradications are not included, nor are plant or invertebrate eradications (but see Tobin, et al., 2014; Hoffmann, et al., 2016). As of 2016, the database holds records for more than 1,200 eradication attempts. The database is publicly available in Spanish and English, at <diiise.islandconservation.org>, and represents an ongoing partnership between the University of California at Santa Cruz, University of Auckland, IUCN Invasive Species Specialist Group, Landcare Research and Island Conservation.

Here we present database history, parameter definitions and database considerations. During 2017, a major update to the data is underway with a goal of using the 2017 Island Invasives Conference as a venue to engage island restoration practitioners to help improve the dataset.

MATERIALS AND METHODS

Database history

The first synthesis of the database (then known as the Global Islands Invasive Vertebrate Eradication Database) was published in the proceedings of the Island Invasives: eradication and management conference in Auckland in 2010 (Keitt, et al., 2011). Data for this synthesis were gathered from published, grey and unpublished literature, with the majority of data from reviews of eradications for rodents (Howald, et al., 2007), goats (Campbell & Donlan, 2005) and cats (Nogales, et al., 2004; Campbell, et al., 2011). Following the conference, the database was shared with all of the attendees of the conference (240 topic experts from 20 countries) with the goals of checking facts and adding missing eradication events. Attendees were encouraged to share the database with their networks to help achieve these goals.

In 2013–2014 an update of the database was undertaken using additional review papers on invasive mice (MacKay, et al., 2007) and small Indian mongoose (Barun, et al., 2011), the two Island Invasives conference proceedings (Veitch & Clout, 2002; Veitch, et al., 2011), summaries of eradication on inhabited islands (Oppel, et al., 2011; Glen, et al., 2013) and regional summaries for New Zealand (Clout & Russell, 2006), Europe and overseas territories (Genovesi, 2005; Genovesi & Carnevali, 2011), USA and territories (Witmer & Fuller, 2011), Galapagos (Carrion, et al., 2011; Harper & Carrion, 2011; Phillips, et al., 2012), California Channel and north-western Baja California Islands (McChesney & Tershy, 1998), Mexico (Aguirre-Muñoz, et al., 2008; Aguirre-Muñoz, et al., 2011), Hawaii and Central Pacific (Hess & Jacobi, 2011), France and overseas territories (Lorvelec & Pascal, 2005) and Seychelles (Beaver & Mougal, 2009).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 628–632. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Other resources reviewed include, but were not limited to, IUCN SSC Invasive Species Specialist Group Invasives listserv, Pacific Seabird Group listserv, Pacific Invasives Initiative listserv; new sites including Agreement for the Conservation of Albatrosses and Petrels <http://acap.aq/news>, Seychelles Island Foundation newsletter <http://www.sif.sc/index.php?langue=eng&rub=19>; industry sources including the Australian Invasive Animals Cooperative Research Centre <https://www.pestsmart.org.au/tag/invasive-animals-cooperative-research-centre/> and <https://invasives.com.au/about/our-legacy/>, Mediterranean Small Islands Initiative <http://initiative-pim.org/> and the Web of Science for the key words "island" and "eradication". Further, we were fortunate to benefit from communications with practitioners who maintain regularly updated databases for territories including the Falklands / Islas Malvinas (Falkland Islands Rat Eradication Register, S. Poncet pers. comm.), France and overseas territories (O. Lorvelec pers. comm.), Seychelles (G. Rocamura pers. comm.), and worldwide (J. Parkes pers. comm.). This effort also included an evaluation period where entries were cross-checked with experts, and review of emails sent to directly to database managers.

During 2017, a third update began, including review of regional assessments including Italy (Capizzi, et al., 2016), Australia (Gregory, et al., 2014), California (California Department of Fish and Wildlife (CDFW, 2015) and the Indian Ocean (Russell, et al., 2016). Additional listservs and new sites reviewed include the NZ Department of Conservation media <http://www.doc.govt.nz/news/media-releases/>, South Pacific Regional Environment Program media <http://www.sprep.org/news>, Pacific Invasives Learning Network soundbites <http://www.sprep.org/piln/soundbites-documents>, Battler resource base <https://piln.sprep.org/>, and BirdLife news <http://www.birdlife.org/news>. The keyword 'eradication' was used to search these sites, plus the word 'deratisation' for French language sites. This review is expected to continue through 2017 including an expert review to validate new or changed entries.

Parameter definitions

Keitt et al (2011) describe the general methods used to populate the DIISE for the first synthesis. Each eradication event is an attempt to eradicate an invasive vertebrate population from an island. Where multiple invasive species are eradicated from an island these are considered separate eradication events, even if using the same technique. Each eradication event has a unique identification number and can generally be identified by the combination of the key parameters of species removed + island + eradication end date + eradication status. Citations for each eradication event are recorded.

For the 2013–2014 update, the parameter definitions were expanded to also include data quality, primarily to classify how eradication events were verified for inclusion the database. We assessed the quality of data available for all eradication attempts within the database using criteria in Table 1. We encourage other users of DIISE data to use data classified as good or satisfactory data quality event only. We retain events classified as poor data quality in the online database in the hope others can help us further qualify or remove these events.

Each eradication event was linked to an island. Each island was given a unique ID based on the World Conservation Monitoring Centre (WCMC) Global Islands Database (GID) (Depraetere, 2007), a spatial dataset with 180,000 unique island locations of the world. Eradications on different islands were recorded as separate events, regardless of whether it was in the same archipelago or treated concurrently (e.g. Montebello islands in Western Australia). For coral atolls, if the project targeted individual motu these were treated as separate events and linked to individual motu accordingly. However, projects that occurred at the atoll scale were treated as one event. For islands that were not in the GID we allocated our own ID number and metadata. Locations were verified in Google Earth and corrected if necessary. Island names are standardised to the common proper noun within the larger country/territory, excluding frequently used words for 'island' (e.g. islets, rocks, etc.). Country or territory was based on International Standards Organization (ISO) 3166-1 alpha-2 codes. In 2016, the DIISE island locations were migrated to the GID2, a higher resolution product by WCMC that holds approximately 460,000 islands. Each polygon used for the DIISE was validated for island location and size against Google Earth and other satellite imagery.

Each invasive species has a unique ID code, and the common name, scientific name, family, trophic level (omnivore, herbivore, carnivore), and nominate type [amphibian, flying bird; non-flying bird; rodents (*Mus*); rodents (*Rattus*); cat; dogs or foxes, mongooses or weasels, rabbits or hares, reptiles (excluding snakes), snakes, ungulates, or other mammals] were recorded. Invasive species populations were either classified as feral, semi-feral, domestic, or a combination, with semi-feral defined as having some human care but not restricted in movement (e.g. fences).

We also sought to classify the eradication type, based upon the extent of the established invasive species population on the island and thus the scale of the operation necessary to achieve eradication. The aim of the database is to only include events where the goal was complete removal of an invasive species population from the island, and not removal from only part of an island such as fenced

Table 1 Data quality definitions

Data quality	Data quality definition
Good	We can verify the attempt; we have a copy of the primary reference (e.g. from a report, or peer reviewed publication) that details the effort, typically allowing us to populate almost all fields
Satisfactory	An expert practitioner has verified the event and/or we have limited information about an eradication but what we do have has come from a verifiable source (e.g. email from a reputable practitioner or cited in a review paper), and we can typically identify all of the following attributes: the island, end year (if applicable), invasive species type, eradication status, and primary eradication method
Poor	We cannot verify the attempt (conflicting information nor unverifiable resource) and/or we lack evidence for at least one of the following parameters: island, end year (if applicable), invasive animal type, eradication status, or primary eradication method
Unknown	The data quality has not yet been assessed for this event

areas (however, note we retain events where fences are used as a tool to achieve eradication at an island scale). We delineate whether the operation required treatment of the entire island, or only part of the island (restricted range), to achieve eradication of the invasive species population at the island scale. We also delineate between incursion responses and restricted range, whereby incursions represent operations to remove a recently arrived population prior to their spread across the island. If an incursion response fails, it is assumed a new eradication operation would be necessary. Although some incursion responses are recorded in the database, there is not a deliberate attempt to record every incursion response for each island because these may reflect a minor or ongoing management activity that may go unrecorded in the sources accessed. A classification of unknown is also used if it is unclear what the eradication type was, and this is also typically used where the cause of the extirpation of the invasive species population is unknown.

The timing of the eradication operation is typically based on the end date for the operation and is reported in years only. We considered eradication end date to be the year that major eradication operations ceased. This typically coincided with the end of hunting / trapping for ungulates and predators or the end of toxicant application (or other methods) for rodent projects. We note that monitoring required to determine if an operation was successful often occurs in years after the operation ending. The primary and secondary method of the eradication is collected, including disease, hunting, trapping, toxicant, other, or unknown. Where toxicant was used we sought to identify the baiting method, including aerial broadcast, bait station or bait piles, hand broadcast, unknown, or other, plus the toxicant compound used.

Eradication status is based on definitions in Table 2. When an eradication event is declared successful, the target invasive was removed from the entire island. We considered failures to be operational failures, i.e. the project did not successfully remove the entire invasive population. We considered reinvasion as separate to operational failure and recorded this separately. Reinvasion was defined as a previously successfully removed population becoming re-established back on the island. In the case of rodent eradications, reinvasion may also represent misdiagnosed failure (Russell, et al., 2010) but can be assessed through techniques such as genetic analyses, distance to potential source populations and the time elapsed between the eradication operation and subsequent rodent detections. When experts or source material indicated uncertainty about whether an invasive rodent population remains due to an operational failure or a reinvasion back onto the island, we assumed operational failure and classified data quality for the event as 'poor'.

DISCUSSION

Collating the location, method, outcome and target animal for invasive vertebrate eradications on islands offers a unique opportunity to contribute to global indicators for conservation. Collating these data over time offers insight into the response of a state-pressure-response model (Niemeijer & de Groot, 2008). The DIISE dataset holds many characteristics identified as necessary for effective threat (i.e. pressure in the state-pressure-response model) databases at a global scale, including: being freely available, spatially explicit, inclusion of a measure of expert validation, and is updated in a reasonable timeframe (Joppa, et al., 2016). The DIISE can contribute towards measuring progress of Aichi Target 9 of the global Convention on Biological Diversity, whereby signatory parties (nations) are committed to controlling or eradicating priority invasive alien species by 2020 (Convention on Biological Diversity, 2011), and is being used for the Biodiversity Indicator Partnership accordingly <https://www.bipindicators.net/indicators/trends-in-invasive-alien-species-vertebrate-eradications>.

The collation of more than 1,000 different eradication events inevitably encounters challenges. Reconciling the area (ha) and location (latitude and longitude) of small islands targeted for invasive species eradications against global data layers, has presented challenges to maintaining accuracy. In general, relying on one dataset (the GID) provides consistency, and seeking to validate those locations with satellite or other imagery should improve rigour. For rodent eradications, there is the risk that some projects classified as successful but reinvaded were in fact misdiagnosed operational failures. The time

Table 2 Eradication status definitions.

Eradication status	Definition
Successful	The operation to eradicate the invasive was successful and confirmed
Failed	The eradication operation was completed (there is an end date) yet it failed to remove the entire invasive population. Operational failure (as opposed to reinvasion). For rodent eradications, if there was uncertainty about why the invasive population remained (failure versus reinvasion), we assumed operational failure and classified data quality as 'poor'
To be confirmed	The eradication effort is complete, but the operation has yet to be "confirmed" as successful or failed. This stage is typical for rodent eradication operations, with confirmation monitoring occurring 1–2 years after the eradication operation has ended
In progress	Eradication operation is currently in progress at time of reporting
Planned	Eradication is being planned for the island at time of reporting. End year will be unknown accordingly
Incomplete	An eradication was started, but not followed through to completion
Trial or research only	The eradication was undertaken for trial or research purposes and the goal was to gain new knowledge, not eradicate invasive species
Unknown	Information does not allow allocation into one of the other mutually exclusive categories and an expert cannot do the same (e.g. unclear if an eradication took place or if the species "died out" naturally). Selection of this category will often be aligned with poor data quality
Unknown pre-status	Eradication was undertaken but the status of the invasive species was unclear beforehand. Typically undertaken for precautionary measures for rodent eradications

elapsed between the operation and invasion, and robust genetic analyses can confirm this classification (Russell, et al., 2010), but these may not be available on all projects, particularly islands that are not visited regularly, or for older projects where genetic tools were not available (Holmes, et al., 2015). In general, data in the DIISE rely on the eradication status provided by the practitioner. Including successful but reinvaded in data summaries may overestimate the success rate, but this can be mitigated by excluding those events. Similarly, outcomes of multiple adjacent islands that may function as a single eradication unit may skew success rates if they are treated as separate events. This can be accommodated for by selecting one representative island in that unit (e.g. see Holmes, et al., 2015).

Opportunities exist to improve and expand the schema and content of the DIISE. The DIISE is currently organised by island unit but currently does not link events based on operation (islands treated concurrently) or eradication unit (Abdelkrim, et al., 2005), whereby an invasive animal population may move freely between adjacent islands based on swimming or flying ability ('natural' reinvasion risk – Harris, et al., 2012). Most (98%) of the target animals in the DIISE are invasive mammals. A handful of bird eradications are recorded although they may require a different spatial organisational unit and consideration, particularly where entire archipelagos are invaded, and birds can move freely between islands. Some areas of the world may be under-represented in the database, including Small Island Developing States (Russell, et al., 2017) where resources to report outcomes may be scarcer, and the known lack of expert contacts in SE Asia, possibly reflecting a language barrier. More deliberate attempts to track these data may expand the dataset.

The DIISE dataset is freely available online, and requests for datasets to answer specific questions are responded to as best possible. There is a genuine resource cost to maintaining this data accessibility and a more significant investment required to undertake a major update. Thus, ensuring financial investment is key to maintaining this service. Despite the best of intentions, errors and omissions may occur in the dataset and, depending on the significance of the end goal users require the data for, additional validation of events in the DIISE may be warranted (e.g. Holmes, et al., 2015). A commonly sought-after use is summary statistics, for which we encourage those to check existing literature as they may already exist from sufficiently recent summaries (e.g. Russell & Holmes, 2015). For those seeking novel statistics not reported elsewhere, using only good or satisfactory data quality events is encouraged, as is being conscious of eradication type (whole island or restricted range). Events generating failure rates for rodents may need to consider that some reinvasion events may be misdiagnosed failures, and for events targeting species that have agricultural or domestic analogues (ungulates, dogs, cats), consideration may need to be given to whether domestic or feral populations are included. Using the data requires agreeing with a terms-of-use and checking with database managers is strongly encouraged to guide appropriate use of data.

Conservation databases provide a key role for informing decision making and assessing trends (e.g. the IUCN Red List) (Joppa, et al., 2016). At a project scale, data from the DIISE regularly features within feasibility assessments, by providing a comparison of proposed activities against past efforts. Data from the DIISE dataset has been used as a baseline to inform other conservation-based studies. Holmes, et al. (2015) and Russell & Holmes (2015) used the data to evaluate trends evident in why rodent eradication failed at higher rates in the tropics although note that predicting failure from operational covariates is not a panacea. Russell, et al. (2017) evaluated trends in where eradications occur, or may be under-reported, amongst different countries of the world. Importantly, recent efforts include Jones, et al. (2016) and Brooke, et al. (2017), who used validated DIISE data to explore biodiversity conservation outcomes, and seabird demographic response to invasive mammal eradications, respectively. Jones, et al. (2016) reported 596 populations of 236 native species on 181 islands benefiting after eradications. These types of studies are immensely valuable for measuring the true 'effect' (Kapos, et al., 2010) of eradication of invasive species on islands as a management action.

ACKNOWLEDGEMENTS

The Database of Islands and Invasive Species Eradications has benefitted greatly from many significant contributions of many island restoration practitioners around the world. Thank you kindly for the support of keeping this database online and up to date. Numerous volunteers have provided time to review data provided and enter it into the database. The Center for Integrated Spatial Research at the University of California of Santa Cruz developed the online database portal and maintains the website. Development of the DIISE was supported by the David and Lucile Packard Foundation, and the National Fish and Wildlife Foundation.

Abstract We are on the edge of the sixth mass extinction on Earth. Islands represent ca. 5% of the earth's land area yet are home to 61% of extinctions in the past 500 years, and currently support 39% of critically endangered species. Invasive species are a leading cause of extinction and endangerment on islands. Invasive vertebrates, particularly mammals, are among some of the most damaging invasive species on islands. Eradicating invasive mammals is an increasingly utilised conservation tool. Nevertheless, conservation intervention needs greatly outstrip the island restoration community's capacity. There are thousands of islands where invasive vertebrates are driving species toward extinction. So, how can the effort be matched to the scale of the problem? One approach is to improve outreach and communications to increase the resources available for projects. There are great stories; but these need to be told compellingly and repeatedly. Increasing social acceptance and support for invasive species eradications will reduce project costs associated with stakeholder engagement. Broadening the funding base can be accomplished by building stronger cost benefit valuations as well as engaging funders of climate change, marine conservation, human wellbeing, and food security. Furthermore, it is important to build upon existing partnerships to create or grow coalitions that can access these resources as part of broader, holistic efforts to address multiple conservation issues.

Keywords: communications, eradication, funding, invasive species, stakeholder engagement

INTRODUCTION

Multiple lines of evidence demonstrate that we are facing a significant global extinction crisis through the loss of biodiversity (Dirzo, 2003; Barnosky, et al., 2011). At a global scale, the response to this crisis includes the 2011–2020 strategic plan for biodiversity, highlighted in 20 targets to reduce pressures on the environment and to curb biodiversity loss (CBD, 2011). Islands are a logical place to focus conservation efforts because they offer a disproportionately higher rate of biodiversity and threatened species per unit area. Islands represent only ca. 5% of the earth's land area yet support ca. 39% of critically endangered species on the IUCN Red List (Tershy, et al., 2015), and an endemic richness of plants and vertebrates that is 8–9 times that on mainlands (Kier, et al., 2009).

Invasive alien species have been implicated as a leading cause of extinctions and endangerment for native plants and animals on islands (Tershy, et al., 2015). In particular, invasive mammals pose a significant risk (Doherty, et al., 2016). The development of tools and techniques to completely remove invasive mammal populations from islands has been a valuable intervention strategy for island managers to overcome this threat (Veitch & Clout, 2002; Veitch, et al., 2011). To date there have been more than 1,200 vertebrate eradication attempts on more than 700 islands with an 85% success rate (DIISE, 2014), and the pace and scale of eradications on islands is increasing (Simberloff, et al., 2018). Following successful eradications, demonstrable biodiversity conservation gains have accrued. A recent literature review found 596 populations of 236 native insular species benefited from 251 invasive mammal eradications on 181 islands (Jones, et al., 2016). Benefits included resident population recovery, recolonisation and unassisted colonisation, plus the enabling of reintroductions and conservation introductions. Similarly, Brooke, et al. (2017) investigated population growth rates in seabirds following invasive mammal eradications on islands and found a median population growth rate of 1.119 based on 181 populations of 69 seabird species.

NOTABLE ADVANCES AND INNOVATIONS

Several key innovations were critical to increasing the rate at which eradications of invasive mammals on islands have occurred. For rodents, New Zealand based programmes that researched the effectiveness of bait station approaches led to a series of successful implementations on small islands (Howald, et al., 2007). The advancement of aerial application techniques, including the use of satellite navigation systems, enabled efforts on larger islands and increased the number of islands treated, including >11,000 ha Campbell Island (Towns & Broome, 2003). These techniques have been exported internationally, with Macquarie Island at >12,000 ha recently declared successful, and implementation units recently treated within the South Georgia eradication reaching almost 30,000 ha. Likewise, for invasive ungulates, the advent of aerial hunting, extensive near real-time data management combined with mapping technology to coordinate large teams and different eradication methods, and the use of Judas goats enabled similar increases in number and size of islands treated (Campbell & Donlan, 2005) whereas aerial application, toxicant development and remote trap monitoring allowed continued increases in island size, efficiency and efficacy to be obtained on cat eradications (Campbell, et al., 2011), including the currently on-going treatment of ca. 65,000 ha Dirk Harthog Island in Australia.

The cumulative impact of numerous existing and on-going innovations is expected to increase the scope and scale of eradications on islands. Models to confirm eradication success (Ramsey, et al., 2009; Ramsey, et al., 2011) provide significant opportunities to reduce costs, particularly for large projects using hunting and/or trapping techniques, by increasing the efficiency of determining when a project is complete. Increased use of these tools, and associated real time, digital data collection and analysis tools, is recommended to increase efficacy, reduce costs and provide more information to enable post project review and analysis for future improvements (Will, et al., 2015).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 633–636. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Efforts are ongoing to reduce reliance on second generation anti-coagulants for rodent eradications, whose efficacy comes with a trade-off of greater risk to nontarget species (Howald, et al., 2007). These include expanding the use of first generation anticoagulants that pose less risk to non-target species (Poncet, et al., 2011), investigating alternative compounds, such as Norbamide, and investigating new bait recipes that could increase efficacy, such as crab deterrents (Campbell, et al., 2015). Self-resetting traps, a relatively new tool, that have been deployed successfully for eradication on small islands in Puerto Rico and New Zealand, present another alternative on small islands where rodenticide use may not be possible (Carter, et al., 2016). These self-resetting traps present significant potential for biosecurity management and can provide long term protection where reinvasion risk from swimming rodents is high.

New strategies have been developed to overcome the higher failure rate in rodent eradications in the tropics. After a series of high profile rodent eradication failures on tropical islands, a workshop of practitioners, The Tropical Rodent Eradication Review, was convened to evaluate reasons for these failures and develop recommendations to increase success rates in the future. These guidelines were published in 2015 (Keitt, et al., 2015) and several projects implemented since have followed the spirit of these guidelines. It remains to be seen whether efficacy rates will increase as a result, though the second attempt on Desecheo, which followed the guidelines, was declared successful (Will, et al., 2019).

Another promising approach is genetic tools that can lead to eradication of rodent populations (Campbell, et al., 2015, Campbell et al., 2019). Genetically modifying rodents to produce sterile offspring or only males and using gene drives to push for near 100% inheritance of this trait, could lead to eradication at large scales, including on inhabited islands where eradication is not currently feasible. This technology is in the early stages of development for house mice and it is unlikely that it would be available for field trials sooner than a decade from now; longer for commensal rat species. However, there has been significant concern raised about the safety and ethics of pursuing this line of conservation, particularly around the potential for a gene drive to run through an entire species and lead to extinction (National Academies of Sciences, Engineering, and Medicine, 2016). If this technology can be proven safe and gain the appropriate social and political approvals, it could have wide ranging impact on the conservation of large inhabited islands while also providing significant benefit to humans through reduced disease transmission and reduction in agricultural loss.

LOOKING TO THE FUTURE

These efforts have made significant contributions to global progress in protecting biodiversity. However, there remains much to be done, and the conservation need is high. Jones, et al (2016) predicted that 107 highly threatened insular terrestrial vertebrates (229 populations) have benefitted in some way from invasive mammal eradications on islands, however this represents just 12% of all 860 highly threatened terrestrial vertebrates occurring on islands. The picture is brighter for seabirds, where 47% of critically endangered and 74% of endangered species were predicted to have benefitted from invasive mammal eradications to date. Considering the future, McCreless, et al. (2016) found that efforts to control or eradicate relevant invasive species could prevent 41–75% of future predicted extirpations of populations of threatened vertebrate species. Almost half of these extirpations reflect species with a single population (endemic) and thus extirpation is the same as extinction.

The number of islands targeted for eradication are few compared to the number of islands worldwide. Invasive rodents are widespread, with estimates of 80% of the world's island groups being invaded (Atkinson, 1985). Recent estimates suggest there are > 400,000 islands in the world > 10 ha (UNEP-WCMC, 2013) yet only ca. 450 have been the focus of rodent eradications (DIISE, 2014). Thus, the need to increase the scope and scale of efforts to eradicate invasive vertebrates is known (Philips, 2010). A considerable number of these invaded islands are outside the boundaries of what is considered feasible for invasive species eradications today, and innovative approaches will need to be established to realise these opportunities (Campbell, et al., 2015). These include use of some of the innovations mentioned above as well as ones yet to be envisioned. Two additional focal areas for development include the social acceptability of these projects and increased funding to implement projects.

CONSERVING SPECIES ON INHABITED ISLANDS – UNDERSTANDING THE SOCIAL CONTEXT

Due to the overlap of human settlements and biodiversity there has been an increasing interest in eradication projects on inhabited islands (Oppel, et al., 2011). Simberloff, et al. (2018) reported 194 eradication attempts on 94 inhabited islands, and a "sharp uptick" in numbers of attempts on inhabited islands for all species except rodents in 1960 and for rodents in 1990. Notable projects under consideration include Lord Howe Island, Robinson Crusoe, Great Barrier Island and Floreana Island. Glen, et al. (2013) make the case that inhabited islands often support a suite of invasive species and thus restoration efforts can require multi-species eradications that must take into account the ecological impacts of improper sequencing of removals and potential negative consequences of allowing some invaders to remain. Combining this challenge with that of gaining social license to achieve eradication, inhabited islands have been hailed as a next great challenge for conservation (Glen, et al., 2013).

It is likely that most land managers attempting to implement invasive vertebrate eradications on islands would prefer to do so in the relatively accommodating social environment of New Zealand, where signs in tourism shops proudly report on their efforts to control invasive species. Understanding the underlying reasons for social acceptance, or lack thereof, for eradication projects, is an important aspect of planning an appropriate process to achieve stakeholder support and approval for a project. As an example, the New Zealand conservation movement arguably began with efforts to protect its endemic birds, including the national bird, the kiwi (genus *Apteryx*) (Stoltzenberg, 2011). Given that invasive species currently are their greatest threat, it is natural that control and eradication enjoy broad support within the country. Contrast this with the United States, where some suggest the environmental movement can be traced back to Rachel Carson's Silent Spring (1962), which highlighted the imminent extinction of the US national symbol, the bald eagle, (*Haliaeetus leucocephalus*) from pesticide exposure. It is exactly these kinds of underlying human conditions that can impact attitudes about invasive species and the tools to control and eradicate them. Island restoration projects have typically applied significant rigor to the biological science necessary to understand invasive mammal eradication projects. As projects face more complex human dimensions, it will be necessary to apply the same rigor to the social sciences in order to achieve the necessary project support to proceed.

INCREASING FINANCIAL AND STAKEHOLDER SUPPORT

To expand funding opportunities for island restoration projects it is important to expand project justifications beyond biodiversity conservation to include human health and livelihoods, and ecosystem services. This will require new research to document and communicate the non-biodiversity impacts of these projects. For example, the Lord Howe Island rat eradication project underwent a comprehensive Cost Benefit Analysis that demonstrated there would be a benefit cost ratio of 17.0, i.e. 17 dollars in benefits for every dollar spent on the project (Gillespie, 2016). A similar approach was completed for the Cabritos Island donkey eradication in the Dominican Republic (Rijo, 2014). This analysis showed a benefit cost ratio of between 2.0 and 4.2 depending on the methods used to remove all of the donkeys and resulting cost of the work. Additional efforts to highlight the value of vertebrate eradications on islands to humans, including human health (de Wit, et al., 2017), ecosystem services (Peh, et al., 2014), and agriculture will be key to securing the necessary support, both financial and stakeholder, to meet the challenge.

Making a strong link between island restoration and marine conservation is important for maximising available resources. Islands serve an important function in marine ecosystems (Gove, et al., 2016), including providing key breeding habitat for species that are dependent on marine resources. Most seabirds, sea turtles and marine mammals are dependent on islands to reproduce yet are key members of marine ecosystems. Making this case to marine funders and incorporating goals to protect and maintain populations of top level native predators in the management plans of these reserves is a good place to start.

Climate change is projected to have a significant impact on islands and island species and there are significant global financial resources available for addressing climate change impacts. Tershy, et al. (2015) argue that some of the same attributes that make island species vulnerable to invasive species, primarily smaller ranges and population sizes and less genetic diversity, also make them vulnerable to climate change. For many island ecosystems, invasive mammal eradications, in combination with other restoration actions, can increase resilience to projected climate change impacts, and provide refugia for species whose habitat is projected to be lost. However, proposed island restorations on low elevation islands should consider future sea level rise projections (Courchamp, et al., 2014) and include this in the project cost/benefit analysis.

Partnerships are not new to conservation, yet as island restoration projects expand in size and scope, diverse partnerships become more important to their success. Non-governmental organisations and governments working collaboratively together are becoming more commonplace. For example, the United States Fish and Wildlife Service has established a national level Memorandum of Understanding with other government agencies and US based NGOs to facilitate invasive species work and move from a project focus to a more programmatic one. Collaboration between NGOs internationally is also becoming more commonplace in the implementation of eradication projects. An example is the partnership between Island Conservation and Birdlife International on the multi-island, multi-species eradication in the Acteon and Gambier archipelagos, a project led by the local Tahitian NGO, and Birdlife Partner, SOP Manu. There are opportunities to expand these types of governmental and non-governmental partnerships, to enhance the capacity for conservation actions worldwide. Much is written about how to create successful partnerships, and common tenets to these types of partnerships are working to clarify shared values, programme goals, respective responsibilities and definitions of success.

Perhaps one of the greatest opportunities to grow support for island conservation work in this increasingly connected and wired planet is through communication and outreach. Effective communication requires sharing the right information with the right audience at the right time. Story-telling is a communication approach that can make difficult to understand ideas, such as the need to kill non-native species to conserve native ones, more accessible. Having island residents and stakeholders tell their stories or presenting a project from the viewpoint of the native species that will benefit, can resonate far more than statistics and summaries of what has happened somewhere else. The Goodman Center (<www.thegoodmancenter.com>) is a resource that can help train how to develop and tell compelling stories. For island restoration, the audiences are varied – funders, stakeholders, island communities and practitioners. This requires creating story arcs that reflect the values of key decision-makers and involve rigorous and defensible research to create story content. The recovery associated with removing invasive species from islands is often exceptional, providing compelling and dramatic messages that can be shared to generate interest in projects. Investing in the monitoring to document these stories is often under-valued, yet the link to funding future projects is clear. The platform for telling stories and reaching some audiences is evolving quickly alongside technology, thus these social media platforms require constant innovation and novel approaches to reach audiences. Conversely, many island communities communicate the same way they did decades or even a century ago, with shared experiences and face-to-face time as the key medium. Effective and thoughtful planning of communications will continue to evolve as necessary components of island restoration.

CONCLUSION

There are few conservation approaches that can match the return on investment of invasive mammal eradications on islands. As the earth continues to lose biodiversity at a rapid pace, with islands disproportionately affected, it is urgent to increase the rate at which islands are restored. Innovation has played a key role in past increases in eradication efficacy and efficiency (Keitt, et al., 2011) and new innovations are primed to do the same (Campbell, et al., 2015). However, these innovations must expand beyond the technical aspect of how to eradicate invasives and include ways to increase funding and stakeholder engagement and support. With greater buy in for island restoration projects they will become easier to implement.

Tackling invasive non-native species in the UK Overseas Territories

G.E. Key and N.P. Moore

GB Non-Native Species Secretariat, Animal and Plant Health Agency, Sand Hutton, York YO41 1LZ, UK.
<jillian.key@apha.gov.uk>.

Abstract The 16 UK Overseas Territories (OTs) together account for 94% of the UK's unique biodiversity and make a significant contribution to global biodiversity. Being predominantly islands, the OTs are very vulnerable to the introduction of potentially harmful invasive non-native species, and pressures are increasing with the continual growth of international trade and impact of climate change. Biosecurity is acknowledged as the most cost-effective means of addressing invasive species threats for small islands, and yet the OTs face many challenges in the implementation of biosecurity controls. In 2016 a UK Government funded project "Tackling Invasive Non-Native Species in the UK Overseas Territories" was initiated to improve the biosecurity of the OTs against non-native species in order to improve their environmental resilience and food security through technical assistance and capacity building. A gap analysis carried out in early 2017 assessed the strengths and weaknesses for all 16 OTs along the biosecurity continuum in three areas: (1) prevention (2) early warning and rapid response, and (3) long-term management. Overall, capacity is weakest in the area of prevention and greatest in that of long-term management. Border activities, where implemented, are primarily linked to agricultural production and animal health. Few OTs have carried out horizon scanning or comprehensive pathway analysis or have the capacity to carry out pest risk analysis. Greatest capacity is seen in the relatively well resourced Antarctic and sub-Antarctic territories, and in St Helena Island which was the subject of a 4-year project in anticipation of air access. Legislation is generally weak, and few OTs have developed territorial biosecurity policies or strategies. Officers responsible for biosecurity often have a range of functions in addition to their biosecurity roles, lack access to specialist expertise and diagnostic facilities, and may also lack access to appropriate training. This compromises their ability to deliver effective biosecurity. This situation is common to many small island states.

Keywords: biosecurity, capacity, gap analysis, horizon-scanning, pathway-analysis, prevention

INTRODUCTION

The 16 UK Overseas Territories (OTs) together account for 94% of the UK's unique biodiversity and as such make a significant contribution to global biodiversity (Churchyard, et al., 2014). Despite this, involvement of the UK government in the OTs with regards provision of financial and other resources is minimal, with the OTs receiving only project funding from the UK (e.g. Vaas, et al., 2017). Being predominantly islands, the OTs are very vulnerable to the introduction of potentially harmful invasive non-native species, recognised as the biggest threat to island biodiversity, as well as to food security and sustainable development (Copsey, et al., 2018). Pressures are increasing with the continual growth of international trade, the main driver of the spread of invasive species, resulting in higher numbers of individuals of more species being moved around the world, both deliberately and accidentally. The chances of a new potentially harmful species arriving and establishing in a new area are therefore greater. The implementation of biosecurity measures is aimed at minimising this risk (Copsey, et al, 2018), and contributes towards achievement of Strategic Goal B of the Convention on Biological Diversity, *Reduce the direct pressures on biodiversity and promote sustainable use*, and specifically Aichi Target 9 (UNEP, 2011).

Biosecurity, defined as measures to reduce the risk of introducing or spreading invasive non-native species (and other harmful organisms such as diseases) in the wild, has long been acknowledged as the most cost-effective means of addressing invasive species threats for small islands (for example Tye, 2009). To be effective, actions need to be implemented across the biosecurity continuum, with pre-border controls at the country of origin, inspections and interceptions at the border, and post-border surveillance and interventions in the wider environment, all applied to both deliberate (legal and illegal) and accidental introductions. Once implemented, biosecurity actions must be maintained as part of normal government practice.

The IUCN announced the Honolulu Challenge at the World Conservation Congress 2016, calling for greater action to tackle the issue of invasive non-native species across the globe, with particular attention to preventative action and the development of effective biosecurity policies (IUCN, 2017).

As part of the UK Government's response the 3-year project *Tackling Invasive Non-Native Species in the UK Overseas Territories* was initiated. Its objective is "to improve the biosecurity of the OTs against invasive non-native species to improve their environmental resilience and food security; achieved through reducing the risk and impact of invasion and natural hazards via technical assistance and capacity building".

In order to plan the appropriate capacity building activities, a gap analysis was carried out in January 2017 on biosecurity practices and capacity in all 16 UK OTs (Fig. 1) (information from McPherson, 2016):

Anguilla: one main and a number of smaller islands in the Caribbean region with a total area of 90 km^2 and population of 13,572.

Ascension Island: a single main island in the South Atlantic, with an area of 87 km^2 and population of 1,000.

Bermuda: eight connected islands and over 190 smaller islands in the wider Caribbean with a total area of 53.7 km^2 and population of 65,038.

British Antarctic Territory (BAT): the Antarctic Peninsula and two groups of nearby islands, with a total area of 1,709,400 km^2 and no permanent population.

British Indian Ocean Territory (BIOT); archipelago of over 50 small low-lying islands in the Indian Ocean, with a total area of 50 km^2 and no permanent population, but a large permanent military presence.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 637–642. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

British Virgin Islands (BVI): Four main islands and over 50 small islets and cays in the Caribbean, with a total area of 151 km^2 and population of 28,882.

Cayman Islands: three islands in the Caribbean, with a total area of 264 km^2 and population of 54,397.

Cyprus Sovereign Base Areas (CSBA): two separate areas, Akrotiri-Episkopi (the Western SBA) and Dhekelia (the Eastern SBA), on the island of Cyprus in the Mediterranean, with a total area of 254 km^2 and population of 15,700.

Falkland Islands: two main islands and over 770 smaller islands in the South Atlantic, with a total area of 12,173 km^2 and population of 2,841.

Gibraltar: a peninsula at the southern coast of Spain, with an area of 6.8 km^2 and population of 31,465.

Montserrat: a single island in the Eastern Caribbean, with an area of 102 km^2 and population of 4,922.

Pitcairn Islands: four islands in the South Pacific, with a total area of 48.7 km^2 and population of 47, all resident on the main island.

St Helena Island: a single main island in the South Atlantic, with an area of 121 km^2 and population of 4,534.

South Georgia and South Sandwich Islands (SGSSI): one main island and several small ones in the South Georgia group and a group of 11 small islands in the South Sandwich Islands Group, all in the sub-Antarctic. Total area is 3,903 km^2 with no permanent population.

Tristan da Cunha: four islands in the South Atlantic, with a total area of 207 km^2 and population of 268.

Turks and Caicos Islands: two island groups of over 120 small islands in the Caribbean, with a total area of 417 km^2 and population of 49,000.

METHODS

A questionnaire was designed, identifying the components required for an effective biosecurity programme along the biosecurity continuum. Emphasis was given to the pre-border and post-border activities targeted by the project, grouped in three areas: 1) Prevention; 2) Early Warning and Rapid Response (EWRR); and (3) Management, Prioritisation and Frameworks (MPF) in the components defined as follows:

Prevention

Pest Risk Analysis (PRA): system established and in use to evaluate the likelihood of the entry, establishment, or spread of a pest or disease, and the associated potential biological and economic consequences. Both phytosanitary and zoosanitary risks covered.

Non-Native Species Risk Analysis (NNRA): comprehensive risk assessment frameworks exist to assess the risk of non-native species (plant and animal) becoming invasive.

Pathway Analysis: prioritised pathways of entry identified, and results used as the basis for procedures.

Horizon Scanning: horizon scanning exercise carried out to identify invasive species most likely to invade via identified pathways.

Contingency Planning: formalised generic contingency plan or plans in place to deal with priority invasive species that are likely to arrive. This is divided into (i) Plants, including both plants and plant health risks (non-native plant pests and diseases); (ii) Animals, including both vertebrates and animal health risks (non-native vertebrates, animal diseases and parasites); and (iii) Other risks (invertebrates other than plant pests, and marine species).

Border Operations: in-place and operational, considering staffing, provision of dedicated facilities, procedures and protocols in place, public awareness, and levels of compliance. Both phytosanitary and zoosanitary risks covered.

Early warning and rapid response

Alert System: clear system in place for reporting incursions or new species, for both plant and animal (vertebrate and invertebrate) risks.

Surveillance: generic and/or incursion specific programmes in place for surveillance of priority invasive

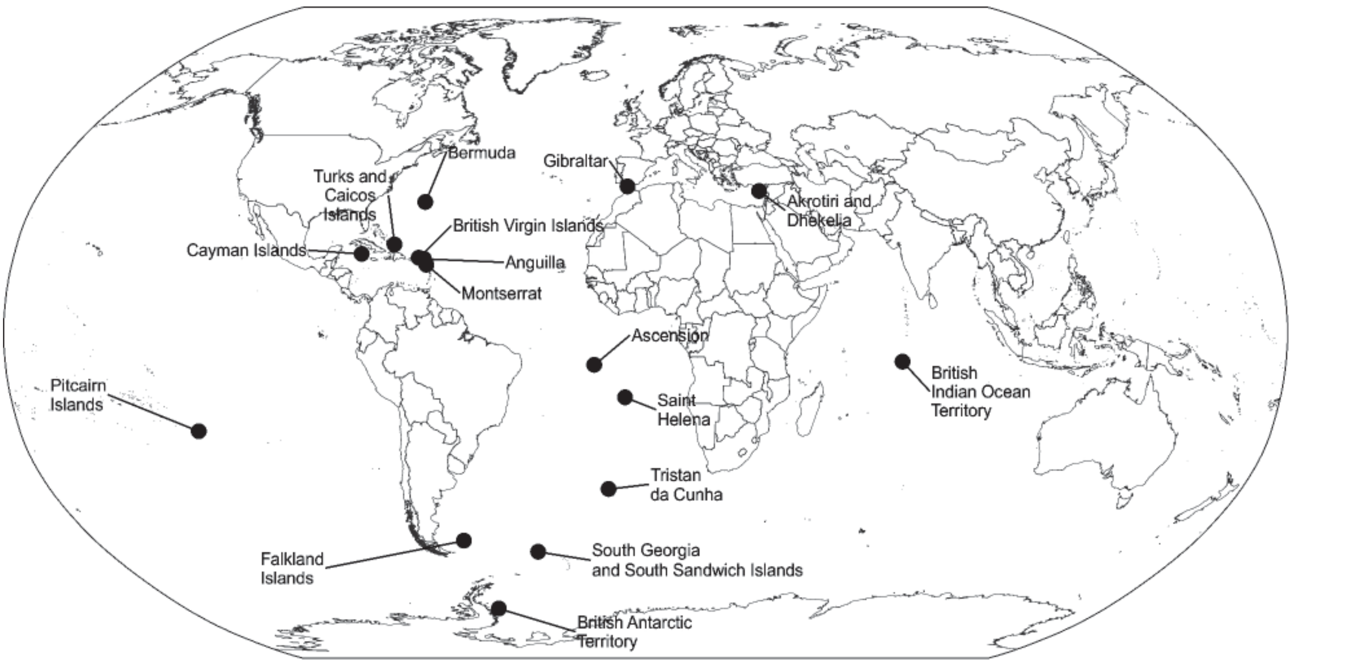

Fig. 1 The 16 UK Overseas Territories.

species. This is divided into (i) Plants, including both plants and plant health risks (non-native plant pests and diseases); (ii) Animals, including both vertebrates and animal health risks (non-native vertebrates, animal diseases and parasites); and (iii) Other risks (invertebrates other than plant pests, and marine species).

Monitoring: generic and/or incursion specific programmes in place for monitoring established priority invasive species.

Rapid Response Capacity: capacity (capability and resources) to provide rapid response to incursions. This is divided into (i) Plants, including both plants and plant health risks (non-native plant pests and diseases); (ii) Animals, including both vertebrates and animal health risks (non-native vertebrates, animal diseases and parasites); and (iii) Other risks (invertebrates other than plant pests, and marine species).

Management, prioritisation and frameworks

Prioritisation: prioritised established invasive species for control/eradication based on global risk management best practice, such as the *Guidelines for invasive species management in the Pacific* (Tye, 2009).

Baseline Data: baseline inventories available for plants (native and non-native), animals (terrestrial vertebrates and invertebrates), and other (marine species).

Territorial Framework: biosecurity legislation in place and enforced; biosecurity strategy or policy in place or endorsed, and being implemented.

Contacts were established in each OT for both agriculture and environment sectors, and territory capacity assessed though a combination of email, telephone interviews and face to face interviews. At least two people were involved in each territory, with the exception of BAT where there was only one. Capacity for each component was rated and scored as follows:

None - No action taken / Nothing in place. Score of 0

Basic - Some actions taken / Basic framework or actions in place / Actions planned in near future and expected to take place. Score of 1.

Some - Some substantial advances while other actions remain to be done / Actions being actively implemented along a planned timeframe. Score of 2.

Good - Substantive actions taken / Substantial framework or actions in place / Action being implemented / Action achieved. Score of 3.

Scores were summed across the components and territories to provide a simple index for comparison purposes. The text and ratings assigned to the components were in all cases agreed and approved by the contacts in-country for each territory. The resulting scores were then cross-checked by Dr Niall Moore of the GB Non-Native Species Secretariat to ensure that the ratings matched the comments; any adjustments were then discussed and agreed by the relevant contacts.

Final scores were checked by visitors from the RSPB, IUCN, Animal and Plant Health Agency (APHA), UK, and South Georgia Heritage Trust with recent experience of the relevant territory. Again, any discrepancies were then discussed and agreed by the relevant contacts before the scores were finalised.

RESULTS

Responses were obtained from all 16 OTs. Overall, respondents welcomed the project and expressed frustration where they identified gaps in their territory.

Table 1 Overall scores in the areas of Prevention, Early Warning and Rapid Response (EWRR) and Management, Prioritisation and Frameworks (MPF) and total scores for each of the 16 OTs and the UK in ascending order, out of a maximum overall score of 66. Maximum possible scores per area are 24 (Prevention and EWRR) and 18 (MPF). Overall mean score excludes that for the UK.

Territory	Prevention	EWRR	MPF	Overall score
Turks and Caicos	4	8	7	19
BIOT	3	5	12	20
CSBA	3	7	11	21
Montserrat	5	8	9	22
Ascension	5	8	10	23
Anguilla	8	4	12	24
Bermuda	5	9	12	26
Tristan da Cunha	7	7	12	26
Pitcairn	9	10	7	26
Falkland Islands	11	10	10	31
Cayman	11	9	13	33
BVI	10	14	10	34
Gibraltar	3	17	17	37
BAT	17	11	17	45
St Helena	14	18	13	45
SGSSI	14	19	18	51
UK	21	20	17	58
Overall mean score for the OTs	8.1	10.3	11.9	

Differences between territories

Scores for each territory in the three categories of Prevention, EWRR and MPF are shown in Table 1, with the territories listed from the lowest overall score (weakest capacity) to the highest (most capacity). The estimated score for the UK is given for comparison.

The three highest scoring territories are the two Antarctic and sub-Antarctic territories, and St Helena. BAT and SGSSI (with total scores of 45 and 51 respectively) benefit from their unique environmental status and considerable research input. St Helena (with a total score of 45) has been the subject of a 4-year project to strengthen biosecurity in anticipation of air access. The total score for SGSSI (51) is closest to that estimated for the UK (58).

A group of four territories have total scores between 31 and 36, comprising in ascending order: Falkland Islands, Cayman Islands, BVI and Gibraltar; Gibraltar has a score accounting for less than 20% of their overall score in the area of Prevention, but scores highly in the other areas.

A group of nine territories have the lowest totals, with scores between 19 and 26 and only one or two points between each, comprising in ascending order: Turks and Caicos Islands, BIOT, CSBA, Montserrat, Ascension Island, Anguilla, Bermuda, Tristan da Cunha and Pitcairn. Three territories are particularly weak in the area of Prevention, with scores accounting for less than 20% of their overall score: BIOT, CBSA and Bermuda. All four have ratings of Basic or None for all components in this area with only two exceptions: Bermuda with a rating of Some for border operations, and CBSA with a rating of Some for contingency planning for animals and animal health risks. Anguilla has a total score accounting for less than 20% of overall in EWRR, with all ratings in this area of Basic or None.

Components of biosecurity

The overall capacity is weakest in the area of Prevention, with an average score of 8.1, and strongest in the area of Management, Prioritisation and Frameworks, with an average score of 11.9 (Table 1). Table 2 shows total scores by component out of a maximum possible score of 48.

The highest scoring components are the group encompassing baseline inventories. This is generally good and especially for plants, with a total score of 43. Baseline knowledge for animals (terrestrial vertebrates and invertebrates) and other (marine species) both had a total score of 35.

The next highest scoring component is a group of four with scores of 28 to 30: alert system, prioritisation, legal framework and border operations.

The greatest capacity gaps are those of horizon scanning and contingency planning for other risks, both with total scores of 8. The second greatest gap is a group of three components: rapid response for other risks, surveillance of other risks and non-native risk analysis, all with scores of 12. Only five OTs have carried out horizon scanning, rated as Good only for BAT which has benefitted from considerable research input. The other OTs did not

Table 2 Total scores for each component: the maximum possible score is 48.

Component			Total score
Prevention			
	Risk Analysis (PRA)		16
	Risk Analysis (NNRA)		12
	Pathway Analysis		17
	Horizon scanning		8
	Contingency Planning	Plants and plant health risks	15
		Animals and animal health risks	23
		Other risks	8
	Border operations		30
Early Warning and Rapid Response			
	Alert System in Place		30
	Surveillance	Plants and plant health risks	23
		Animals and animal health risks	17
		Other risks	12
	Monitoring		23
	Rapid response Capacity	Plants and plant health risks	23
		Animals and animal health risks	24
		Other risks	12

		Territorial policy or strategy	20

understand what horizon scanning was. "Other risks" comprises non-crop pest invertebrates and marine species, for which capacity is clearly weaker than for crop pests or plants; even for the UK where surveillance for other risks was the only component which was rated Basic, all the other components being rated as Some or Good.

DISCUSSION

The relatively small population size of the OTs means that biosecurity officers often have a range of functions and responsibilities in addition to their biosecurity roles, lack access to specialist expertise and diagnostic facilities, and may also lack access to appropriate training. This compromises their ability to deliver effective biosecurity. There is a dependence on community support, itself dependant on good levels of awareness and understanding. Officers carrying out biosecurity functions work closely with customs, and this is clearly an important partnership.

Biosecurity practices tend to be based on historic legislation inherited from their colonial pasts and not updated, with procedures aimed at protecting agriculture and production, focusing primarily on managing deliberate introductions to reduce the introduction of crop pests and livestock diseases, with a few exceptions (e.g. BAT and SGSSI). Legislation is weak and scattered across a number of regulations relating to customs, plant health and animal health. The broader threat posed by non-native invasive species to the environment is not being recognised, and extension of biosecurity approaches to species, which are not crop pests or livestock diseases, is generally poor or non-existent.

For many OTs, actions such as border operations and post-border surveillance are focused on easily-identifiable species such as Pacific lionfish *Pterois volitans*, brown tree snake *Boiga irregularis* and Tephritid fruit flies (Diptera: Tephritidae). While this is a good starting point for biosecurity teams, actions need to go further, and target more cryptic species identified as priority, as well as taking a generic approach to detect the unexpected. Biosecurity actions across the continuum are particularly weak for non-crop pest invertebrates, except where there has been a historic incident of note, such as the jacaranda bug (*Orthesia insignis*) outbreak on endangered endemic gumwood trees (*Commidendrum robustum*) in St Helena in the mid-1990s, which raised attention within the Territory to the issue of invasive non-native species.

BAT is distinct in being one of the few OTs which is not an island but one of 29 national Antarctic programmes. As such, BAT has no control over what is done on other stations, or what the tourism industry does with regard to biosecurity unless they come to BAT stations, rendering it vulnerable to intra-Antarctic transfer of non-native species. This issue is recognised as a concern in the Antarctic and included by the Antarctic Treaty Committee for Environmental Protection (CEP) in the 2016 CEP Non-native Species Manual (Anon., 2016a).

CSBA and Gibraltar are also not islands and consist of enclaves adjacent to EU countries (Spain and Cyprus). CSBA has relatively few resources dedicated to biosecurity, and with relatively long leaky land borders with the Republic of Cyprus this is to be expected. Gibraltar puts most attention into actions in the areas of Early Warning and Rapid Response, and Management, Prioritisation and Frameworks, with comprehensive monitoring programmes for existing invasive species, and surveillance programmes and rapid response capability in the event of an incursion. Actions are detailed in the Biodiversity Action Plan (Perez, 2006).

Where OTs have rated capacity as Basic or above in these components it is primarily due to the outcome of a specific research project, usually UK-funded by a competitive research grant such as a Darwin Plus award, or builds on a topical invasive species issue such as the Pacific lionfish (*Pterois volitans*) and pink hibiscus mealybug (*Maconellicoccus hirsutus*) invasions in the wider Caribbean (Morris & Whitfield, 2009; <http://www.cabi.org/isc/datasheet/40171>).

Risk Analysis (PRA and NNRA) comes quite low, with scores of 16 and 12 for PRA and NNRA respectively. Risk analysis, when done correctly, is a time-consuming and complex procedure which requires access to taxonomic and other expertise and, in most cases, funding to bring experts together. The small, resource-limited OTs are challenged to achieve this, and most carry out simplified forms of risk analysis as well as they can, on an ad-hoc basis, with heavy reliance on published databases such as the CABI Invasive Species Compendium and Global Invasive Species Database, and on assessments carried out for Florida, Hawaii and the Pacific Islands for plant species (<http://www.hear.org/pier/wra.htm>). While these make a good match for Pitcairn, their suitability to the other OTs is less certain. Comprehensive, published assessments specifically for the island groups in the Caribbean and South Atlantic would be very helpful.

The introduction of new exotic species as pets is of concern, particularly to the Caribbean territories, due to the risk of escapes or deliberate dumping of potentially invasive species in the wild. In the Caribbean, at least some introductions are linked to hurricanes: in Anguilla it is known that at least two monkeys escaped from an individual, who had them as pets, after a hurricane in 1999, and the green iguana was first introduced on logs of wood during a hurricane in 1995 (R. Connor, Government of Anguilla, pers. comm.). Escapes of exotic fish are not considered a big problem, probably due to the lack of large bodies of fresh water inland in the OTs. Escapes of exotic birds are also not considered a big issue. Currently, one of the commonest domestic species of concern is the cat (*Felis catus*) (R. Connor. pers. comm.). Unwanted kittens are frequently dumped in the wild and form feral populations, threatening wildlife such as the native Anguilla racer snake (*Alsophis rijgersmae*), endemic Antillean iguana (*Iguana delicatissima*), or endemic St Helena wirebird (*Charadrius sanctaehelenae*) (Varnham, 2006).

With the exception of CSBA, all the OTs carry out biosecurity border operations to a greater or lesser extent, and 12 out of the 16 rated this as "Some" or "Good". Focusing limited resources on border inspections and interceptions is cost-effective for islands where the border is clearly defined and defendable. However, in a continental context with leaky borders which cannot be readily defended, an alternative strategic approach is to identify the priority species or pathways of concern and work more widely across the biosecurity continuum, particularly post-border. Tactics adopted are based on the results of pathway analysis and horizon scanning. In this context, high scores across the board for all components aren't necessarily appropriate, instead a package of activities is adopted designed to minimise the identified risks. CSBA and Gibraltar are not island territories and have different priorities. In CSBA, the focus is on the zoosanitary risks of new animal disease outbreaks and public health issues, routine monitoring is of aerial insect vectors, specifically mosquitoes, and rapid response capacity exists to respond in the event of human or animal health outbreak. Gibraltar benefits from strong post-border monitoring, surveillance and prioritisation actions to protect its unique biodiversity, as laid out in the Gibraltar Biodiversity Action Plan and Reserve Management Plan (Anon., 2016b; Perez, 2006).

Ascension Island and BIOT also rated border operations as "Basic". Both territories have limited or no agricultural production and consequently little political incentive in the past to invest in biosecurity border controls. The limited resources available to biosecurity are targeted at post-border actions directed towards the highest risk species, namely mosquitoes of human health concern and fire ants in Ascension Island, and brown tree snake in BIOT. This approach emphasises the importance of horizon scanning, pathway analysis and accurate assessment of risks in the first place, and the need to build capacity in these areas to provide information on where to target resources.

PRIORITIES AND RECOMMENDATIONS

Aiming to build capacity for all OTs so that they have high scores across the board is neither realistic nor suitable. Whereas for many OTs an appropriate strategy would be to devote a substantial proportion of available resources to border operations, for others, such as CSBA or Ascension Island, a more cost-effective strategy instead would be to establish post-border surveillance programmes targeted at identified priority species or pathways. In all the OTs resources are limited, and officers must be very focused in their activities. To do this effectively, each OT needs basic information on the range of potential invasive species (horizon scanning), how they might arrive (pathway analysis) and how to assess risk (PRA and NNRA). Capacity in these fundamentals was found to be lowest in this gap analysis, and initial activities will concentrate in this area:

Building fundamentals:

- Horizon scanning linked with pathway analysis: to determine what potential invasive species are out there and the different ways they can arrive. The information is used to design an appropriate package of responses which guides how the available resources should be best divided up between preventative actions, such as pathway or border operations, and reactive actions, such as surveillance and rapid response.
- Risk analysis: the process of assessing biosecurity risks. OTs need access to support for risk analysis, and a harmonised approach across the OTs to guide practices on-island for:
- Assessment of plant or animal species for potentially invasive characteristics;
- Assessment of the risks of a plant or animal species carrying potentially harmful pests, parasites or diseases.

Establishing the framework:

- Territorial policy or strategy: agreed actions to achieve the appropriate package of response, including a communications strategy for awareness to improve compliance and internal advocacy to promote government support.
- Legislation: regulate across the biosecurity continuum, including actions to contain, control and eradicate established invasive species. Provision of model legislation would allow a harmonised approach across OTs; assistance with drafting to apply it at the territory level is also required.

Delivery:

- Training: on all aspects of biosecurity, with specific needs varying with the Territory. This provides essential underpinning to deliver the fundamentals and framework outlined above.

Adding value:

- Regional coordination: use regional coordination bodies where they exist and are active, linking among the UKOTs and also to appropriate independent countries and other territories.
- Build networks, either strengthening existing or developing new ones, to promote sharing and exchanges, and promote the confidence and inspiration which result from peer-learning networks.

Building capacity in the activities outlined above will equip the officers responsible for biosecurity in the OTs with the capacity to develop other actions such as contingency and rapid response planning.

ACKNOWLEDGEMENTS

We would like to take this opportunity to thank all the people in the UKOTs who responded for their collaboration with the gap analysis work, for taking valuable time and effort to compile information in order to make sure the results are as useful and accurate as possible.

A little goes a long way when controlling invasive plants for biodiversity conservation

Abstract Invasive species, particularly animals, are being eradicated from islands at ever more ambitious scales. In order to protect island biodiversity and the essential ecosystem functions that it provides, however, plant invasions should be given more management attention. While many advances have been made, plant eradication is inherently more difficult than animal eradication due to persistent seed banks, and eradication may not be possible for more extensive populations. While maintenance control has been successful, critics question the sustainability and priority of these efforts, and targets vary widely. Developing consistent and informed targets requires an understanding of how biodiversity varies with invader cover, yet little is known about this topic. Our research suggests that limited control efforts may be highly beneficial. We conducted a meta-analysis of 54 studies to investigate the effects of plant invasions on invertebrate diversity, incorporating invader cover and residence time as potential causal mechanisms. We also contrasted restored plots with otherwise native plots. We found that invertebrate species richness was 31% lower in exotic plots than in native plots, and that there is a threshold at around 70% invader cover after which the negative effects are significant across all studies. Furthermore, these negative effects tended to decrease with time, and invertebrate richness was even greater in restored plots. The implication is that by removing 30% or less of invasive plant cover and restoring natives, we can achieve many of our conservation goals. We argue that by maintaining invasive patches at or below 70% exotic cover at a site in the near term, we can buy time for both the islands' insect herbivores to adapt to use the invader, and for managers to continue improving plant eradication technologies. By retaining native diversity in this way, we can help to increase the resistance and resilience of these systems to global change and other stressors.

Keywords: invader management, invasive plants, invertebrates, island biodiversity, meta-analysis, threshold

INTRODUCTION

Islands support many organisms found nowhere else in the world, and contribute disproportionately to global biodiversity (Kier, et al., 2009). They also provide critical habitat for 45% of the IUCN-listed species (Keitt, et al., 2011). To protect this extraordinary biological diversity, invasive species are being eradicated from islands at ever more ambitious scales (Clout & Veitch, 2002; Burbidge, 2011), and eradication is increasingly promoted as an important direction for island conservation. This is promoting recovery of many rare and endangered species, and of biodiversity as a whole (e.g. Klinger, et al., 2002; Rauzon, et al., 2002). This retained biodiversity can increase the stability of a system (Hautier, et al., 2015), its resistance and resilience to global change (Mori, et al., 2013; Isbell, et al., 2015) and its resistance to further invasion (Tilman, 1999).

Island eradication and control efforts overwhelmingly target invasive vertebrates, as an analysis of previous Island Invasives conference proceedings reveals (Veitch & Clout, 2002; Veitch, et al. 2011; 87% and 97% of the papers, respectively). Yet plant invaders are also key factors in native biodiversity decline (Wilcove, et al., 1998; Gaertner, et al., 2009), with their impacts to disturbance regimes, nutrient cycling, and fluxes of materials and energy altering ecosystem structure and function (Mack & D'Antonio, 1998; Liao, et al., 2008; Ehrenfeld, 2010). Furthermore, invasive animal removals often result in the ecological release of invasive plants (e.g., Klinger, et al., 2002; Zavaleta, et al., 2001). In order to protect island biodiversity and the essential ecosystem functions that it provides, plant invasions should be given more management attention. Yet eradication, the widely preferred alternative to control (Clout & Veitch, 2002; Burbidge, 2011), is often problematic for invasive plants.

Plant eradication is inherently more difficult, and generally more expensive, than animal eradication due to persistent seed banks, although many advances have been made. Under the right conditions, seeds can persist for several hundred years or more (Jha, 2005). On the Pacific Islands of French Polynesia, Hawaii, and New Caledonia, eradication of the invasive alien tree *Miconia calvescens* has not yet been completed despite more than 15 years of intensive control, due to a prolific and persistent seed bank (Meyer, et al., 2011). Similar issues have plagued an eradication programme for *Sagina procumbens* on Gough Island in the South Atlantic, despite an impressive array of innovative control techniques (Cooper, et al., 2011). Invasive plant eradication can be achieved, but it typically involves small populations, treated early in the invasion process, with a swift and strong response (Mack & Lonsdale, 2002; Rejmanek & Pitcairn, 2002).

Where eradication is not feasible, maintenance control may be implemented. Maintenance control is the "coordinated and consistent management of invasive plants in order to maintain the plant population at low levels" (University of Florida, 2018). This approach has been successful, but typically requires a large labour force, and critics question the sustainability and priority of these efforts (Simberloff, 2009). Furthermore, targets for native cover vary widely and invasive cover targets are typically highly stringent. For example, a survey of 21 California habitat restoration plans containing specified thresholds (gathered via a Google search) reveals native cover targets ranging from 15% to 90%, with an average target of 62% (n=20). Exotic cover targets, on the other hand, were never greater than 10% (n=7). It is also unclear how these targets were derived. Developing consistent and informed targets requires an understanding of how biodiversity varies with invader cover, however little is known about this topic.

An important link between plant communities and the greater food web is the invertebrate fauna. Invertebrates are a key component of biodiversity, comprising 97% of all animal species (Spelman, 2012) and playing key roles in nutrient recycling, pollination, seed dispersal, energy flow,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 643–650. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

and structuring plant and animal communities (Gullan & Cranston, 2005). They also respond quickly, sensitively, and locally to environmental changes (Kremen, et al., 1993), and are thus excellent indicators of the consequences of plant invasions and other disturbances. Analysis of invertebrate responses to plant invasions can help delineate the drivers of biodiversity and community patterns, thus guiding the conservation and restoration of diverse native ecosystems (Lodge, 1993; McMahon, et al., 2006).

We conducted a meta-analysis to investigate the effects of plant invasions on invertebrate diversity (as a whole, including both native and non-native species), incorporating invader cover and residence time in the system as potential explanatory variables. We also contrasted the type of sites (restored or intact) used as the native comparison. A meta-analysis approach can be used to combine multiple studies and detect overall trends in biotic responses to environmental factors. Our research suggests that in control efforts, a little may go a long way.

METHODS

We compiled studies through both database queries and subsequent surveys of the references cited in compiled papers. We searched ISI Web of Science in November 2012, using the search string "Topic = (invasive OR exotic AND plant) AND Topic = (arthropod* OR insect* OR invertebrate*). From these searches, we assembled 106 published studies which compared insect, arthropod, or other invertebrate diversity in invaded versus native habitats. These studies were from both island and mainland environments and included dissertations. Studies included by richness and other diversity indices, which were analysed separately. We extracted the data directly from tables or from graphs using the programme DigitizeIt v. 1.5 (Island Bormann, Braunschweig, Germany: <http://www.digitizeit.de>).

Fifty-four studies were eligible for testing using a meta-analysis approach (means, variances and sample sizes were reported) and are included in our meta-analysis (Appendix 1). These studies represent a variety of habitat types throughout the world, ranging from grassland to scrub to riparian. Fifty-two of these studies reported invertebrate richness, and fifteen studies reported values for diversity indices incorporating evenness, with 12 reporting results for the Shannon index, two for the Simpson's index, and one for Fisher's alpha. Insects were the focus of 26 studies, while 16 studies reported results for entire arthropod assemblages, and 12 studies described results for other invertebrate groups.

We extracted descriptor variables, where available, from each study, including latitude, time since establishment of the non-native plant at both the local (study site) and/or regional (hundreds of square kilometres) scale, invader cover, and whether or not the native-dominated site was restored habitat. Where time since establishment was not reported for a given study, we obtained this information from other sources where possible. In order to utilise the studies which reported cover classes or ranges rather than exact values (over half of them), we placed invader cover into six cover classes. We used natural breaks in the data to develop the following classes: <10%, 10–30%, 30–50%, 50–70%, 70–90%, and >90%. Cover was thus considered 'absolute' and not relative. Studies reporting that the invasive plant "formed a monoculture", was "dense and continuous," or "completely dominated the landscape" were conservatively classified into the 70–90% group. We found that model results were not changed by reclassifying these into either 50–70% or >90% cover.

We used the response ratio as an estimator of effect size; in this case, the natural log of the ratio (X_{exotic}/X_{native}), where X represents the mean of either invertebrate species richness or diversity index (analysed separately) for a given study in either the 'exotic' or the 'native' locations. We chose the response ratio for several reasons: first, we were interested in the magnitude of the relative difference in invertebrate diversity between exotic and native vegetation; second, use of the logarithm ensures that deviations in these two variables are treated equally (Hedges, et al., 1999). Lastly, it allowed us to assess both the model and residual variation, giving an estimate of the importance of the variables analysed here.

We calculated a single effect size per study by averaging data collected over multiple years or seasons. When we compared invertebrate richness or diversity in one native area to those in multiple invaded areas or vice versa, we calculated separate effect sizes for each comparison. When studies included multiple levels of descriptor variables (e.g. two or more establishment times), we calculated an average effect size to determine the overall effect of invasion (vs. native plant communities) but calculated separate effect sizes for each level of the descriptor variables when analysing the effects of these descriptor variables on invertebrate richness or diversity.

We performed meta-analyses using the *metafor* (Viechtbauer, 2010) package for R 2.15.0, and used random effects models to calculate overall effect sizes for invertebrate richness and diversity (Viechtbauer, 2010; Gurevitch & Hedges, 1999). To estimate the variation in the effect size described by different categorical variables (cover, study scale, and type of control plot), we used mixed-effects models using the Q statistic. This analysis treats the variables as fixed but includes a random variance component to account for variability across the studies. In one case (invader cover), we also report results from a fixed-effects model, which restricts our inferences to the studies examined. For continuous descriptor variables (latitude, invader time since establishment) we used weighted generalised least squares regression to test their relationships with effect size.

After accounting for the variation attributable to descriptor variables, we estimated residual variation (τ^2) using a restricted maximum likelihood estimator (Viechtbauer, 2005). For studies which reported results for all descriptor variable groups (22), we used the Akaike information criterion (AIC) to determine the model that best fit the data.

RESULTS

Invertebrate species richness was 31% lower in exotic plots than in native plots (effect size = -0.37 ± 0.10 on a 0–1 scale; Z = -5.48, $p < 0.01$; Fig. 1). There was a high amount of variation in the studies using richness to indicate diversity, however (Q = 111, $p < 0.001$). Invertebrate diversity indices that incorporate evenness were less strongly affected than richness values, but still 14% lower in exotic plots (effect size = -0.15 ± 0.10; Z = -3.42, $p < 0.01$). Unlike the effect sizes for species richness, there was not much variation among studies using diversity indices (Q = 13, $p > 0.50$). The absolute value of latitude did not explain a significant amount of heterogeneity in effect sizes for species richness (Q = 1.09, $p = 0.30$), nor did study scale (Q = 0.06, p = 0.97).

Using just data from native plots that had not undergone habitat restoration, invaded plots had lower invertebrate richness compared to native plots (-0.35 ± 0.07; Z = -5.02, $p < 0.01$). There was a stronger effect when plots restored to native species were used for comparison (-0.61 ± 0.17; Z = -1.73, p = 0.08), although this was just a statistical trend, likely due to both low sample size (n=11) and high variability. When analysed together, effect sizes were significantly more negative for the comparisons between invaded and restored sites than invaded vs. otherwise native sites (Q = 5.1, p = 0.02; Fig. 1), indicating that invertebrate diversity was even greater in restored plots than in native plots that did not undergo habitat restoration.

At the local scale, the negative effects of invasive plants on invertebrate richness were greatest at the shortest time since establishment and decreased with time, but this pattern relies on a few key data points and was only marginally significant (Q = 3.0, p =0.08, Fig. 2). At the regional scale, time since invader establishment was not related to effect size (Q= 0.40, $p > 0.50$).

The impact of exotic plants on invertebrate species richness was highly variable below 70% invader cover, and only cover classes above 70% had confidence intervals that did not overlap zero (Fig. 1). When the cover classes below 70% were combined into a single category, the difference in effect sizes between exotic plant cover classes was marginal in a mixed-model analysis (Q = 4.7, p = 0.09), while the groups were very different when the data were fitted to a fixed effects model (Q = 176, $p < 0.0001$).

In all models except time since establishment, residual heterogeneity was significant (p < 0.01), indicating substantial amounts of variation in the effects that were not explained by the models. The effects of descriptor variables on effect sizes for diversity indices were not analysed, both because low sample sizes prevented it and because low residual heterogeneity obviated the need for it.

DISCUSSION

Our results showed a clear negative effect of plant invasions on invertebrate richness and diversity. This has important implications for the diversity and function of the system as a whole, since insects and other invertebrates perform so many important roles in an ecosystem – including food provisioning for higher trophic levels such as reptiles and amphibians, birds, and small mammals (Weisser & Siemann, 2004).

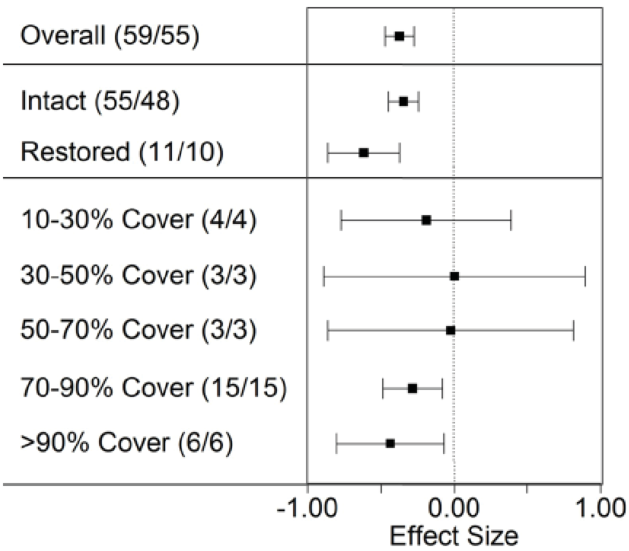

Fig. 1 Mean invertebrate richness effect sizes (± 95% confidence limits) across all studies (top panel), as well as between studies contrasting effect sizes where native plots represented restored or intact habitats (middle panel). The bottom panel shows mean richness effect sizes for exotic plant cover classes. Numbers in parentheses indicate the number of effect sizes and the total number of studies, respectively (some studies had more than one comparison).

Furthermore, the most consistent and significant negative effects of plant invaders on invertebrate richness occur when invasive plants comprise over 70% of cover. One likely reason for this threshold is a decline in the diversity of other plant species when an invader comes to dominate; for instance, Almeida-Neto, et al. (2011) found that only host plant richness explained the unimodal relationship they found between insect herbivore richness and invasive grass cover. Many previous studies have shown that insect and arthropod diversity is positively related to plant species richness, presumably owing to structural and food diversity as well as abiotic variables (e.g., temperature, moisture) (Price, et al., 2011).

The implication of these results is that, in general, with a moderate reduction of invasive plant cover and restoration of native plants to at least 30% cover, we can achieve meaningful progress towards the goal of biodiversity conservation. While some invasive plants will have impacts below this threshold (e.g. Knapp, 2014) this provides a general guideline in the absence of species-specific impact information. If a critical level of plant and invertebrate diversity can be maintained, then so can key ecosystem functions such as nutrient cycling and pollination (Gullan & Cranston, 2005).

Many will be legitimately concerned about indefinite “maintenance management” of plant invaders. Invasive plant management is challenging, and requires a long-term commitment (e.g. Mack & Lonsdale, 2002; Meyer, et al., 2011). However, holding that 70% line by removing invaders and, when needed, restoring at least 30% native plant cover will buy time, both: 1) to allow the islands’ insect herbivores to adjust to using the invader, and 2) for managers to continue improving plant control technologies and eradication strategies. We elaborate on these points below.

A novel plant species may be avoided by insect herbivores because it differs from native plants in characteristics such as nutritional quality, chemical composition, and architecture (Strong, et al., 1984; Kuhnle & Muller, 2009). Even a plant that can technically be eaten may be avoided because it is not recognised as a food source (Lankau, et al., 2004; Dudley, et al., 2012). The number of different herbivores using a novel plant tends to increase with the invader’s time since establishment, however (Kennedy & Southwood, 1984; Brandle, et al., 2008).

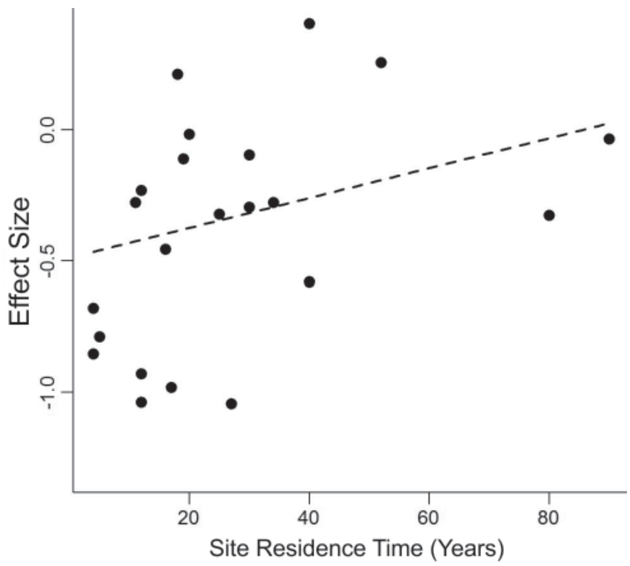

Fig. 2 Relationship between effect size for invertebrate richness and time since invader establishment at a site for the 22 studies for which these data were available. Dashes indicate line of best fit.

In our meta-analysis, where we consider the richness of invertebrates as a whole including multiple feeding guilds in addition to herbivores, we found a trend for invertebrate richness to increase with time since invader establishment (Fig. 2). This effect was only marginally significant – perhaps because it was driven by just a few key points, or perhaps because the effect of residence time is not as strong for invertebrates as a whole as it is for insect herbivores alone.

While these natural enemies are adapting to utilise invasive plant species over time, our control techniques are improving – allowing for both larger and more efficient, effective projects. For instance, a transition from ground to helicopter shooting enabled the eradication of goats on Western Australian islands (Burbidge & Morris, 2002), as did Judas goat technologies (Campbell & Donlan, 2005). Aerial surveys help with plant detection and eradication as well (Coulston, 2002; Knapp, et al., 2011), and treatment techniques have improved to avoid vectoring plant material (Coulston, 2002). Experimentation with techniques from hand-pulling to herbicide to heat and saltwater applications have improved the efficacy of invasive grass control efforts on Laysan Island (Flint & Rehkemper, 2002). Similarly, better herbicides and mapping systems have improved invasive plant control in New Zealand (Wotherspoon & Wotherspoon, 2002). Improvement in baiting technology has enabled the eradication of rats in multiple locations (Thomas & Taylor, 2002; Howald et al., 2007). Lastly, targeting multiple species at one time has proven to be both efficient and effective (Griffiths, 2011; Morrison, 2011).

It is heartening that our results showed restored plots containing even more invertebrate species than other native plots relative to invaded plots (although with greater variability). Flower visitors can be more diverse at restoration than reference sites, even after ≤ one year (Waltz & Covington, 2004; Lomov, et al., 2010). This may be because early-colonising butterflies can be attracted to more open, sunny restored areas disturbed by earth moving, invasive plant removal, and outplanting (Magoba & Samways, 2010; Hanula & Horn, 2011a). Conversely, butterfly richness can decrease as percent plant cover rises (Florens, et al., 2010). Higher invertebrate richness in restored areas is likely also related to greater plant richness and cover (Hanula & Horn, 2011), perhaps due to elements of both early- and later-successional communities being present. In this case, richness would also decrease with time as succession occurs.

CONCLUSION

The theme of this conference is "Scaling Up to Meet the Challenge." Invasive species eradication successes are being achieved at ever-increasing scales, but more attention should be paid to the significant threat of plant invasions. Although invasive plant control is challenging, our research suggests that reducing invader density to just 70% cover can have significant benefits for invertebrate biodiversity and thus ecosystem function. Furthermore, habitat restoration can give that diversity an extra boost. While the existence of seed banks dictates that this is a long-term proposition, we argue that, over time, insect herbivores will adapt to using the invader, while land managers develop ever-better control technologies. The biodiversity that is thus conserved will increase the resistance and resilience of these systems to further invasion and other stressors such as global climate change (Millennium Ecosystem Assessment, 2003; Haddad, et al., 2011), and allow us to truly achieve island conservation.

Achieving large scale, long-term invasive American mink control in northern Scotland despite short term funding

X. Lambin[1], J.C. Horrill[2] and R. Raynor[3]

[1]School of Biological Sciences, University of Aberdeen, Tillydrone Avenue, Aberdeen AB24 2TZ, UK. <x.lambin@abdn.ac.uk>. [2]Rivers and Fisheries Trusts of Scotland, 11 Rutland Square, Edinburgh EH1 2AS, UK. [3]Scottish Natural Heritage, Great Glen House, Leachkin Road, Inverness IV3 8NW, UK.

Abstract The American mink *(Neovison vison)* has invaded most of the United Kingdom following escapes from fur-farms over decades. Its escalating impact on riparian and coastal biodiversity, including seabirds and water voles, is well documented. Starting in north-east Scotland in 2004, long-term, multi-institution mink control efforts have harnessed the enthusiasm of volunteer conservationists to push back the mink invasion over a vast area. Rather than the outcome of a single project with secured long-term funding, this achievement resulted from four successive joined up projects each with short-term funding. The beginnings of the project (2004–2006), under the auspices of the north-east Scotland Biodiversity Partnership were small scale (30 km^2) and centred upon a lowland remnant water vole meta-population. Mink control efforts were scaled-up to 6,000 km^2 of mostly marginal mink habitat as part of the Cairngorms Water Vole Conservation Project (2006–2009) centred on the newly established Cairngorms National Park. The project, led by the University of Aberdeen, was funded by a charity, a UK Research council and Scottish Natural Heritage and involved the national park authority, and three local fisheries trusts. The approach was to deploy a "rolling carpet" of mink control based on the use of mink rafts operated by volunteers and that facilitated mink detection and removal. Substantial funding was then secured for a successor project, the Scottish Mink Initiative (2010–2014) involving, all previous partners plus 14 local fisheries trusts coordinated by the Rivers and Fisheries Trusts of Scotland. Mink were pushed back over a vast area (29,000 km^2) and their spread in coastal areas of north-west Scotland was countered. After a period with minimal bridge funding, coordinated mink control efforts resumed, thanks to the newly funded Scottish Invasive Species Initiative (2017–2021) seeking to extend the approach used with mink to other riparian invasives. Mink remain scarce or absent and water voles are recovering spectacularly. Coordinated mink control delivered tangible conservation benefits and improved understanding of the socio-ecological system despite the challenges of short-term funding.

Keywords: adaptive management, American mink, *Arvicola*, *Neovison vison*, participation, Scotland, water vole

INTRODUCTION

While there have been enormous achievements and improvements in the eradication of a small number of invasive mammalian species (brown (*Rattus norvegicus*) black (*R. rattus*) and Pacific (*R. exulans*) rats, house mice (*Mus musculus*), rabbits (*Oryctolagus cuniculus*), feral cats (*Felis catus*)), on islands of increasing size (DIISE, 2015), there has been comparatively little progress with efforts and guidelines on how to durably control invasive species in those areas where eradication is presently an unattainable goal. Yet, prevention has failed in many areas, such that focussing invasive management efforts exclusively on islands where eradication can be achieved leaves much valued biodiversity impacted by invasive species. Thus, when considering whether to expand resources to protect native biodiversity against the impact of invasive species, a key unknown is what, if anything short of eradication, can be achieved cost effectively and what management regimes might be both ecologically effective and sustainable over the long term.

Eradication can only be achieved where immigration can be prevented or managed (Bomford & O'Brien, 1995). Where this condition is not met, as is the case on continental mainland and large island areas, control of invasives must be the management objective. New Zealand's so-called 'mainland islands' are areas where intensive conservation adaptive and integrated pest management regimes are applied and outcomes are closely monitored (Saunders & Norton, 2001). They are adjacent to other areas where invasives are not managed to the same extent, hence subjected to immigration that, if not dealt with, could lead to recolonisation.

A key feature of mainland islands is that conservation management must be designed so as to last in perpetuity to ensure that the biodiversity and socio-community gains are not lost. It is therefore especially crucial that siting considers all features that may make a mainland island defensible. This may include topography (e.g. presence of peninsulas), ecological gradients or socio-economic interest of the local community that may affect their willingness to participate in ongoing management and adopt biosecurity measures and even the erection of conservation fences (Glen, et al., 2013). An unavoidable corollary of planning for the very long term, is the need for long-term funding commitments. This is crucial to negate the risk that ecosystem restoration will one day be undone should a lack of resources preclude a rapid and decisive reaction following incursion by invasives into a mainland island. In this respect, the fact that New Zealand's mainland islands are operated by the Department of Conservation, a government agency, provides a degree of continuity lacking elsewhere.

Owing to a lack of reported successful instances of control of invasive species in mainland areas, and to a few well publicised failures (e.g. Sheail, 2003; Santulli, et al., 2014), managers have little guidance as to the circumstances under which a mainland island approach might prove successful. Of particular interest is how complex institutional and funding environments need to be navigated when planning long term control of invasives. In the UK, for instance, protected areas are largely privately-owned; conservation legislation incentivises rather than mandates conservation management activities; a significant proportion of conservation action is initiated in a bottom up fashion by non-governmental organisation or local communities (often enabled by government agencies); and funding for projects rarely exceeds 3–5 years in duration.

In this paper, we present an account of the development of a mainland island invasive control effort that grew in spatial extent over 15 years from a localised community-led effort to operate on a vast scale (29,000 km^2) in the north of Scotland. It progressed from pilot, to demonstration

and, eventually, mainstreaming stages without secured long-term funding but as an enduring partnership between academic researchers and practitioners under an adaptive management framework.

Invasive American mink threatening Ratty the water vole, a British cultural icon

The initial motivation for the project was the protection of the water vole (*Arvicola amphibius*), riparian rodents that used to be very abundant in Britain but that experienced a cumulative mean loss of occupied sites of 98.7% across all regions of England, Scotland, and Wales by 1998 from the 1939 baseline (Moorhouse, et al., 2015). Thus, the water vole was included amongst Species Action Plans and devolved Local Biodiversity Action Plans (LBAPs) when the UK Government launched those plans for the recovery of threatened species and habitats as part of the UK Biodiversity Action Plan in response to the Convention on Biological Diversity in 1994 (UK Biodiversity Partnership, 1995; JNCC, 2006). One of several suggested causes for the catastrophic decline of the water vole was the American mink *(Neovison vison)* that had invaded all but the north-westernmost corner of the UK following historical escapes from fur farms (Fraser, et al., 2015). Its overriding influence became clearer over time (Aars, et al., 2001; Moorhouse, et al., 2015). Accordingly, LBAPs included controlling mink, but little guidance or prescriptions on how this should be implemented were included.

SCALING UP MINK CONTROL: FOUR PHASES OF SPATIAL EXPANSION

Water voles in the catchment of the River Ythan (1995–2007): 100–644 km²

Research into metapopulation processes by ecologists from the University of Aberdeen funded by the Natural Environment Research Council (NERC) (1995) identified a handful of highly fragmented remnant water vole populations in a 100 km² portion of an intensely farmed lowland area north of Aberdeen in NE Scotland (Telfer, et al., 2001) (Fig. 1). Structured surveys revealed that water voles had become regionally scarce or absent where they were once common (Lambin, et al., 1996; Lambin, et al., 1998; Lambin, et al., 2002). The intensively studied metapopulation network was gradually shrinking under the influence of American mink predation, causing the extinction of multiple adjacent colonies (Lambin, et al., 1996; Telfer, et al., 2001) (Table 1).

Fig. 1 Map of northern Scotland showing the five stages of expansion of successive mink control projects from a sub-catchment of the River Ythan (thick black line, numbered 1), the entire catchment of the River Ythan (Grey dashed lined, numbered 2), the Cairngorms National Park (thin black line, numbered 3), the area of the expanded Cairngorms project (dashed black line, numbered 4) and the area where the Scottish Mink Initiative operated (Continuous thick black line, numbered 5).

With funding secured by north-east Scotland's Local Biodiversity Action Plan group from Scottish Natural Heritage (SNH), the government agency tasked with promoting, caring for and improving Scotland's natural heritage (£145,000 over eight years, Fig. 2), the first stage of the northern Scotland control mink project was initiated in 2002. Its modest objective was to safeguard the remnant lowland water vole metapopulations by preventing further encroachment by mink. Initially, a member of staff from the local Ythan District Fishery Board, a statutory body empowered to protect, enhance and conserve Atlantic salmon and sea trout within the Ythan catchment, was employed on a part time basis to control mink (2002–2003). Subsequently, a full-time member of staff, employed by the University of Aberdeen (UoA), was appointed over five consecutive one-year contracts (2003–2007) as mink control activities were extended to the entire 644 km² area of the catchment of the river Ythan as evidence accumulated that it was possible to protect remnant water vole colonies from encroachment by mink (Fig. 1).

This early step was arguably an instance of last ditch conservation, focussed on safeguarding a fast-shrinking isolated remnant water vole metapopulation. It was nevertheless influential in shaping ways of working that became crucial as the project area was expanded 45-fold over the next 10 years.

Key features were:

i) Close links between research on water vole and mink population dynamics and conservation delivery;

ii) Systematic deployment of mink rafts that make it possible to detect the presence of mink and to target cage trapping to those sections of waterways where current mink presence is confirmed (Reynolds, et al., 2004);

iii) Involvement of local residents who were encouraged to volunteer to monitor and report the appearance of signs of mink on mink rafts in their neighbourhoods, allowing a single project officer to effectively control mink of an entire catchment through targeted trapping.

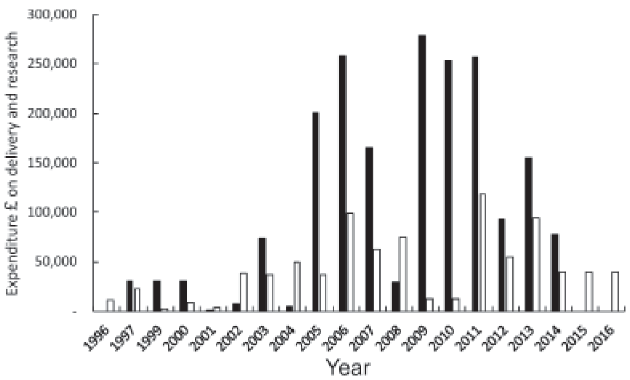

Fig. 2 Annualised expenditure of all projects relevant to water vole conservation and mink control broken down as funding for enabling or evaluating research (white bars) or conservation delivery (black bars).

iv) Partnership with organisations tasked with the management, conservation and enhancement of native freshwater fish and their environments in Scotland and increasingly involved in invasive species management.

In 2009, the river trust in the adjoining catchment of the River Deveron, emulated the project and obtained funding from SNH for an integrated package of invasives control, including American mink. The likely disappearance of the Ythan water vole population was averted, and this population is now thriving and extends across the entire lowland NE Aberdeenshire plain (W Morgan, E McHenry, X Lambin unpublished data).

The Cairngorms Water Vole Conservation Project (2007–2009): 5,500–10,570 km^2

Further surveys of water voles in the uplands of NE Scotland commissioned by SNH and research into metapopulation genetics processes by UoA (1998–2000) uncovered large water vole metapopulation networks in the area that was to become the Cairngorms National Park (CNP) in 2003 (Aars, et al., 2001; Lambin, et al., 1998; WildCRU, 2004) (Table 1). These populations, while in slow decline, had not yet been affected by the American mink invasion to the same extent as lowland populations, owing to the low density of alternative prey for mink in the uplands (Oliver, et al., 2009). They presented the opportunity to preserve functioning metapopulations and the associated ecosystem functions arising from the ecosystem engineering activities of water voles on upland riparian vegetation (Bryce, et al., 2013) as opposed to the more desperate task of rescuing critically endangered survivors.

The CNP encompasses a mountain massif, dominated by heather moorland where shooting of red deer (*Cervus elaphus*), red grouse (*Lagopus lagopus*) and fly fishing of salmon (*Salmo salar*) provide much needed income to the rural economy. In order to make these leisure activities possible, a large number of game keepers and fishing ghillies are employed to intensively manage heather moorland through rotational burning, killing predators of grouse and accompanying anglers. These individuals were recognised as a potential trained workforce that already culled ~ 60–70 mink annually in CNP, hence had the expertise and a professional interest in the issue. Their willingness to step up and coordinate hitherto patchy mink control was ascertained through consultation funded by the newly established CNP in 2004. Thus, we reasoned that the CNP was a potential defensible mainland island stronghold for water voles where mink control could be sustained in perpetuity.

Funding bids to the Tubney Charitable Trust, a charitable organisation for projects that conserve the natural environment in the UK, and to the NERC outlining the ambition to implement a formal active adaptive management approach to control American mink on the large scale of CNP (encompassing 5,500km^2, Fig. 1) were prepared. SNH had again committed match funding should either bid succeed. The Cairngorms National Park Authority (CNPA) and three river trusts managing important salmon rivers flowing from the Cairngorms (River Dee Trust, Spey Foundation and Deveron, Bogie & Isla Rivers Charitable Trust) were also formal partners committing in-kind staff time. Both bids were funded and substantial funding was in place for three years (2006–2009), facilitating the employment of three project officers and one postdoctoral research fellow by UoA.

A detailed account of the project's approach and achievements is given in Bryce, et al. (2011) and Oliver, et al. (2016) and a brief summary only is given here. The approach was to deploy mink rafts with an approximate spacing of 2 km in a 'rolling carpet' fashion to first remove mink from upland areas and subsequently expand coverage

Table 1 Sequence and main findings of research at the University of Aberdeen that enabled the next step of mink control efforts by characterising the system to be managed, that evaluated the achievements of mink control efforts or that provided a strategic evaluation of different ways or working.

downstream to remove mink from an increasingly large area, hence protecting the uplands with increasing depth; a version of the 'remove and protect model' with depth (Bell, et al., 2019). The systematic use of mink rafts was made possible by the work of 208 volunteers. We sought volunteers willing to adopt a mink raft and report to a project officer or trapper in their local community whether a mink was present. Only when fresh mink signs were detected was a cage live trap set, hence minimising the time wasted checking empty traps at least once every 24 hours as mandated by law. If a mink was caught (as occurred following 10–22% of detections according to season), it was humanely killed before the raft was returned to monitoring mode. The project officer played a crucial role in coordinating the efforts of volunteers, not all of whom were equipped or qualified to humanely despatch a mink. On detection of the presence of a mink by a volunteer, the full capabilities of the larger volunteer force could be called upon to effectively trap and despatch the mink.

Project officers sought permission to access the land and deploy a mink raft and then recruited local volunteers to operate the raft. Game-keepers who are licenced to carry fire-arms were partners of choice to adopt and operate mink rafts, although it proved difficult to dissuade them from their traditional practice of deploying traps irrespective of evidence of the presence of the focal species (Fig. 3). Two of three project officers had prior family or professional associations with the local game keeping community and this undoubtedly facilitated building constructive relationships. The adoption of rafts by local residents was key to allowing project officers to deploy further rafts downstream in the more biologically productive parts of the CNP and where landownership is more fragmented and residents with a wider diversity of professions live. Here, we adopted a functional approach to participation (Pretty, 1995) whereby local people were co-opted to meet the predetermined objectives of achieving coordinated mink control. Thus, recruitment of volunteers to operate rafts was targeted toward individuals with an interest in nature conservation and natural resource management, such as forest or local government rangers, fishing ghillies, bailiffs, nature reserve managers, but also included numerous local residents made aware of opportunities to become involved in the project through community talks and publication in the local press. Where required, project officers would check mink traps or despatch mink themselves but volunteers were always encouraged to step up their involvement from monitoring rafts only, to trapping or becoming a trained despatcher.

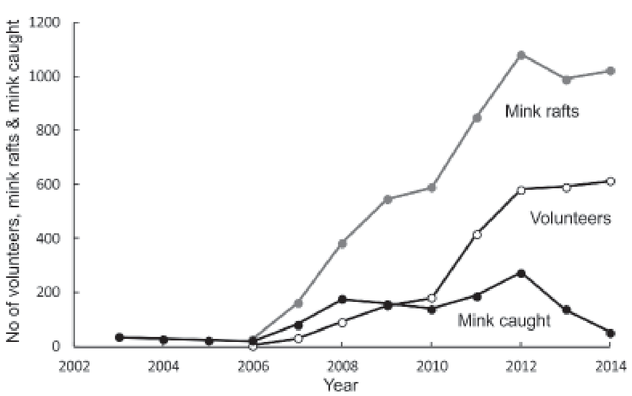

Fig. 3 Temporal dynamics of the number of mink caught per year (black line, black circles), the number of mink rafts deployed (grey line, grey circles) and the number of volunteers contributing to the projects (black line, white circles).

The large project area was subdivided into sub-catchment management units encompassing major tributaries of main catchments (median size: 55 km^2). Analyses of the impact of culling on the population used, as a reference point, the time when mink raft deployment was deemed complete in a sub-catchment by the local project officer. The number of mink captured per km of waterway decreased from an average of 0.16 to 0.06 to 0.01 for sub-catchments in the first, second and third years after inception of control, respectively. This was despite higher fecundity amongst mink that had survived culling (Melero, et al., 2015; Oliver, et al., 2016). Most mink caught in the third year after inception of control were males, reflecting their high propensity to disperse from the natal area. This was also reflected in the high proportion of juvenile males amongst the few mink caught in the higher elevations of the CNP which were cleared of mink by the end of 2007. No mink at all were caught in 3,417 km^2 of montane and moorlands areas of CNP but 376 mink were removed from 5,381 km^2 covering moorland and pastoral areas of lower altitude. There was further evidence of high mink mobility within and between river catchments resulting in compensatory immigration, as mink capture rate in a sub-catchment increased with connectivity to mink still present in other sub-catchments (Bryce, et al., 2011; Oliver, et al., 2016).

The key lessons from the ongoing evaluation of management efforts were:

i) The presence of large-scale lowland-highland source-sink dynamics in mink such that most mink impacting upland biodiversity had dispersed from more productive lowland areas. This motivated a change in the scope of the project when the management group endorsed downstream expansion from 5,500 to 10,570 km^2 at the end of the second year of the project (2007) so as to deplete mink where most were born (Fig. 1).

ii) Deploying a large number of mink rafts and recruiting volunteers is a gradual process and a pool of volunteers must be replenished to make up for volunteer turn-over (Beirne & Lambin, 2013). Different communities and river trusts vary in their ability to embrace conservation volunteering and the resulting asynchrony in the inception of mink control delayed region-wide eradication.

iii) Mink disperse widely and dispersal connects major river catchments, implying an inter-dependence between river catchments and the organisations that manage them. Thus, high mobility of mink dictates that control should be on a very large scale so as to avoid the effects of compensatory immigration.

The Scottish Mink Initiative (2011–2015): 10,570 –29,000 km2

The achievement of the Cairngorms Water Vole Conservation Project elicited much enthusiasm from volunteers who had been part of a rare conservation good news story, as well as from private and public land managers (e.g. CNPA) and Scottish Natural Heritage. As the three-year funding period was coming to an end, there was a real risk that the project would fall from a funding cliff edge such that not only would all biological gains be lost but the volunteer community would become despondent if abandoned. SNH had also been working with the Scottish Wildlife Trust (SWT) and local fisheries' trusts in the north-west Highlands to remove mink in that area, so there was an opportunity to develop a more strategic approach to mink control across the north of Scotland by amalgamating and expanding the various projects into a single, much larger scheme. SNH, along with two other key funders (CNPA and the Tubney Trust) expressed their willingness to renew their funding commitments for a further three years (£478,000; £8,932; £100,000, respectively). However, the partnership research grant scheme run by the UK research council had been discontinued and funding commitments did not include the overheads universities expect from research grants. This made it impossible for UoA to continue as the lead partner of what was increasingly an ambitious conservation delivery project rather than a combination of this and research. Furthermore, it was evident that local organisations managing common natural resources and representing private entities gaining economic benefits from harvesting salmon would be more appropriate long-term custodians of a mainland island project than a university and thereby ensure it had a long-term legacy.

Accordingly, a new partnership was formed involving Rivers and Fisheries Trusts of Scotland (RAFTS) and SWT. RAFTS was a charity with a formal objective comprising "the conservation and enhancement of native freshwater fish and their environments in Scotland". Twenty-six river trusts and foundations were members of RAFTS and it was already actively involved in (mostly riparian plant) invasive management. It had a strong track record in fundraising and project management for its members. It proved to be the ideal body to lead an expanded project and to ensure coordinated action using best practice by its member river trusts at a scale commensurate with the biological challenge posed by mink. Nine river trusts in northern and north-east Scotland were enlisted in a new partnership and they committed in kind resources to removing mink from their river catchments. The renewed funding commitments were critical in allowing an application to the EU-funded LEADER scheme operated by the Scottish Government. The aim of LEADER is to increase support to local rural community and business networks to build knowledge and skills, and encourage innovation and cooperation, in order to tackle local development objectives. A competitive application involving multiple local areas was assembled and further funds (£229,000 from LEADER, and £14,000 from river trusts) were secured, facilitating the appointment of three project officers and a coordinator employed by RAFTS. For the second time, mink control efforts in northern Scotland bounced back from a financial cliff edge.

Owing to the time required for the evaluation of the funding bid and recruiting new project staff, mink volunteers had been left without support or certainty on the future of mink control efforts during the 19-month gap that elapsed between the end of the Cairngorms project in October 2009 and the start of the new Scottish Mink Initiative (SMI) in April 2011. Over that period, a skeleton staff was retained from previous projects to maintain the volunteer and associated mink raft network prior to further expansion (Raynor, et al., 2016). This included one part-time member of staff from the north-west Highlands project. It had adopted a "*cordon sanitaire*" approach, comprising a double line of mink rafts intended to prevent mink from invading northern Scotland, following from recommendations in an unpublished report to SNH (Harrington, et al., 2008). That approach turned out to be flawed owing to mink dispersal abilities, evident in data collected as part of the Cairngorms project but that were unpublished at that time (Oliver, et al., 2016), and to the importance of the coastal environment in driving invasion range expansion (Fraser, et al., 2015).

Four newly appointed SMI staff had to be trained and build new trust relationships with volunteers previously supported by other staff. While some volunteers had continued with their activities in the intervening time and caught a minimum of 139 mink in 2010, many no doubt concluded that the project had come to an abrupt end and ceased their activities. This led to reinvasion of some of the project areas, especially in the vicinity of the crucial catchment of the River Don where inadequate local support had prevented progress with mink control as part of the Cairngorms project (contrast figure 2 in Oliver, et al., (2016) and figure 3 in Melero, et al., (2015)).

Once the full complement of project officers was again embedded in the local community and supported by local river trusts, the approach refined in the previous project was scaled up substantially by SMI resulting in 837 volunteers operating up to 1022 rafts and removing a minimum of 646 mink between 2011 and 2014. This resulted in a vast area encompassing ~29,000 km^2 bounded by seas becoming free of breeding mink as determined by the absence of footprints on mink detection rafts, the metric chosen by the steering group to gauge the effectiveness of the project (Fig. 1), hence increasing our ability to deal with the constant flux of mink moving up from the south. Mink were regularly detected in the southern and western edges of the project area (51 in 2014) especially, reflecting primarily immigration by males during the rut period. A more detailed account of its achievements and of some of the challenges encountered is found in Raynor, et al. (2016).

The Transition to Scotland's Invasive species Initiative (2018-2022): 29,500 km^2

One ultimate objective of SMI was to engender a sense of ownership of the mink management and wider biosecurity, considering the threat posed by aquatic invasives such as the salmon fluke (*Gyrodactylus salaris*) and the giant hogweed (*Heracleum mantegazzianum*), amongst the local fisheries trusts as appropriate to any mainland island project. There was also an aspiration to further build on the partnership by involving more and more trusts, as resources allowed. Thus, during the second half of the funded period (September 2013–August 2015), there was a process of hand-over of all local processes to 10 local rivers and fisheries trusts. This included transfer of responsibility for managing existing networks of volunteers and mink rafts, including all access agreements with land owners, health and safety and standard operating protocols, and all relevant databases. A project coordinator remained employed by RAFTS and each participating river trust received payment to cover costs incurred in undertaking a combination of mink raft checking and maintenance, as well as data collection and support and coordination for the local volunteer network.

Two main limitations to the effectiveness of the handover have been: 1) not all areas of high mink productivity on the lowland coastal plain in the extreme corner of NE Scotland have sufficient salmon resources to maintain functional river trusts. Without additional resources, such areas could again become a source of dispersing mink into adjacent better controlled areas; 2) maintaining mink raft coverage in remote areas of north-west Scotland, where the low human population density; a predominance of red deer over grouse as the primary game species; difficult topography including many coastal islands; and a limited road network all placed significant restrictions on the ability to maintain required coverage for surveillance. The handover arrangements have been severely tested, with mixed results, by the absence of any financial support to any of the trusts between August 2015 and November 2017. During this period, a major reform of freshwater fisheries governance that would have led to river trusts and boards being disbanded was mooted by the Scottish Government and this precluded the submission of grant applications for the successor project by RAFTS.

The proposed reform was ultimately abandoned but led to the demise of RAFTS as an organisation. Scottish Natural Heritage, a key long-term supporter of the project from its very outset, stepped in as lead partner for an application to the Heritage Lottery Fund and an award of £1.59M was announced in August 2017. Thus, after a protracted period without secure funding, a successor to SMI, centred on applying the citizen conservationist approach to a suite of riparian invasives and prepared by RAFTS, will operate from 2018–2022. The new project, the Scottish Invasive Species Initiative, will tackle the challenge of reviving the volunteer network and undoing unavoidable partial reinvasion of the project area for another four years and further increase engagement in invasive management by local communities (Horrill, et al., 2019).

DISCUSSION

Over 15 years, a vast mainland island area has been established in northern Scotland that protects native riparian biodiversity including water voles from the destructive influence of the invasive American mink. The endeavour is the outcome of a succession of research and implementation projects conducted in partnership that optimised mink control effort so they could be scaled-up. Implementation projects progressed from a small-scale pilot phase (in the Ythan), to a two-stage demonstration phase, first evidencing the feasibility of scaling up mink raft deployment and enthusing volunteers to become citizen conservationists (the Cairngorms project) and then, the feasibility of devolving management of such a large scale project to local organisations engaged in natural resource management (the SMI) according to a wider, more strategic framework. The later stage of SMI was the beginning of embedding mink control within the activities of rivers trusts working autonomously but in a coordinated manner. The most recently funded successor project has the ambition to extend the approach refined with mink to a suite of containable riparian plant invasives that are widespread in Scotland.

Long-term invasive species management was achieved despite short-term funding as a result of a succession of fixed-length short-term discrete projects each of three to four years duration, rather than the result of any integrated long-term joined-up endeavour underpinned by secured funding or any strategic decision on the size of any area where mink could be controlled on Scotland's mainland. As the feasibility of controlling mink on a large scale was demonstrated and the endeavour's spatial ambition grew, the very existence of the project was in jeopardy on multiple occasions and some of its achievements were eroded during four gaps between funding cycles. Its future is secured for another four years after the latest two and a half year funding gap since the end of SMI. Although the large spatial reach of the project, its cost effectiveness and hence attractiveness, results from the use of volunteer citizen conservationists, the lack of continuity in funding has been highly detrimental to the trust relationship built between the project and volunteers giving their time freely for conservation. Invasive species control in mainland areas is, by definition, an open-ended commitment and it is paramount the limited resourcing required to maintain what has been achieved should be in place conditionally on evidence of success and sustainability being presented.

The cumulative cost of all components of the project, including the research by EU-funded fellows and four PhDs that enabled the project or contributed to its evaluation under the adaptive management, was £2,800,000. The cost-effectiveness of the project resulted from the use of a workforce of 866 unpaid "citizen-conservationist" volunteers. Based on the assumption that their time contribution amounted to 30 min/2weeks = 13 hours per year per volunteer, the total 2,652 volunteer years is equivalent to 21.6 standard person years, crudely valued at £1,404,00 using the assumptions of Robertson, et al. (2019). Arguably, the value of their contribution is greater still because of the increased awareness of the issues caused by invasives and community cohesion benefits (Evely, et al., 2011).

Although the volunteer approach is relatively cheap, it is not cost-free as volunteers require a degree of support, encouragement, information and re-supplying by project staff. The successive incarnations of the mainland mink control efforts have involved an increasing number of volunteers (peaking at 612 in 2014 Fig. 3) supported by a fixed and small number of project officers. Volunteer retention over time is less than 100 % such that it is constantly necessary to recruit new volunteers. Despite project staff consistently reinforcing the message that "no mink is good news", it remains that the enduring absence of mink on a volunteer's raft contributes to some volunteers dropping out (Beirne & Lambin, 2013). The greatest risk causing volunteer drop-out is the perception that the project has come to an untimely end in the absence of communication from project staff, as arose during the funding gaps, even if efforts to fund-raise for a successor project are underway.

SNH, Scotland's governmental organisation responsible for the management of natural heritage including the threat posed by invasive species, has been an enduring and crucial funder at all stages of mainland mink endeavour ever since 1995. It contributed 45 % of the total £2,803,950 cash cost over 21 years and 62% of the subset (£1,900,000) spent on conservation delivery. SNH is also the main funder of the Hebridean Mink Project (Macleod, et al., 2019), hence is committing substantial resources to managing American mink. However, as with all government agencies, including in New Zealand and the USA, it is constrained by its inability to commit long-term funding for managing established invasive species. Even SNH's Species Action Framework scheme that made sizeable financial contributions to SMI (£710,000 including extensions) was a five-year programme of targeted species management. Furthermore, contributions from SNH were conditional on funding being secured from other funders. Fund-raising by UoA and RAFTS was successful but time-consuming and added complexity to project management and reporting. It is a major concern that given EU funds covered 20 % of total costs and provided for 40% of the research work, the departure of the UK from the EU in 2019 will potentially leave a major hole in funding.

Through all phases of the project, the programmes of research that enabled and evaluated the development of large scale invasive control were always funded by separate funding streams to those used for conservation delivery (such as species recovery or habitat management). This was in response to implicit or explicit indications that while funders of conservation delivery like the sound of adaptive management, they are less keen to pay for it. The modicum of adaptive management achieved resulted largely from universities having access to lots of (predominantly) young, enthusiastic people keen to gain qualifications in conservation through applied research. For adaptive management to be a reality and not just an aspiration, there is a clear need for more integrated (research–management) funding streams delivering vital continuity of support.

Our work demonstrates there is no technical difficulty in expanding working with citizen conservationists for pushing back huge scale invasion. Partnerships and relationships had a critical role in achieving this work (across all project phases). The outcomes have been achieved through those networks and the empowerment of volunteers and interested/affected 'stakeholders', all in spite of repeated uncertainty of funding. There is little doubt that even more could have been achieved had continuous funding been in place. Indeed, short-term funding is a major impediment to efficiency and increases the overall cost of long-term invasive control as lost ground must be recovered. Repeated gaps in funding, associated staff turnover and re-badging of projects are all damaging to the trust relationships built with volunteers. It makes no economic sense to embrace long-term control of invasives without funding it. Scotland, like other countries, needs a long-term stream of funding if it is going to manage invasive species. Thus, the future will tell whether our efforts were bold and trail blazing or overly ambitious and ultimately wasted if the SMI's ambition to become embedded within local management practice in perpetuity is not borne out.

Battling invasive species in the Pacific

D. Moverley

Invasive Species Adviser, Secretariat of the Pacific Regional Environment Programme (SPREP). <davidm@sprep.org>.

Abstract This paper is a snapshot of how Pacific invasive species battlers are protecting their islands with the assistance of the Global Environment Facility's Pacific Alliance for Sustainability (GEF-PAS) project "Prevention, control and management of invasive alien species in the Pacific". The aims of the project are presented, along with examples of how implementation increased awareness and capacity, and management of invasive plants and animals, throughout the Pacific. Over 100 IAS activities took place across nine countries between 2011 and 2016. The project, one of the largest investments in invasive species management in Pacific history, has raised the benchmark of invasive species management in the Pacific and enhanced regional mechanisms. Hopefully the people within this story inspire and assist other battlers to join the fight and protect our islands from invasive species.

Keywords: Cook Islands, Federated States of Micronesia, GEF-PAS Project, Kiribati, Niue, Palau, regional project, Republic of the Marshall Islands, Samoa, SPREP, Tonga, Vanuatu

INTRODUCTION

The Pacific region is populated by diverse people and spans a third of the earth's surface and encompasses about half of the global sea surface (Fig. 1). There are ca. 2,000 different languages and ca. 30,000 islands. Pacific ecosystems are one of the world's biodiversity hotspots, with a large number of species found only in the Pacific and nowhere else. There are 2,189 single-country endemic species recorded to date. Of these species, 5.8% are already extinct or exist only in captivity. A further 45% are at risk of extinction (SPREP, 2013). The region faces some of the highest extinction rates in the world. The largest cause of extinction of single-country endemic species in the Pacific is the impact of invasive alien species (IAS). Invasive alien species also severely impact economies, ability to trade, sustainable development, health, ecosystem services, and the resilience of ecosystems to respond to natural disasters. Fortunately, we can do something about it. Even in this diverse region, many things are shared in common. The people are self-reliant, rely heavily on their environment to support their livelihoods and share many common IAS issues as they are ultimately connected. Sharing what is learnt regionally benefits the people and their families economically, culturally, and in their daily lives. The 2013 State of Conservation in the Oceania assessment (SPREP, 2013) showed that IAS are the most important driver of species loss in the region and contribute directly to the loss of ecosystem function and loss of resilience, and ability to respond to climate change threats. Invasive alien species also severely impact Pacific economies, ability to trade, sustainable development, health, ecosystem services, and the resilience of ecosystems to respond to natural disasters. The status of the IAS issue in the Pacific is "poor" according to the report on the State of Conservation in Oceania (SPREP, 2013).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 658–662. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

The "Guidelines for invasive species management in the Pacific: a Pacific strategy for managing pests, weeds and other invasive species" (SPREP, 2009) provide a comprehensive framework for the Pacific Region to respond to IAS at the regional and national levels, endorsed in 2009 by members of both the Secretariat of the Pacific Regional Environmental Programme (SPREP), and the Pacific Community (SPC). This framework is used throughout the Pacific for structuring the National Invasive Species Strategies and Action Plan (NISSAP) and the Territorial Invasive Species Strategies and Action Plan (TISSAP).

The Guidelines were implemented to achieve the objective of reducing the environmental, economic, and human health impacts of IAS in both terrestrial and marine habitats in the Pacific region. The classification of the IAS management themes within the Guidelines allows current and future IAS management activity and success to be measured both nationally and regionally and enables the identification of gaps which need to be addressed.

The project "Prevention, control and management of invasive alien species in the Pacific Islands" (GEF-PAS) was implemented by the United Nations Environment Programme (UNEP) and executed by the SPREP and national partner agencies from 2011 to 2016. The GEF-PAS project goal was to 'conserve ecosystems, species and genetic diversity in the Pacific Region'. The GEF-PAS project structure followed the 'Guidelines for Invasive Species Management in the Pacific' (SPREP, 2009) with three major components: (i) foundations; (ii) problem definition, prioritisation and decision making; and (iii) management action.

This regional approach has supported the establishment of the Pacific Invasive Species Guidelines Reporting Database, a database of national, territorial and regional progress in implementing the "Guidelines", with indicators on priority IAS initiatives. SPREP coordinates two Pacific IAS networks. The Pacific Invasives Partnership (PIP) is an umbrella group of IAS experts from organisations who work on IAS issues in more than one Pacific country. PIP is focused on coordinating IAS assistance in the Pacific region and aims to build cooperation among Pacific experts who provide assistance to Pacific countries and territories. SPREP also coordinates the Pacific Invasives Learning Network (PILN), a peer network of cross-sectoral IAS practitioners in the Pacific. The PILN aims to build cooperation between Pacific countries and territories on IAS issues. There are PILN teams in all but three of the 21 SPREP Pacific island member countries and territories.

A knowledge management system was initiated by the development of the Pacific Invasive Species Battler Series launched in 2016 with nine booklets to date focused on common IAS issues, based on Pacific examples and serving the Pacific Region. They are available from the Pacific Invasive Species Battler Resource Base (<https://piln.srep.org>), a searchable resource base providing the latest information on IAS issues, case studies, and introductory guides on common IAS issues. This resource is designed to increase the capacity of Pacific countries and territories in an effective and efficient manner, The "battler" brand has developed from Pacific IAS practitioners' internal/external communications over the years and serves as an ongoing reminder that if we don't achieve any change on the ground as practitioners we have been ineffective, it reminds us that IAS management is a long-term challenge that most of us will be working on for the rest of our lives and that as a regional collective we are not alone on our individual islands.

OUTCOMES OF THE GEF-PAS PROJECT

Ten Pacific Island countries originally participated in the GEF-PASIAS project: the Cook Islands, Federated States of Micronesia, Kiribati, Marshall Islands, Niue, Palau, Papua New Guinea, Samoa, Tonga and Vanuatu. These were reduced to nine countries with the withdrawal of Papua New Guinea following the mid-term review, due to issues related to the country's readiness to engage with the project. The project was therefore responsible for delivering support to a culturally, geographically and economically diverse set of Small Island Developing States (SIDS) spread across the vast geographical scope of the Pacific Ocean.

In-country subprojects and activities were facilitated by National Project Coordinators and overseen by national Invasive Species Coordinating Committees. The project's goal "to conserve ecosystems, species and genetic diversity in the Pacific region" is broad and aspirational and is backed by the objective "to reduce the environmental, economic, and human health impacts of invasive alien species in both terrestrial and marine habitats in the Pacific region". The project budget was US$7,010,890 consisting of US$3,031,818 in GEF funds and US$3,979,072 in SPREP and country co-financing. The project consists of five components, three of which can be described as core components which relate to the three major areas of work and nine thematic directions.

Component 1 – Foundations: generating support

This component addresses the limited understanding of the threats posed by IAS to the environment, economies, human health and cultural values of decision makers, the private sector and the general public. It aims to raise awareness across all sectors of society of the importance of IAS risks and impacts, and of the benefits of IAS management for biodiversity, the economy and human health. It also aims to actively support IAS management. With raised awareness, it is expected that sufficient resources will become available to enable all national and regional IAS priorities to be addressed and, most importantly, enable capacity building efforts to flourish alongside the development of supportive policy and legislation.

The three thematic directions addressed by Component 1 are:

Generating support— Raising awareness of the impacts of invasive species on biodiversity, the economy, human health and socio-cultural values, and generating support for action to manage and reduce them.

Building capacity— Developing the institutions, skills, infrastructure, technical support, information management, linkages, networks and exchanges required to manage invasive species effectively.

Legislation, policy and protocols— Ensuring that appropriate legislation, protocols, policies and procedures are in place and operating, to underpin the effective management of invasive species.

Component 2 – Problem definition, prioritisation and decision-making: baseline and monitoring

This component aims at addressing the chronic lack of information and data on IAS within the region which impacts on the ability of governments to define priorities, develop national strategies and establish supportive policies and legislation. It aims to ensure that information and data on IAS, their distribution and status is readily available to support informed decision making, strategic planning and effective management. Importantly, the component also aims to address the potential biosecurity and economic impacts of IAS through improved knowledge of trans-boundary movement and regional status of critical IAS.

The three thematic directions addressed by this Component are:

Baseline and monitoring— Establishing a baseline of information on the status and distribution of invasive species and a programme for detecting change, including range changes and emerging impacts.

Prioritisation— Establishing effective systems for assessing risk and prioritising invasive species for management.

Research on priorities— Understanding priority invasives, including species biology and impacts, and developing effective management techniques.

Component 3 – Management action

This component addresses the practical requirements of managing IAS. Until management action is implemented, no progress is made on addressing IAS. The three thematic directions addressed by this component are:

Biosecurity—Preventing the trans-boundary and inter-island movement of IAS in the region by encouraging the establishment of cost-effective biosecurity measures (e.g. rapid response protocols) aimed at reducing the need for costly post-invasion control measures. It aims to assist the establishment of effective systems throughout the Pacific to regulate introductions and to detect and manage unauthorised or accidental introductions across borders or to new islands within countries.

Management of established invasives—Reducing or eliminating the impacts of established invasive species, by eradication, containment, exclusion, or population reduction by physical, chemical or biological control.

Restoration—Restoring native biodiversity or ensuring recovery of other values, after invasive species management.

Each of the above three components dovetails directly with the priority thematic areas of the Guidelines which were developed as a result of an extensive regional stakeholder consultation process in 2007/2008. As such, they reinforce the rationale and justification for the IAS project and its legitimacy in the eyes of the regional IAS stakeholders and their international partners and networks. Together, the three components also address the IAS management weaknesses identified in the Guidelines.

Components 4 and 5 – Project management & monitoring and evaluation

These management-related components establish SPREP as the designated project Executing Agency and support a Project Facilitator and half-time Financial Manager for this purpose. SPREP funding covered the costs of the Project Manager. SPREP also had designated responsibility to ensure an effective monitoring and evaluation framework is established at inception. This role is consistent with SPREP's regional mandate and role to foster national and Pacific-wide strategies consistent with international best practices. SPREP is also able to engage the member organisations of the umbrella coordinating body the Pacific Invasives Partnership to further the goals of the project through provision of advice and the PIP members' own IAS management and capacity building interventions. The project activities strengthened capacity by improving IAS outreach, policies, laws, prevention and management. The project helped participating countries and others in the Pacific region to address existing and future biological invasions.

ACTIONS

More than 100 IAS activities took place across nine countries between 2011 and 2016 (SPREP, 2016). Here the scope and range of the purpose of actions undertaken and examples of those actions are highlighted.

Awareness raising and capacity building

Awareness of the impacts of IAS was increased at the local, governmental and political level. As an example, a royal visit to Toloa Rainforest by His Majesty King Tupo VI and Her Majesty Queen Nanasipau'u raised the profile of IAS management in Tonga. School scholarships were also presented by Her Majesty Queen Nanasipau'u to the top three Tupou College forest restoration team members at a national school prize-giving.

Awareness of IAS is important to create or support actions. For countries to take control of their responses to invasives, the first steps were to develop awareness in communities (local to national, and across a range of social roles), to mainstream IAS issues, to create or access long-term external funding mechanisms, and to generally increase the support for IAS issues. As an example, engaging posters were made by teams in Palau, Vanuatu, and the Cook Islands to communicate which species were invasive, what they affected, and boost the idea that individuals can take action. Outreach is a vital component of battling IAS because an educated, engaged community produces fast, effective action.

Capacity building of institutions, skills, infrastructure, technical support, information management, networks and exchanges required to manage IAS effectively were developed. Particularly given the strong customary land ownership in the Pacific, on-site management requires whole-of-community engagement, and the strong community ties in the Pacific are a strength for IAS early detection and rapid response. Local people with site knowledge and experience were integral to project implementation and benefited from learning new field techniques and scientific approaches, enhancing regional capacity. Direct engagement with field action makes local communities more likely to maintain site management, value their environment, and support or generate future conservation.

As examples, biosecurity training was provided in Kiribati, and a multi-country workshop was held in Samoa to support the prevention of IAS movements between islands. Training to detect and manage little fire ants was conducted in Vanuatu. A workshop on eradicating rodents from small islands was held in 2015, with participants from Kiribati, Republic of the Marshall Islands, Tonga, and Wallis and Futuna practising the eradication techniques on Malinoa and Motutapu islands in Tonga. The removal of the rats (*Rattus* spp.) has already boosted bird populations, such as the fuleheu or wattled honeyeater (*Foulehaio carunuculata*) and misi or Polynesian starlings (*Aplonis tabuensis*). Black-naped terns (*Sterna sumatrana)* were nesting and had eggs on the beaches of both islands.

The Pacific region is under-resourced regarding research capability and IAS, biodiversity, and ecosystem data. The limited resources available for IAS management demand that achievable goals are prioritised based on research and available data and that priorities meet the expectations of all stakeholders. Further, as Parties to international environmental agreements such as the Convention on Biodiversity, the region needs to show progress and success in meeting their obligations under these agreements.

Invasive plant species actions

Weed risk assessments can be costly and time-consuming, and vital information for assessments such as seed viability may not be known. Given the limited resources available to Pacific island countries and territories and the existence of almost 2,000 species with existing weed risk assessments for the Pacific, the most effective first step is to ensure that existing weed risk assessments are being used. This was a focus of the project and resulted in the Battler series publication "Find answers online to common invasive species questions".

Weed risk assessments contribute to prioritisation of target species, areas, and activities in combination with stakeholder consultation and local knowledge during NISSAP formulation. There are ongoing priority weed programmes operating in the Pacific which are showing success towards eradication. Widespread weeds can sometimes be targeted using biological rather than chemical or physical control: 36 natural enemies have established on 19 weed species in the Pacific. Since 1911, 17 countries and territories have deliberately released biological control agents on weeds in the Pacific. There are many opportunities for distributing existing agents further around the Pacific and opportunities to target new species.

Unlike biological control agents that were introduced to target invasive animals but were devastating to those islands to which they were introduced, such as the Indian mongoose for controlling snakes and the rosy wolf snail for controlling the giant African snail (Lissachatina fulica), the use of biological control to manage widespread weeds has been much more successful and much safer following standard international protocols such as host-specificity testing on other possible desirable plants. Internationally, 483 agents have been released with none resulting in unpredictable non-target effects (M. Day & L. Hayes, pers. comm.).

The development of biological control agents for weeds can be initially expensive. However, once agents are researched and located, they can provide an endless service of controlling invasive plants to a degree where their impact is greatly reduced. Further, once the initial agents are confirmed as effective, it is relatively cheap to move them to new countries or locations following any additional location-specific host-testing that may be required.

Vanuatu was fortunate to benefit from two new agents being developed for African tulip tree under a Landcare Research New Zealand project with the Cook Islands. The agents required minimal further host specificity testing and are due to be introduced to Vanuatu in the near future.

Palau has benefited from many years work on *Mikania micrantha*, which has a natural rust enemy already established in many countries. Accordingly, previous host specificity testing has been carried out extensively for many countries, leaving just one plant for which Palau was required to do tests on. The rust was introduced to Palau but was not successful for undetermined reasons. It is planned that the rust will be moved to some states within the Federated States of Micronesia, such as Yap, where *Mikania micrantha* is a serious weed. *Mikania micrantha* is located in 20 Pacific countries and territories; however, the rust agent has only been introduced to six to date.

Invasive animal species actions

There are good examples of sustainable control projects operating in the Pacific. A key action for environmental protection is to prevent the spread of IAS across international or internal borders. The four main stages are pre-export control, pre-border control, at-border control, and post-border rapid response.

Niue created a harmonised Biosecurity Bill which allows environmental concerns to be addressed along with the traditional agricultural and trade concerns. Early detection and rapid response (EDRR) plans have been created for the Cook Islands, Kiribati, and Samoa. The plans detail the staff and funding requirements, identify best practices regarding known target species, and convey decisions made about the country's approach to the known and potential IAS. Simulation exercises were completed to identify gaps before a response becomes necessary.

The Battler series booklet "Catch it early: invasive species early detection and rapid response" outlines the components of effective IAS response systems. The creation of response plans, training of staff, and procurement of equipment needs to be supported by ongoing engagement, regular refresher simulation exercises, and greater public awareness to maintain fast responses to incursions. The accidental introduction of five mongooses to Tonga in 2016 demonstrated the need for rapid, planned response action. Long-term management is often required for IAS that cannot be eradicated due to their value as a cultural or livelihood resource or simply the amount of resources required to do so. Such management requires ongoing resourcing but may be the only option available, so the value that is being protected from the IAS needs to outweigh the cost of management.

Managing pigs is a balance between cultural or food needs and environmental needs. Domestic pigs are kept in pens as an important food source, but pigs that get out of pens cause a lot of damage. Investing in upskilling locals to the level of professional hunters has paid off in Niue. In 12 months, approximately 130 pigs have been hunted by locals, reducing the population by one half from the estimated pre-hunt total. Professional pig-hunting dogs, global positioning systems, and expert mentoring have resulted in a sustainable, low-cost method for managing pigs on Niue. In Samoa and Vanuatu, crown of thorns starfish is the target of on-going control. Although a native species, crown of thorns can become invasive following modifications to the environment by man or natural disasters such as tsunamis and cyclones. In both countries, the local communities are provided with tools, procedures, and support to lower the impact that the outbreaks have on their local marine ecosystem.

Many IAS are already widespread in the Pacific and impacting biodiversity, including in protected natural areas. When this is the case, there are still options to protect these species and ecosystems with a site-led or asset-based approach. Exclusion of IAS is an option if the surrounding environment contains widespread or otherwise unmanageable IAS which may affect high-value areas. It can also be used as a short-term measure until a solution becomes available. In Mount Talau National Park in the Vava'u islands of Tonga, a rare plant *Casearia buelowii*, which is endemic to Mt Talau and only survives through fewer than 20 individuals, was being continually undermined by pigs, exposing the roots to damage and the heat of the sun. A Tongan pig fence was constructed around the site to exclude the pigs until a long-term pig management solution can be found. Widespread IAS may also be contained to restrict their arrival in uninfested areas. On Niue, the primary infestation of taro vine is situated within the villages of Alofi and Alofi South. Isolated infestations are targeted to contain the infestation to the primary infestation site.

There are good examples of site-led or asset-based restoration projects operating in the Pacific. Restoration supports species recovery and the continued provision of ecosystem services. Ideally, restoration involves the community at multiple scales because restoration is a long-term, if not continual, process. The Kingdom of Tonga is restoring two key ecological sites: the Toloa Rainforest and

Mt Talau. The Toloa Rainforest restoration efforts include a Pacific (*R. exulans*) and ship rat (*R. rattus*) control programme, via bait stations, for the whole forest to save native bird and plant species from predation. Replanting of native trees in the rainforest began in 2014 to improve structure and size and to reintroduce plant species that have gone extinct within the forest. Planting will continue until the extension of the forest is complete and the forest sub-canopy and disturbed sites are restored. Weed and rat control will continue into the future. Toloa Rainforest is the last remaining stand of native forest on the main Tongan island of Tongatapu and serves as an educational resource for the schools of Tonga. A key aspect of the project is making information readily available for people who visit the forest, and many of these informational products explain native species and IAS threats. A trail, with rest and wildlife viewing stops throughout, has also been developed.

Hengahenga, or Tongan whistler (*Pachycephala jacquinoti*), are recovering on Mt Talau following rat control. Rodents have been controlled for four years with statistically significant increases in the number of Tongan whistler (endemic to Vava‘u) and other birds such as the Polynesian triller (*Lalage maculosa*) and Polynesian starling. Rats heavily impact the survival and productivity of the Tongan whistler because the birds build an open bowl nest that is easily accessed by rats. The control programme is run by the local community with the assistance of the Vava‘u Environmental Protection Association. It uses a rat bait-take database that captures, stores, and reports on bait take at each bait station during the programme and allows analysis of bait take to inform success at lowering the rat population, identify areas of high rat activity, and allow for more economical use of the bait. Hengahenga are now seen and heard in the surrounding area with many Tongans witnessing this bird for the first time in their lives.

Samoa has also embarked on restoring two important sites, Mount Vaea Reserve and O Le Pupu Pu‘e National Park. On Mt Vaea, the focus has been on controlling widespread weeds, which form 90 percent of all stems within the regular survey sampling plots. Following weed control, each area is re-vegetated with native trees which quickly form a canopy, reducing the ability of the light-demanding weed species to grow. The weed species that are adapted to grow under low light conditions are regularly managed. Six hectares of Mt Vaea have now been restored, with the on-site nursery having provided19,000 trees for volunteers and the local village to plant. The focus at O Le Pupu Pu‘e has been on planting to suppress the *Merremia peltata* infestations that are restricting regeneration following disturbances such as cyclones. Again, the closed canopy of the revegetated areas is supressing this light-demanding species.

FUTURE PACIFIC PROJECTS

The GEF-PAS Project was evaluated by the United Nations Environment Programme (UNEP, 2017). The summary of project criteria “Strategic relevance”, “Achievement of outputs”, “Communication and public awareness”, “Supervision, guidance and technical backstopping” all had overall ratings of Highly Satisfactory; “Socio-political sustainability” had an overall rating of Highly Likely; “Preparation and readiness” had an overall rating of Unsatisfactory.

The increased establishment and support of existing national institutionalised IAS programmes needs to be carried forward, building upon the success of GEF-PAS. Project under-preparedness and -readiness is common to most Pacific projects due to the lack of capacity and increased logistical challenges in such a large geographic area. Future project preparation times for large, complex projects in the Pacific need to be extended for one year to allow for this.

The “Guidelines for Invasive Species Management in the Pacific” provide an effective framework to plan IAS programmes and can be directly used to plan actions within NISSAPs to measure and analyse actions between countries with consistency. Regional support was vital in achieving quality outcomes. The GEF-PAS project allowed support to be increased substantially, and this needs to continue. Empowering country coordinators and stakeholders through coaching, capacity building, and support in-country, is the most important means to sustain IAS management capability. This needs continued support.

The Pacific Invasives Learning Network appears to be the most effective means for Pacific practitioners to work together and learn from each other. PILN creates and supports the regional flow of information regarding IAS management. PILN requires sustained support. Successful projects resulted in increased visibility and support by local communities, other related sectors, and at the political level. This support is indicated by institutionalisation within government agencies of a core IAS role, as has been the case in some countries, and the commitment to progressing IAS management within the following Global Environment Facility replenishment cycles and other funds.

The GEF-PAS project has made significant progress. The implementation of GEF 6 and EDF 11 projects will build substantially on these successes and continue to refine and enhance the management of IAS in the Pacific Region. Climate change is increasing the intensity and urgency of the response to IAS by reducing the capacity and resilience of Pacific ecosystems and societies to adapt to climate change. Invasive alien species management needs to be an accepted tool for Pacific ecosystems and communities to adapt to climate change.

ACKNOWLEDGEMENTS

The project outcomes were achieved by dedicated Pacific country teams from the Cook Islands, the Federated States of Micronesia, Kiribati, Niue, Palau, Republic of the Marshall Islands, Samoa, Tonga and Vanuatu with the assistance of the SPREP Invasive Species Team. The project was funded by the Global Environment Facility and implemented by the United Nations Environment Programme. This paper was compiled by the SPREP Invasive Species Team and has benefited from the persistence of Dick Veitch and the review and editing of James Russell. A big thanks and congratulations on the achievements of this project.

Maximising conservation impact by prioritising islands for biosecurity

Abstract Invasive alien species are one of the primary threats to native biodiversity on islands worldwide, and their expansion continues due to global trade and travel. Preventing the arrival and establishment of highly successful invasive species through rigorous biosecurity is known to be more economic than the removal of these species once they have established. However, many islands around the world lack biosecurity regulations or practical measures and establishing biosecurity will require social and financial investments. Guiding these investments towards islands where native biodiversity is at highest risk from potential invasions is of strategic importance to maximise conservation benefit with limited resources. Here we implement an established prioritisation approach, previously used to identify which islands will have the greatest conservation gains from the eradication of invasive species, to identify which islands would benefit the most from establishing or improving biosecurity. We demonstrate this approach for 318 islands in the Caribbean UK Overseas Territories and Bermuda where we considered all threatened native terrestrial vertebrates that are vulnerable to the most harmful invasive vertebrates (black and brown rats, cats, small Indian mongoose, green iguana). The approach calculates the increase in conservation threat score resulting from anticipated negative effects of potential invaders on native biodiversity, and highlighted Sombrero (Anguilla) and Cayman Brac (Cayman Islands) as important islands where threatened reptile species would likely be eliminated if rats, feral cats or mongoose invaded. Feasibility and cost implications should now be investigated more closely on the highlighted islands. The prioritisation presented here can be expanded to more islands and more invasive/native taxa (herbivores, plants and invertebrates), but requires a classification of the severity of potential impacts between invasive and native species for which currently little information exists. Besides highlighting opportunities for biosecurity, this approach also highlights where knowledge gaps about population sizes of and threats to reptiles with restricted ranges exist.

Keywords: Caribbean, feral cat, iguana, invasive mammals, mongoose, rats, reptiles

INTRODUCTION

The majority of the world's archipelagos have been invaded by non-native species, some of which have detrimental effects on native biodiversity (Atkinson, 1985; McCreless, et al., 2016; Turbelin, et al., 2017). Although some islands can be restored by eradicating certain invasive species, such operations can be expensive (Martins, et al., 2006; Holmes, et al., 2015). The limited amount of funding available for island restoration efforts has motivated managers to prioritise the islands where an eradication would yield the greatest biodiversity benefits at global and regional levels (Brooke, et al., 2007; Dawson, et al., 2015; Stanbury, et al., 2017). However, current technologies limit restoration via eradication to 15% of islands that have been invaded (Keitt, et al., 2019), hence eradication is not a universal solution to preserve global island biodiversity.

Preventing harmful species invading those islands which still have globally significant biodiversity values is an important and efficient avenue to prevent loss of biodiversity (Broome, 2007; Russell, et al., 2008; Spatz, et al., 2017). Biosecurity measures also require financial investments, both initially and in perpetuity, to detect and eliminate any potential invaders to islands (Oppel, et al., 2011; Key & Moore, 2019). Because the costs for biosecurity can be considerable, financial constraints can also limit the number of islands that can be protected with effective biosecurity measures (Moore, et al., 2010; Greenslade, et al., 2013). Here we propose to use established prioritisation approaches (Brooke, et al., 2007; Dawson, et al., 2015; Stanbury, et al., 2017) to guide the investment of resources for biosecurity to minimise the risks of invasion of non-native vertebrates to islands where they would cause the greatest loss of biodiversity. We demonstrate this approach for 318 islands that belong to United Kingdom Overseas Territories (UKOTs) in the Caribbean and Bermuda.

The islands in the Caribbean UKOTs feature globally important biodiversity (Forster, et al., 2011; Dawson, et al., 2015; Churchyard, et al., 2016), with a large number of endemic reptiles, birds, and plants. Due to centuries of human habitation and inter-island trade, most islands have been invaded by some non-native species (Hilton & Cuthbert, 2010), but only a few islands contain the complete suite of invasive vertebrate species present in the Caribbean region. In addition, >100 small and uninhabited islands are still free of invasive vertebrate species and function as refugia for some globally threatened species that cannot coexist with harmful invasive vertebrates (Dawson, et al., 2015). Preventing the invasion of non-native vertebrates that have caused significant declines to native species on other islands could secure globally significant populations of threatened vertebrates. Despite the recognised threat of invasive species to endemic biodiversity, biosecurity regulations and implementations are generally insufficient to reduce the risk of further spread of invasive species between islands in the Caribbean region (RSPB, 2017; Key & Moore, 2019).

We conducted a prioritisation that identifies those islands where the invasion of five potentially harmful invasive vertebrates could cause the greatest loss to biodiversity in the Caribbean UKOTs. We recommend immediate investment in feasibility studies and biosecurity on those islands to avoid the invasion of these five species and the subsequent loss of native biodiversity, and we recommend that similar approaches should be used in other regions, or indeed globally, to identify islands where investment in biosecurity is most urgently needed.

METHODS

Study area

We used all 318 islands in the five Caribbean UKOTs (Anguilla, British Virgin Islands, Cayman Islands, Montserrat, and Turks and Caicos Islands) and in Bermuda, which is situated 1,500 km north of the Caribbean but

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 663–669. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

is climatically similar (Fig. 1). These islands are mostly tropical and range from small sandy islets of 0.01 ha to islands with mountain ranges and a variety of habitat types > 20,000 ha. Only 14 islands are permanently inhabited by human communities of up to 65,000 people, while the remaining islands are either completely uninhabited, function only as tourist resorts or destinations, or are visited temporarily by fishermen.

Selection of potential invasive species

To assess biodiversity loss that could result from the invasion of harmful animal species, we selected the five most harmful invasive terrestrial vertebrates (McCreless, et al., 2016) that are widespread in the Caribbean region. Green iguanas (*Iguana iguana*) are known to hybridise and compete with native reptiles (Gibbon, et al., 2000; Vuillaume, et al., 2015), small Indian mongoose (*Urva auropunctata*) are versatile predators considered one of the worst invasive species (Hays & Conant, 2007; Barun, et al., 2008), brown (*Rattus norvegicus*) and black rats (*R. rattus*) and feral cats (*Felis catus*) are efficient predators that can have detrimental effects on island biodiversity (Towns, et al., 2006; Jones, et al., 2008; Medina, et al., 2011; Nogales, et al., 2013). These five species are distributed widely across islands in the Caribbean (Kairo, et al., 2003; Dawson, et al., 2015) and are therefore potential invaders of all islands in the region.

Distribution of native and invasive species

For each island we previously collated information on the presence of native and invasive terrestrial vertebrate species for an eradication prioritisation (Dawson, et al., 2015) and a general inventory of biodiversity (Churchyard, et al., 2016), and updated these previous compilations with recent information and threat assessments (IUCN, 2017). We considered all globally threatened terrestrial vertebrate species (including marine turtles) as listed on the International Union for Conservation of Nature Red List of Threatened Species (IUCN, 2017) and all colonial seabird species and restricted range bird species. We also included reptiles of conservation concern that are endemic to a single territory or inhabit fewer than 15 islands across their range (Dawson, et al., 2015). We updated this information with new records shared by local partner organizations since 2013 (Hedges, 2017). We considered the green iguana that exists on Montserrat as a genetically distinct conservation management unit, because it is genetically closely related to the iguana on Saint Lucia, which is treated as a native

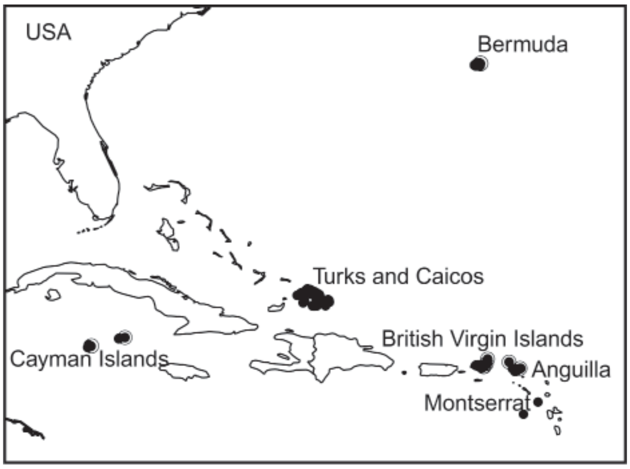

Fig. 1 Location of 318 islands (black dots) in six United Kingdom Overseas Territories where the priority for biosecurity was assessed. Circles around islands indicate the location of the highest priority islands listed in this paper.

species of conservation concern (Powell, 2004; Stephen, et al., 2013; Vuillaume, et al., 2015). Due to the lack of sufficient distribution data and limited existing knowledge of interactions, native and invasive plant or invertebrate species were not considered in this prioritisation.

Calculating the conservation threat score of islands

We followed the approach of Dawson, et al. (2015) to calculate the conservation threat score (termed 'conservation value' in Dawson, et al., 2015) of each island based on the sum of each native species' vulnerability. The vulnerability was calculated as the product of the global threat status, the irreplaceability, which indicates the global significance of an island's population, and the severity of impact of the most harmful invasive vertebrate species already present on an island (i.e. the species with the greatest severity of impact score; Dawson, et al., 2015; Stanbury, et al., 2017). We scored threat and impact categories on both a linear and logarithmic scale to address the arbitrariness of assigning quantitative values to normative categories (Game, et al., 2013; Helmstedt, et al., 2016). The severity of impact was classified in three categories, depending on whether an invasive species had no impact on a native species (0), small to moderate impact that would reduce population size but allow the native species to persist (1), or a severe impact that would eventually lead to the local extinction of the native species (2). We classified unassessed reptiles as 'At Risk', which received a numerical value equivalent to 'Vulnerable' (Dawson, et al., 2015).

Simulating the invasion of islands to calculate increase in conservation threat score

To quantify the magnitude of biodiversity loss that could result from invasion, we first assessed which of the five selected invasive species were already present on an island in 2016, and then simulated the arrival and invasion of those species that were not yet present in 2016. We then re-calculated the conservation threat score of each island as described above, where the vulnerability of each native species was adjusted to reflect the most harmful invasive species on the island, which may be one of the simulated invaders. We assumed that all invasive species not yet present on an island would invade, because biosecurity measurements should, in our opinion, not be tailored for a single species but guard against the arrival of a broad suite of species. However, we emphasise that our prioritisation could also be performed for single species invasions, but assessing the merits of guarding against one or another invasive species would require information about the relative invasion risk of various species.

The calculation of the conservation threat score depends on a classification of the threat posed by each invasive species to each native species, but these threats can be hypothetical for interactions between certain island endemic species and invasive species that have so far not invaded the respective island. Consequently, we drew on taxonomically related or otherwise very similar species to specify the potential threat that would result from invasion. For example, if black rats adversely affect a small *Sphaerodactylus* gecko on one island, we assumed that a similarly sized *Sphaerodactylus* species that is endemic to an island without any rats would suffer similar effects if the island were invaded by rats (Case & Bolger, 1991).

Prioritising islands for biosecurity

Islands that should receive the most immediate investment into biosecurity are those where the native fauna would face the greatest increase in conservation threat score if the five selected vertebrate species invaded. We therefore calculated the difference in conservation value at present and after the simulated invasion of the five vertebrate species, and ranked islands based on the magnitude of this difference. We present the results as a ranking table and include information on island size and human population size for each island. These aspects will affect the complexity and cost of biosecurity measures, as well as the probability of invasive species arrival and establishment, but they did not factor into our prioritisation of islands for biosecurity, which was entirely based on the potential threat to native biodiversity. All calculations were performed in R 3.2.5 (R Development Core Team 2015) based on the code provided by Dawson, et al. (2015).

RESULTS

Of the 318 islands in our assessment, 125 did not have any invasive species on them, and 150 (47%) did not have any of the five focal invasive species. Of the islands with any of the five focal invasive species, 31 (10%) had one invasive, 117 (37%) had two, 12 (4%) had three, 6 (2%) had four, and only two islands (Tortola and Virgin Gorda, British Virgin Islands) had all five of the focal invasive species. On 183 islands (57.5%) the invasion of any of the five focal invasive species would not lead to an increase in the conservation threat score, because the native vertebrates on these islands were not at greater risk of predation from those invasive species that have not yet invaded. Thus, biosecurity measures to prevent the invasion of at least one of the five focal species would be useful on 133 islands in our assessment.

We identified several important islands across the Caribbean UKOTs and Bermuda where biosecurity could help prevent the loss of globally important biodiversity (Table 1). Two islands emerged where an invasion of non-native vertebrates could lead to an increase in the conservation threat score more than five times greater than on any other island included in our study, mostly due to the potential loss of Critically Endangered endemic reptiles (Table 1): Sombrero (Anguilla), and Cayman Brac (Cayman Islands).

Among the most important islands we identified for biosecurity, three were inhabited by >1000 people and have existing populations of rats, feral cats, and green iguanas (Cayman Brac, Grand Cayman, and Montserrat, Table 1). However, the small Indian mongoose is so far absent from those islands and reducing the risk of invasion of this efficient predator on islands that already have other harmful invasive species could help secure globally important biodiversity. Together with Montserrat, Anegada in the British Virgin Islands was among the top priorities for biosecurity to reduce the risk of invasion of black rats and small Indian mongoose, despite both islands also being a high priority for the eradication of already existing invasive species (Dawson, et al., 2015).

DISCUSSION

We show that effective biosecurity on islands in the Caribbean UK Overseas Territories could reduce the risk of further spread of harmful invasive vertebrates to islands where globally threatened reptiles and birds would be at risk. Investing in effective biosecurity procedures and educating the public and policy makers about the risks to their national heritage when no biosecurity is in place should be the immediate next steps of UK and local governments, private island owners, and international funding bodies. Our approach offers the guidance to focus on a limited number of vulnerable islands, as more than half of the islands we evaluated are not at immediate risk of further biodiversity loss from the invasion of the five invasive vertebrate species that we selected.

Similar to other prioritisations identifying islands for eradication of invasive species (e.g., Harris, et al., 2012; Dawson, et al., 2015; Stanbury, et al., 2017), our list is subject to incomplete information about the distribution of both native and invasive species. The distribution of several reptile species is poorly documented across many islands of the Caribbean, and their threat status is also poorly assessed on the IUCN Red List, both of which may affect our assessment of their local importance and therefore introduce bias to our projections of loss in conservation value (Russell, et al., 2017). Further surveys to increase the knowledge of native and invasive species on islands would be beneficial but should not be used as an argument to delay the immediate adoption of effective biosecurity protocols to safeguard the most important islands that we identified.

Besides thorough knowledge about the native and invasive species occurring on an island, our approach also requires a classification of the interactions between native and invasive species. Because these interactions can be hypothetical for single-island endemic native species that have not been exposed to invasive species, due caution is necessary when interpreting the output of our prioritisation. We used the response of taxonomically similar species to the same invasive species to predict biologically plausible consequences of an invasion, but interactions between native and invasive species are often complex and unpredictable (Simberloff & Von Holle, 1999; Simberloff, 2006). We encourage researchers to provide robust and reliable predictions about the potential consequences of invasions to assist with strategic investment decisions for reducing the risk of invasive species becoming established on islands harbouring globally important biodiversity (Moore, et al., 2010).

In summary, we demonstrated that biosecurity is not only important on small uninhabited islands or privately owned tourist resorts where natural habitats remain and endemic and globally threatened species persist. Even on large and populated islands such as Grand Cayman, Cayman Brac, and Montserrat, the invasion of small Indian mongoose could result in a significant deterioration of the conservation status of several globally threatened vertebrates (Hays & Conant, 2007). We therefore urge local governments, private island owners (e.g. Mosquito Island) and communities to carefully inspect all incoming cargo and people and establish ongoing measures to detect and remove any new invasive species. Training of border officials and conservation staff, public education and awareness campaigns targeting the accidental introduction of invasive species onto uninhabited islands by visiting people (e.g. fishermen, tourists) should also be implemented, because international and domestic biosecurity measures are currently weak across all Caribbean UK Overseas Territories (Key, 2017; RSPB, 2017). Laws governing biosecurity measures in the Caribbean UK Overseas Territories and Bermuda are disjointed, not comprehensive and scattered through various environmental, agricultural and customs regulations. Collaboration under existing national legislative mechanisms may improve the situation quickly prior to enacting any new legislation (RSPB, 2017). We would also encourage regional collaboration in developing biosecurity measures, information sharing and learning from any existing biosecurity initiatives.

ACKNOWLEDGEMENTS

We greatly appreciate the support of all the UK Overseas Territory governments and BirdLife International partner organisations for providing data on the distribution of native and invasive species. We are grateful to Montserrat National Trust, Anguilla National Trust, National Parks Trust of the British Virgin Islands, Turks and Caicos

Table 1 The top 25 islands in Caribbean UK Overseas Territories and Bermuda where the invasion of five common vertebrate species could potentially cause the greatest increase in threats to native biodiversity. Note that some invasive species are already present on some islands (i.e. those with current threat score > 0), and only the potential new invaders are listed; islands with a current threat score >0 would also benefit from the removal of already existing invasive species. Human population size and island area are provided for information, as they will affect invasion risk and effort required for biosecurity. The current and post-invasion threat scores are calculated as the sum of all impact scores of invasive species on all threatened native species present on an island before and after potential invasion.

Working with the local community to eradicate rats on an inhabited island: securing the seabird heritage of the Isles of Scilly

Abstract The inhabited Isles of Scilly, 45 km off the south-western tip of the UK, are home to 13 seabird species including European storm petrel (*Hydrobates pelagicus*) and Manx shearwater (*Puffinus puffinus*), for which the UK has a global responsibility. Between 1983 and 2006, the overall seabird population in Scilly declined by c.25%. This decline triggered the establishment of the Isles of Scilly Seabird Recovery Project, a partnership with the aims to reverse seabird decline and engage the local community and visitors in conserving Scilly's seabird heritage. The eradication of brown rats (*Rattus norvegicus*) from St Agnes and Gugh represented the result of over a decade of preparatory work, involving raising awareness and gaining 100% support from the community. The two islands are home to 85 people. Therefore additional, and somewhat unusual, preparations were required (including clearing sheds, communicating with school children and taking precautions to ensure the safety of pets) during the ground-based baiting operation. In 2016 St Agnes and Gugh were officially declared 'rat-free', meaning worldwide this is one of the largest community-based eradications to have been successful. Biosecurity on inhabited islands is complex, so to ensure the project's sustainability, efforts have been community-led. The community has taken ownership of protecting its seabirds, with 100% saying rat removal and the subsequent increase in seabirds has had, or will have, a positive effect on ecotourism, a key source of income for the islands. No less than 68% of the community said their businesses have directly benefited. This project represents a case study for other community-based projects, showcasing how eradications can gain community support and benefit both wildlife and human populations.

Keywords: biosecurity, brown rat, eradication, Gugh, inhabited, public support, St Agnes

INTRODUCTION

The eradication of invasive species from islands has become one of the most important tools for biodiversity conservation but it can also improve local socio-economics, human health and ecotourism. Rodents have been successfully eradicated from islands throughout the world, including a number of UK islands (Bell, et al., 2000; Zonfrillo, 2001; Towns & Broome, 2003; Bell, 2004; Howald, et al., 2007; Bell, et al., 2011; Thomas, et al., 2017; Bell, 2019). Most of these islands have been uninhabited and many consider that islands with significant human populations, an unreceptive local community or occurrence of livestock and domestic animals are unlikely to be feasible for eradication (Campbell, et al., 2015). Given that an increasing number of eradications are being investigated on inhabited islands, the importance of the engagement and inclusion of local communities has been highlighted in a number of recent eradication and research projects (Oppel, et al., 2010; Bryce, et al., 2011; Eason, et al., 2011, Walsh, et al., 2019). The opinions and safety of the local community need to be a priority in any eradication planned for inhabited islands (Stanbury, et al., 2017). Without compliance of the full community, access to properties may be denied which may result in the failure of eradicating every rodent or following the eradication, community members may compromise ongoing biosecurity measures.

Human activities can affect the success of an eradication campaign, particularly waste management, food storage, buildings harbouring rat nesting materials, and limited access to certain areas of the island. On the inhabited UK islands where previous eradications have been completed, they have been staffed by personnel working for the owners of the island, for example Lundy, UK (Bell, 2004) and Isle of Canna, UK (Bell, et al., 2011) whereby the parties involved are working within the confines of employment contracts. This is not the case with community members. Other wildlife control projects may have seen decision-makers 'persuade the community' to accept their decision, e.g. the delayed rodent eradication programme for Lord Howe Island (Australia) whereby many inhabitants felt excluded from initial planning (Crowley, et al., 2017b).

The purpose of this paper is to set out the community involvement through the various stages of the Isle of Scilly Seabird Recovery Project, how the views of the local community were collected and used in the design and delivery of the project to establish and maintain community support and evaluate how successful the project was in achieving this.

Background to 'Isles of Scilly Seabird Recovery Project'

The Isles of Scilly are 45 km off the southwest tip of the UK (Fig. 1). As an island group, they are made up of five inhabited islands (St Mary's, St Martin's, Tresco, Bryher and St Agnes and Gugh) and up to 190 uninhabited islets and stacks (1,641 ha, Parslow, 2007). The Isles of Scilly are nationally important for many species of seabirds, supporting 20,000 birds of 13 native species including the burrow-nesting species Manx shearwater (*Puffinus puffinus*) and European storm petrel (*Hydrobates pelagicus*) (Lock, et al., 2006). Declines of 25% had raised significant conservation concerns about the future of the seabirds on the islands. The Isles of Scilly 'Seabird Liaison Group' (SLG) is a partnership between Royal Society for the Protection of Birds (RSPB), Natural England, Isles

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 670–678. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

of Scilly Wildlife Trust (IOSWT), Area of Outstanding Natural Beauty (AONB) and Isles of Scilly Bird Group, working within the 'Isles of Scilly Seabird Conservation Strategy' since 2006 (Lock, et al., 2006; Lock, et al., 2009; St Pierre, et al., 2014). This strategy describes the status and context of the seabird populations on the Isles of Scilly and identifies priority actions including current and future measures to improve the available habitat for seabirds (Lock, et al. 2006; Lock, et al. 2009; St Pierre, et al., 2014). The eradication of brown rats (*Rattus norvegicus*) from St Agnes and Gugh was identified as a priority action to remove the threat of mammalian reinvasion on the neighbouring uninhabited island of Annet and provide the opportunity for Manx shearwaters and storm petrels to breed successfully once St Agnes and Gugh were cleared of rats.

St Agnes (105 ha) and Gugh (37 ha) are two islands connected by a rock and sand bar at low tide and are separated from the island of St Mary's by a deep,1 km wide channel. The main habitats are farmland, ponds, maritime heathland and grassland, rocky shores and sandy beaches (Parslow, 2007). Non-native *Pittosporum crassifolium* and *Coprosma repens* were introduced as part of the flower farming industry as shelter hedges in the late 1800s. There is a pub, a Post Office and shop, two cafes, a campsite and two community halls. Brown rats were accidentally introduced to the Isles of Scilly from shipwrecks in the 1700s and were widespread and abundant across both islands (McCann, 2005). The 'community' of St Agnes is defined as the 85 residents who live full time on St Agnes, plus two part-time residents who live on Gugh for six months of the year in holiday homes.

Prior to and during the period of the 'Isles of Scilly Seabird Conservation Strategy 2006–2013', seabird conservation awareness activities were delivered on the islands through community engagement by RSPB, IOSWT and AONB. These activities were delivered through press releases, articles and presentations updating residents on the outcomes of annual seabird monitoring surveys, seabird youth education, advocacy at the island fetes and beach cleans. These activities represented a decade of preparatory work enabling the community of St Agnes and Gugh to learn about and take pride in protecting its seabird heritage.

Fig. 1 Map of the Isles of Scilly, 45 km south-west off the tip of the UK.

In 2010, the SLG held a workshop on St Mary's, to initially obtain the views of residents on all inhabited islands regarding options for control, eradication and the importance of seabirds. This workshop provided the mandate for the SLG to commission a detailed assessment into the feasibility of eradicating brown rats from St Agnes and Gugh (Bell, 2011a). Due to eradication projects failing on other inhabited island elsewhere in the world (Oppel, et al., 2010), SLG required the feasibility assessment to include social and economic evaluation. It was not known how the community would feel about eradicating rats; whether they would feel the proposed action necessary, or how they would evaluate social, economic and health benefits of such an operation. If a person's values and sensitivities are dismissed, then they will not engage with operational processes which can jeopardise the whole project. The assessment had to focus on obtaining the opinions of all community members. The feasibility assessment was conducted by Wildlife Management International Ltd (WMIL; Bell, 2011a; 2011b)

The 'vision' for the project primarily focused on protecting Manx shearwaters and storm petrels, because rat eradication was considered the only land-based option that would feasibly increase the abundance of these species.

MATERIALS AND METHODS

Feasibility phase

The community firstly needed to understand that *control* of rats was not an option and that eradication was only a viable goal if all parties worked together. The feasibility study therefore set out to ascertain each resident's opinion on whether they would support the eradication of rats, what benefits they would expect for themselves and the community, and what would motivate them to keep the islands rat-free. Face-to-face interviews using a standard questionnaire were conducted with all adults on St Agnes and Gugh. Controversial topics are often better received if personnel are open to discuss less positive outcomes, acknowledging inherent risks and ethical challenges as it allows questions to be voiced and addressed from the outset (Crowley, et al., 2017a).The risks stated were (a) inconvenience (e.g. temporary or long-term changes in waste disposal, pet and livestock treatment), (b) time away from other activities due to volunteer participation during eradication and long term biosecurity and monitoring, (c) adjustment to new regulations (e.g. undergoing rodenticide training), (d) that economic benefits may take time and only apply to some community members, and (e) funding for eradication may come from grant funding, which communities may feel reduces the availability of financial resources for alternative projects.

In order to make their own decisions, community members each needed to have a full understanding of the technical aspects of the rat removal operation, and what their personal role in the project could potentially be. The feasibility assessment incorporated two general community workshops; a combined meeting with the six farmers to discuss the eradication in detail, covering aspects that were specifically relevant to stock, crops and farms as well as face-to-face meetings on each farm; visits to St Agnes School; and face-to-face meetings with representatives from each household. Every resident was asked to provide full details of their willingness to support a potential eradication and any stipulations they had. Achieving complete rat eradication was only part of the process, the legacy of the project was to keep the islands rat-free in perpetuity. The feasibility study therefore also set out to ascertain the willingness of each community member to carry out biosecurity measures in the long term.

Interim phase

While RSPB and AONB continued to deliver education work to invest in on-the-ground community relationships between June 2011 and January 2013, a Project Steering Group and Communications Group were formed.

Start of the project; preparation for 'rat-removal ready' phase

When funding was confirmed, the five-year 'Isles of Scilly Seabird Recovery Project' (IOSSRP) was launched. Two staff members were employed by RSPB, providing continuity for the community at each phase. Through a competitive tender process, WMIL were the successful contractors for rat eradication. Community conservation actions at this stage were named 'rat-removal ready' actions and were focused on reducing potential rat food and harbourage to a minimum, so rats could be easily detected and take bait when the eradication phase commenced.

The IOSSRP recognised the importance of monitoring the response of other species on St Agnes and Gugh following the eradication of brown rats and implemented a monitoring programme for birds, mammals (shrew and rabbits), invertebrates and vegetation. This work was completed under contract by Spalding Associates. Most species benefit from rat eradications on islands, but there have also been unforeseen and negative impacts recorded in several projects around the world (Courchamp, et al., 2003; Towns, et al., 2006; Bell, et al., 2011).

Eradication and short-term monitoring phase

The eradication delivered by WMIL, was a ground-based bait station operation using rodenticide over winter when natural food was minimal (Bell, 2019). Monitoring tools were used to detect any rats not taking bait or avoiding bait stations. Community members were required to assist WMIL with specific eradication activities such as checking bait stations in their own homes and reporting rat sightings. During the eradication phase, WMIL and IOSSRP personnel built good relationships with community members to create the best foundation for well-coordinated actions for on-going biosecurity and potential incursions in the future.

Post eradication monitoring and final check phase

WMIL produced a Biosecurity Plan and returned for a six-week 'final check' phase in winter 2016. IOSSRP personnel trained community members to assist with the monthly checks of the permanent biosecurity stations and surveillance after a 'rat on a rat' (ROAR) call (a 24-hour hotline based at IOSWT where anyone can report rat sign or a suspected rat sighting). A ROAR required a monitoring grid extending 300 m in all directions from the sighting spot with daily checks for a month (and was removed when no evidence of a rat was detected). During the 'final check', questionnaires as part of semi-structured interviews were carried out. The community questionnaire consisted of 22 socio-economic evaluation questions, 14 delivery questions and eight biodiversity questions. Semi-structured interviews represented feedback from the full population of St Agnes and Gugh. Qualitative analysis was deemed the best fit as interviews allow each person to express themselves, including personal narrative, and common themes can emerge (Crowley, et al., 2017a). It is known that successful eradication of rodents has turned some islands into attractions for visitors, facilitating the establishment of local tourism businesses (Oppel, et al., 2010). Therefore, specific questions were asked to ascertain whether tourism or other businesses had benefited on St Agnes and Gugh following the eradication of rats. During these interviews, community members who were able to commit to long-term biosecurity actions were registered with RSPB as Seabird Heritage Volunteers (SHVs) and were provided with additional training and support to complete these actions.

Long-term monitoring phase

The SHVs took ownership of their biosecurity roles to continue to keep the islands rat-free after the formal end of the IOSSRP project. SHV Coordinators were recruited in the community to coordinate these community volunteers and record data from each biosecurity action. An updated Biosecurity Plan for St Agnes and Gugh was prepared by IOSSRP with contributions from SHVs. A Maintenance Plan was written by the partners and the community aspects were 'sense-checked' by the SHVs.

RESULTS

Feasibility phase

All community members valued seabirds and supported the eradication of rats for the protection of seabirds. The collective support for the project was not solely for seabirds but for the added benefits to people (Bell, 2011a; Bell, 2011b). Rats were having an impact on the livelihood, health, enjoyment and lifestyle of the local community as well as the biodiversity of the island (Bell, 2011a; Bell, 2011b). Farmers reported rats were damaging crops and taking or damaging stock food, fishermen reported rat damage to lobster pots and nets and the campsite suffered damage to tents and customer's food and belongings. Over ¾ of residents reported rats entering their houses. It was estimated that rats were costing the St Agnes and Gugh community approximately £15,000 per year (between £10 and £1,000 per household per year), due to purchasing bait and damage to property and goods (Bell, 2011a; Bell, 2011b).

While explaining that *'the decision to carry out the project is yours'*, the eradication methodology and actions were discussed with the community to ensure that they had all the information needed to make the decision of whether to proceed with the project or not. This gave the community an opportunity to air concerns such as finding adequate funding (86% of residents), incorrect waste management causing eradication failure (80% of residents) and community involvement and support (77% of residents). These concerns were addressed or actions to mitigate these concerns were outlined including information on possible funding streams; bespoke waste training at each property, eatery and farm; provision of rat-proof garbage bins and composters; revised process for waste collection and removal to St Mary's; and the communication strategy (including a 24-hour call line).

Interim phase

A number of activities were completed during the interim phase including putting 'Frequently Asked Questions' on project partner websites, addressing community and wider community questions; delivering two press releases; education and outreach activities on how to detect rats and shrews and providing funding updates to the community. Funding applications were completed and included fully-costed mitigation options for identified issues collected during the feasibility assessment.

Preparation 'rat-removal ready' phase

A five-year 'activity programme' was developed for the community and visitors. A full audit of St Agnes and Gugh was carried out in June 2013 to prepare the islands and provide final 'rat- removal ready' instructions to all residents as requested by the community during the feasibility assessment.

Eradication and short-term monitoring phase

All community members allowed daily access to property for WMIL personnel to carry out the ground-based bait station eradication using rodenticide (either Contrac®, containing the anticoagulant bromadiolone at 0.005% w/w or Roban Excel®, containing the anticoagulant difenacoum at 0.005% w/w) in more than 1,000 stations between October 2013 to March 2014 (Bell, et al., 2019). There was no rat-sign after three and a half weeks (Bell, et al., 2019).

There were no instances of non-target species being affected by the bait (Bell, et al., 2019). Nine rats were picked up above the surface; six of them were discovered by community members, and eradication personnel responded immediately by collecting the carcasses (Bell, et al., 2019). WMIL trained IOSSRP personnel to gain expertise in eradication techniques, which enabled them to further support the community for the later phases. WMIL and IOSSRP personnel delivered the activity programme which included two community update talks, weekly update newsletters and school education sessions.

The eradication methods were reviewed throughout by the Project Steering Group and adaptations were made when necessary. On farms a number of baiting tunnels were dislodged by stock (no bait was consumed) and a number of monitoring stations (i.e. non-toxic flavoured wax) were eaten by cows, so farmers and WMIL liaised to organise a rotation of paddocks where cows would graze, allowing tunnels and monitoring tools to be moved in and out of these areas at certain times and remain intact (Bell, et al., 2019).

Post eradication monitoring and final check phase

Monitoring of the key species showed breeding success for the first time in living memory post-eradication. There were eight Manx shearwater chicks recorded in 2015 and 32 in 2015. Storm petrels returned to breed in 2016 with nine breeding pairs recorded. IOSSRP personnel trained 12 community members to assist checking the permanent monitoring stations and surveillance from 'rat on a rat' (ROAR) calls (Fig. 2).

Fig. 2 IOSSRP personnel train the SHV Coordinators in biosecurity methods. Credit Nick Tomalin.

There were 28 ROAR reports during this post-eradication monitoring phase. Community members assisted the IOSSRP team establish and maintain the ROAR surveillance grid. After the final check was completed, it was deemed appropriate to adapt a ROAR response to the community checking the permanent biosecurity stations only instead of establishing and maintaining a 300 m wide monitoring grid (unless additional evidence of a rat was identified).

The questionnaire responses showed that the entire community felt the eradication had a positive effect on the island and the community (Tables 1–7).When asked what they liked about the project, 31% of the community enjoyed having the eradication team on the islands, 15% liked having no rats on the islands any longer, 10% liked the eradication team and community working together towards the successful completion of the eradication and 5% liked how the project worked closely with the St Agnes School (Table 1). The community thought the project gathered the island together and allowed everyone to work together towards a common goal (Table 2). Half the residents felt that this project had made a positive change to the history for the island including raising cultural awareness of the seabirds and their importance to St Agnes and Gugh and the Isles of Scilly (Table 3). All of the community felt that the project had benefited the economy of the island, with several businesses on the island directly benefitting during and after the eradication (Tables 4 and 5).

Table 1 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'What did you like about the project?'

Theme of reply	No.	%	Social (S) Biodiversity (B) or Delivery (D) theme
The team being on the islands – nice people to have around	18	31%	S
No rats	9	15%	B
Team and community working together for a common goal	6	10%	S
Team were unobtrusive and respectful which made the experience enjoyable	6	10%	S
The project worked with the school	5	8%	S
Manx shearwaters and storm petrels breeding success	4	7%	B
Team helped me learn about wider island biodiversity	4	7%	B
Learnt about rats and their ecology	2	3%	S
The eradication was professionally delivered	2	3%	D
Like to see the bait-take in real time and the speed of operation in daily updates from the team and in newsletters	2	3%	D
I was sceptical at the start but was proved wrong, complete eradication is possible	1	2%	D

Table 2 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'Do you think there have been any positive or negative impacts to community by the removal of rats from St Agnes and Gugh?'.

Theme of reply	No.	%
Negative or no impact	0	0%
Positive (no further comment)	16	28%
Positive, community no longer needs to worry about damage caused by rats	14	24%
Positive impacts for farms and visitor accommodation	12	21%
Positive, the project generated interest in the community	7	12%
Positive as it was nice for the community to have the team on the islands in winter	4	7%
Positive, the community was united and not divided in any way, it was a community project	3	5%
Positive, due to the school and children being involved throughout	1	2%
Positive, apart from the increase in rabbits which is negative for farmers	1	2%

Table 3 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'Do you think there have been any positive or negative impacts to culture/history by the removal of rats from St Agnes and Gugh?'

Theme of reply	No.	%
No impact	29	50%
Positive, as we are making history here on St Agnes	10	17%
Positive impact (no further comment)	7	12%
Positive, culturally we have all worked together as a community	3	5%
Positive, raised cultural awareness of where birds are in our history, memory, collective consciousness, part birds played in our community. Better for historical buildings	2	3%
Positive, as part of our history that we bought rats over and now we are putting our mistake right	2	3%
Positive, we have better waste management and awareness of how to think carefully about staying rat-free	2	3%
Positive, as the project will reinstate historical bird lovers	2	3%
Positive, we can look back and feel proud. I have kept all articles about the project for a community scrapbook to help us remember details correctly.	1	2%

Table 4 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'Do you think there have been any positive or negative impacts to economy by the removal of rats from St Agnes and Gugh?'

Theme of reply	No.	%
Positive (no further comment)	17	29%
Positive in respect to what other community members have told them, but not personally to them	12	21%
Farmers and/or fishermen will not lose profits from rat damage	8	14%
The project itself brought extra business to the islands (using accommodation/ shop/boats)	6	10%
Don't have to spend money on rat control and damage	5	9%
More boating/bird tours	4	7%
More visitors due to not having rats in lets/tents	3	5%
More visitors in the future if we market the islands as 'rat- free'	3	5%

Table 5 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'Has your business benefited from this project?

Theme of reply	No.	%
Not applicable	19	32%
No longer have to worry about rat damage to any goods	12	20%
More tourists in holiday lets and accommodation as a result of media exposure	4	7%
Profit in the shop, accommodation	3	5%
Business is now more hygienic and safe for visitors without rats	3	5%
The project team used the boats more, visitors on wildlife trips have increased by 200%, there has been more publicity through the project	3	5%
Yes (no further comment)	3	5%
Composter and bins provided by the project have benefited business	2	3%
Tourists have a more positive experience on the islands	2	3%
Yes, more visitors camping and buying ice-cream as they know the campsite is rat-free	2	3%
The WMIL team using holiday lets	2	3%
Possible knock-on effect as more visitors	1	2%
Guests are actively interested in the project, improving their stay	1	2%
Team bought eggs	1	2%
'Lifelong learning' has benefited from walks and talks	1	2%

Table 6 Response 'themes' from St Agnes and Gugh community members (shown as number of people and percent of the community) to the question 'Do you think there have been any positive or negative impacts to tourism by the removal of rats from St Agnes and Gugh?

Theme of reply	No	%
Positive (no further comment)	14	24%
Positive in respect to what other community members have told them, but not personally to them	4	7%
Positive, visitors' experience of the islands could be negative due to rats in tents/lets/on beaches	21	36%
Positive, more birdwatcher and tourists will visit to see more seabirds	12	21%
Positive if we market being rat-free more to visitors	4	7%
Positive, already heard good feedback from visitors	2	3%
Positive, the project has already promoted the islands as a travel destination, tourists told me they were here as they saw the project/islands on BBC Countryfile	1	2%
Positive, seabird boat tours have had far more visitors onboard due to the project, my business has a 10% increase in turnover due to the project	1	2%

Long-term monitoring phase

Legacy workshops held in 2016 confirmed the role of the SHVs in the on-going biosecurity of St Agnes and Gugh. Quarterly biosecurity monitoring completed by the community SHVs to date has not detected any rats (J. Peacock, St Agnes, pers. comm.).

DISCUSSION

Feasibility phase

Community 'stipulations' or requirements to address concerns were developed following the questionnaire and face-to-face interviews.

The community requested updates on funding opportunities, waste training and provision of bins and composters, a bespoke audit of actions to get the islands 'rat-removal ready' and clear communication lines between the eradication team and the community through community talks, face-to-face dialogue, newsletters and school education visits.

As most residents had concerns over the health and safety of the children, a 'school education day' was delivered whereby school children saw snap traps, bait, tube and lockable bait stations and received training on how to stay safe (Fig. 3). Concerns about personnel whom residents didn't recognise being on their land were resolved by WMIL suggesting that all personnel wear an identifiable uniform (i.e. blaze orange hats with the project logo). Concerns over where the money for travel and subsistence for the eradication team would be spent were answered by WMIL assuring residents that much of it would be spent on St Agnes and Gugh using local providers (i.e. purchasing milk and eggs from the local farmers and supplies from the St Agnes Store). Concerns were also expressed over the potential poisoning of non-target species, particularly pet cats (24 were present during operation) and dogs (four were present). The safety of pets is always a concern to owners, so the mitigation information was provided sensitively, including explanation of the unlikelihood of accidental poisoning due to the design of the bait station and unlikely access to the rodenticide. Pet owners were given information that the antidote to the anticoagulant rodenticide (vitamin K injections and tablets) would be stored on St Agnes, with WMIL personnel being contactable 24 hours a day throughout the operational phase to administer the antidote if necessary. Residents were asked to alert eradication personnel of any dead rats found above the surface so the carcasses could be retrieved immediately.

Table 7 Response 'themes' from St Agnes and Gugh community members (shown as percent of the community) to the question 'What support will you offer the project?' asked in 2010 (during feasibility phase questionnaires) and 2017 (long-term monitoring phase).

Theme of reply	% of community members changed from 'No' in 2010 to 'Yes' in 2017 (descending order)
In-kind logistical support	59%
Other (mainly in-kind support such as lifts in vehicles)	58%
Volunteering time	55%
Training in rodent detection and identification	41%
Long-term monitoring for rodents	37%
Training in interview and site inspection procedures and methods	30%
Assisting with any contingency operation	22%
Check for rodent damage to your own cargo	19%
Written support to decision makers (e.g. funders, councillors, MPs).	19%
Listed as a reporting location (where any rat sighting is reported to you for action)	17%
Transporting food to and between islands in rodent-proof containers	17%
Installing and maintaining a bait station on your vessel and/or property	13%
Partner to the project	No change
Financial support	No change

Several residents raised the issue regarding the possible impacts of rat eradication on the wider ecology of the islands; in particular in regards to the endemic 'Scilly shrew' consuming bait; rabbits consuming bait during the operation as well as potentially increasing rapidly after the eradication; birds eating the bait; cats prey-switching from rats to other species such as birds. WMIL explained the long-term monitoring and mitigation options for these species such as providing diet information for Scilly shrews (insectivorous diet as opposed to cereal-based diet); mitigation methods for rabbits including additional wires on either side of the bait stations to reduce access, and rabbit control by the community as necessary after the eradication; mitigation methods for birds including bait station design preventing access; and mitigation methods for all non-target species including daily careful monitoring of bait blocks for signs of non-target species consumption, re-sighting of bait stations and the use of 'crow-clips' (which further prevent entry by birds such as gulls and corvids). It was recommended that no new cats come to the island if previous cats were originally kept as ‘ratters’, and collars and bells should be used for all pet cats. Two residents also struggled with the ethical dilemma of eradicating a species but decided that the threat to seabirds was of larger concern, and the complete eradication of rats was the only viable solution to remove the threat to seabirds on the islands.

The feasibility report (Bell, 2011a; Bell, 2011b) detailed the ‘technical conservation actions’ required and confirmed that the entire community on St Agnes and Gugh were supportive and willing to carry out general and bespoke actions.

Start of the project; preparation for ‘rat-removal ready’ phase

Before the eradication phase, the community helped complete a number of required actions including the cessation of any baiting for 12 months prior (snap traps were supplied for local control). Livestock food and bedding on the six farms was reduced to minimum levels and rat-proof feed storage systems were implemented. To ensure there were no areas without bait, livestock pens, paddocks fences, windbreaks and stone walls were mapped using GIS to ensure complete bait station coverage. Where possible, farmers carried out these necessary actions, but any work not completed was carried out by WMIL and IOSSRP personnel the month before the eradication.

Residents’ waste management practices were improved by the provision of new bins and composters as part of ‘Bin Friendly Days’. ‘Shed clearance days’, ‘beach clean days’ and ‘wood collection and bonfire night’ reduced rat food and harbourage around the islands. The St Agnes School held an ‘Apple Day’ to remove wind-fallen apples from the ground. Rats were trapped for resistance testing to confirm final bait choice for the eradication. Index trapping results estimated the rat population on St Agnes and Gugh to be between 3,000 and 3,500 rats. Any restrictions or sensitivities in regard to accessing peoples land and properties was obtained.

Fig. 3 Bait awareness workshop with St Agnes School children.

As entrance to St Agnes and Gugh via boats is not regulated by any authority, this presented the highest risk pathway for biosecurity. Talks to all community members and the Harbour Users Group (for all boat users on Scilly) regarding biosecurity requirements and vigilance were held throughout the project.

Eradication and short-term monitoring phase

The contractors, team members and community members worked well together to ensure complete eradication of rats which would be confirmed after a further two-year check.

Post eradication monitoring and final check phase

Various themes emerged from the post-eradication interviews which are summarised in Tables 1–7, including:

Social: The entire community felt the project had positively affected their day-to-day life. A strong theme was they no longer needed to worry about rats *“They used to be on my mind, worrying about where they are and what they do”.* Most of the community (86%) felt the removal of rats had improved health due to the reduction of diseases spread by rats. When asked ‘what did you like most about the project?’ eleven themes developed with social-themed responses being most popular (Table 1). When asked ‘what did you dislike most about the project?’ the answer ‘nothing’ was overwhelmingly the most popular answer with three other themes (increase in other nuisance species, ethical dilemma and concern about accidental pet poisoning) being mentioned, however they felt that each concern had been mitigated against (Table 1). When asked if the project had any positive or negative impacts on the community, 100% answered ‘positive’ (Table 2). One theme that stood out was that ‘*the community was united and not divided*

Fig. 4 WMIL training community member to store bait box safely. Credit Alastair Wilson.

in any way, it was a community project'. When asked if there had been any impacts to culture and history (Table 3), one person said, "*It has raised cultural awareness of where birds are in our history, memory, collective consciousness and the part birds played in our community"*.

Economy: Again, the entire population felt the project had benefited the local economy (Table 4), with most of this benefit to certain sectors; agricultural, fishing and particularly tourism and that the benefits had potential to increase. Over two-thirds of the community (68%) felt that their businesses had benefited from the project (Table 5). A section of the community (17%) had developed new products; e.g. one farmer explained that '*Apple day had been the catalyst to a new apple juice product and cider products he developed'*. Another community member explained that *'visitors on his 'boating wildlife trips' had increased by 200%, as there has been high publicity of the project, combined with interpretation resources, so he could offer improved tours"*. Publicity was an added benefit to the project, which was not originally anticipated by the IOSSRP 'activity programme'. Shows such as BBC 'Countryfile', BBC 'One Show', BBC 'Springwatch' and a German wildlife show, were viewed by approximately 20 million viewers in total (pers. comms.) and directly led to increased tourism with one community member saying '*A tourist told me they had visited due to seeing the project on BBC 'Countryfile'.* Tourism generates the largest income on the island (Blue Sail, 2011), and 100% of the population felt the project had a positive impact on tourism (Table 6).

Interestingly, once rats had been eradicated, more residents (94% in 2016 compared to 76% in 2010) recognised that they had been having a greater issue with rats than first thought, regarding damage, and on reflection the cost rats had caused them was revised as being higher (Table 7).

Biodiversity: Compared to the 2012 questionnaire, the number of residents being sympathetic to seabirds had increased by 47% (Table 7). Regarding the wider species present on St Agnes and Gugh, none of the community felt that the eradication of rats had any negative impact on any non-target species.

Project procedures and delivery: All of the community were happy with the project procedures and methods (Table 1). When asked if it was helpful having WMIL team members assisting 'rat-removal ready' action 'shed clearance' one person said: *'it generated goodwill in the community and got everyone on board with the project'*. When asked whether the different communication methods were correct, the entire community said yes. Common themes were, '*clear explanation of what we needed to do and when*', '*involved everyone and engagement with all children at the school*', '*the team was passionate about the cause*', '*we felt listened to, as things were altered if we asked for them to be*'.

The final questions asked what support the community could give to future biosecurity to keep the islands rat-free. More residents were willing to offer support compared to 2010 (Table 7). An additional 20 community members said they would volunteer to assist biosecurity monitoring, due to being proud of the project and wanting to play their part to keep the island rat-free. A total of 32 community members have registered with RSPB as 'Seabird Heritage Volunteers' (SHVs).

Long-term monitoring phase

The role of the SHVs was confirmed as covering five tasks; (1) checking permanent monitoring stations once a month; (2) sustaining biosecurity on boats and freight; (3) carrying out surveillance for potential incursions (within 24 hours of a 'ROAR' call'); (4) assisting with incursion response baiting; and (5) assisting with the ecological monitoring of the key species.

Each SHV received LANTRA rodenticide training as well as bespoke training for incursion response protocols; a social media (Facebook) group was set up as a mechanism to send monthly check information to the SHV coordinator; biosecurity protocols were reaffirmed; and incursion response methodology was revised (i.e. check all biosecurity stations within 24 hours of a 'ROAR' especially those with the stations nearest to the report location and report back to the SHV coordinator) and tested by a 'mock incursion response' exercise.

If rat-sign is found at any time in the future, the SHV coordinator will inform IOSWT on St Mary's and the RSPB Conservation Officer in Penzance. The SHVs will swap monitoring wax for rodenticide in their biosecurity stations within 24 hours and report any new rat sign. An RSPB-coordinated incursion team will arrive to assist incursion response baiting for one month, with the SHVs assisting where possible.

In addition to biosecurity monitoring, SHVs assist IOSSRP personnel and IOSWT contractors to survey Manx shearwater and storm petrel breeding sites (using play-back at burrows) and 'evening chick-check walks'.

The IOSWT has committed to fund the work outlined in the 'St Agnes and Gugh Maintenance Plan', including, but not limited to, ongoing biosecurity training for the community, seabird surveys and resources required to keep the biosecurity shed functional.

CONCLUSION

The success of this project was due to three factors; the vision for the sustainability and legacy of the project from concept; robust preparation; and being 'community based'. Community members joined decision-making processes from the offset, and in advance of this, a decade of preparation activities meant relationships had started to be built and methods on how to protect seabird heritage had started to be shared. These relationships then sustained trust through the 'rat-removal ready actions' and eradication phase, enlisting an excellent contractor and team whom worked with the community addressing all stipulations, and having available, adaptive project staff to accommodate community concerns when required. Community members therefore felt listened to and valued.

The IOSSRP experience shows that, to ensure that an island restoration project on an inhabited island runs successfully, the support and agreement from the community must be secured. It is vital that access to all properties is obtained to effectively carry out an eradication. The community must share the project's vision and feel that they are one of the beneficiaries. To do this, they will need to be included in the decision-making process and management of the project. In this way the legacy of the project will be much stronger. The larger the community, the longer, potentially, the project managers will need to ensure that the residents are all at the same position of understanding through the various stages of the project. Archipelagos or groups of islands bring additional stakeholders and interested parties that need to be engaged compared to single islands. Ten years is not an unreasonable timescale depending upon the starting point, the value placed upon seabirds by the community, and the strength of the project partnership.

It is important to recognise the social science requirements for eradications planned on inhabited islands. The views and concerns of each and every resident and stakeholder group are important. Community engagement and consultation should be completed during every stage of an operation. Most importantly, all aspects of the eradication should be debated with the community in the early stages of the proposal. Unlike eradication operators, most members of the public do not have any knowledge of the principles and techniques of an eradication, particularly in regard to rodenticide choice and operational procedures. It is important that each community member understands these aspects and how they will be affected by the day-to-day operational requirements. A lack of public awareness about invasive species impacts and misunderstanding of eradication techniques from island communities are thought to have been responsible for the opposition of proposed eradications on inhabited islands around the world and investing in greater education and consultation effort can ensure a suitable environment for eradication projects to proceed (Bryce, et al., 2011).

The additional, and more unusual, preparations which were required on St Agnes and Gugh (e.g. clearing sheds, communicating with school children and taking precautions to ensure the safety of the community's pets) were essential and would have contributed to what was effectively a three and half week eradication period. Maybe even more importantly, was that these activities were a possible turning point for the community, where they recognised what was involved for the whole project to be successful. The methods used in this project ensured the community knew that staff and community were part of a team striving for the same goal, which would be challenging, but rewarding for birds and people.

The defining factors underpinning the success of the IOSSRP were the professional management of the eradication, dedicated and passionate volunteer team involvement, efficient and systematic monitoring, adapting to local conditions and ensuring a community-inclusive approach. The trust and knowledge the community gained during the preparation and eradication phase paired with the positive impacts the eradication of rats had on the seabirds and socio-economics for the community turned into 'pride and ownership' of *their* project.

ACKNOWLEDGEMENTS

The Isles of Scilly Seabird Recovery Project is a partnership between the RSPB, the Isles of Scilly Wildlife Trust, Isles of Scilly Area of Outstanding Natural Beauty, Natural England and the Duchy of Cornwall. The project was funded by EU LIFE (Scilly Isles LIFE Project 11 UK NAT 387), UK's Heritage Lottery Fund (HG-11-06880) and the Defra-funded Isles of Scilly Area of Outstanding Natural Beauty (AONB) Partnership Sustainable Development Fund. Thanks to all the IOSSRP Seabird Taskforce Volunteers for their hard work throughout the project, the IOSSRP Steering Group members for their support and advice throughout the project and the entire St Agnes and Gugh community for their support, enthusiasm and involvement throughout the project and for their willingness to implement ongoing biosecurity procedures.

A plan for the eradication of invasive alien species from Arctic islands

J.K. Reaser[1], G.R. Howald[2,3] and S.D. Veatch[1]

[1]*National Invasive Species Council Secretariat, U.S. Department of the Interior, 1849 C Street NW, Washington, D.C. 20240, USA. <gregg.howald@islandconservation.org>.* [2]*Island Conservation, 2100 Delaware Avenue, Suite 1, Santa Cruz, CA 95060, USA.* [3]*1531 Appleridge Rd. Kelowna, B.C., Canada V1W 3A5.*

Abstract Invasive alien species represent one of the most significant threats to Arctic ecosystems and their inhabitants. Rapidly changing environmental conditions and a growing interest in resource extraction, settlement and tourism make the Arctic region particularly vulnerable to biological invasion. For this reason, invasive alien species are of substantial concern to the Arctic Council, a multi-national body comprised of Canada, the Kingdom of Denmark (including Greenland and the Faroe Islands), Finland, Iceland, Norway, Russia, Sweden, and the United States, as well as six international organisations that represent Arctic indigenous peoples as Permanent Participants. The Arctic Council's *Arctic Invasive Alien Species (ARIAS) Strategy and Action Plan* includes the priority to: "actively facilitate the eradication of invasive alien species from island ecosystems throughout the Arctic, as well as the recovery of native island species and habitats that have been impacted by invasive alien species." A multi-national team of governmental and non-government partners is collaborating in the development of an action plan (hereafter 'islands plan') for the eradication of invasive alien species from Arctic island ecosystems. The intent of the plan is to provide a vision and strategy for a region-wide approach to the eradication of island invasive alien species as a multi-national commitment. The islands plan will set forth a strategy for prioritising island eradications consistent with the growing pressures on ecological and cultural systems. We have a unique opportunity in the Arctic to take decisive action to prevent and mitigate the adverse impacts of invasive alien species that plague much of the rest of the world. The eradication of invasive alien species from islands in other parts of the world provides useful insights into best practices, including approaches to prioritisation and cost-effectiveness.

Keywords: Arctic Council, invasive alien species, non-native species, policy, prioritisation

INTRODUCTION

Throughout the world, invasive alien species have driven the endangerment and extinction of a wide range of plants and animals (Wilcove, et al., 1998; McNeely, et al., 2001; Bellard, et al., 2016), contributed to the degradation of freshwater, marine, and terrestrial ecosystems (Howard, 1999; Rahel & Olden, 2008; Pejchar & Mooney, 2009) and hastened the alteration of ecological cycles (Chapin, et al., 2000; Towns, et al., 2006; Kurle, et al., 2008; Doherty, et al., 2015). Invasive alien species place constraints on a wide range of ecosystem services that underpin human well-being and economic growth, such as pollination, food and fibre production, disease prevention, climate resilience, and recreational opportunities (Mack, et al., 2000; Mooney & Hobbs, 2000; McNeely, 2001; Ehrenfeld, 2010; Simberloff, 2011). Invasive alien species are regarded as a threat to national security; in addition to undermining food, water, and energy security, they may impede military readiness or cultural survival of native peoples (White House, 2016).

Three primary factors make islands particularly vulnerable to the impacts of invasive species: geographic isolation, size and high percentage of global biodiversity per area (Reaser, et al., 2007; Kier, et al., 2009). While relatively few invasive alien species have been documented in the Arctic region (Fig.1) and there is currently no systematic effort to build a comprehensive dataset and thus provide species lists, biological invasion is expected to increase in concert with increasing human activity and climate change (Walther, et al., 2009; Hall, et al., 2010; Bennett, et al., 2015). The threat that invasive alien species pose to Arctic island ecosystems is thus of growing concern (Meltofte, 2013). Fortunately, Arctic governments and their partners still have the opportunity to act decisively to prevent and mitigate the adverse impacts of invasive alien species that plague much of the rest of the world.

ECOLOGICAL CONTEXT

More than 21,000 species of mammals, birds, fish, amphibians, reptiles, invertebrates, plants, and fungi are native to the Arctic. Highly charismatic species include the polar bear (*Ursus maritimus*), narwhal (*Monodon monoceros*), caribou/reindeer (*Rangifer tarandus*), and snowy owl (*Bubo scandiaca*). The Arctic is characterised by extreme seasonality; many species migrate long distances in order to follow resource productivity, some species by the millions. Although Arctic ecosystems are low in species richness, abundance is often high (e.g. sea birds) (Meltofte, 2013; Fernandez, et al., 2014).

Fig. 1 The Arctic Region. There are varying approaches to defining the Arctic according to geophysical, ecological, or political criteria. For the purposes of this paper, the CAFF delineation of the Arctic is used (including 32 million km²).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 679–686. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Invasion pathways of particular concern in the Arctic include: commercial shipping (i.e. introductions via ballast water, hull biofouling); the introduction of organisms and reproductive material through horticulture and aquaculture activities; large-scale tree planting for aesthetics, fuel, windbreaks, and carbon sequestration; transport of contaminated material and equipment for energy development and mineral exploration; and tourism, including recreational hunting and fishing (e.g. through contaminated boats, equipment, and gear). Examples of other anthropogenic pathways include translocated piers, docks and pilings, marine debris and the release or escape of live animals (e.g. from fur farms or the commensal rodents (*Mus* spp., *Rattus* spp.) inadvertently transported to the islands) (CAFF, 2017). Table 1 provides examples of specific pathways of introduction, the species introduced and the implications for the Arctic. At this time, data are insufficient to develop a comprehensive list of non-native species in the Arctic.

SOCIO-ECONOMIC AND POLITICAL CONTEXT

Numerous people, those who reside in the Arctic and many who do not, benefit from the region's natural resources. Approximately four million people live in the Arctic, including indigenous peoples who depend upon subsistence gathering and harvesting of native species as a major source of their daily food intake and as a vital element of their culture. Each year, commercial fisheries harvest millions of tons of native marine organisms valued in the billions of U.S. dollars (Christiansen & Reist, 2013; Sundet, 2014).

Extractive industries (e.g. oil, gas, and minerals) are already well-established in the region and are expanding their activities as melting ice makes access to natural resources more feasible. The increase in rate and numbers of commercial investments in the Arctic is expected to increase the risk of biological invasion into and throughout the region (Emerson & Lahn, 2012; Miller & Ruiz, 2014; Eguíluz, et al., 2016).

Invasive alien species do not respect jurisdictional boundaries. Effective communication and collaboration with neighbouring countries, stakeholders, and trading partners is of paramount importance in the prevention, eradication, and control of invasive alien species in the Arctic. The Arctic Council—a policy framework that includes Arctic Council member countries (known as States), Permanent Participants (Arctic indigenous communities), and Observers (generally, non-member States)—recognises the connection between economic well-being, social stability, and environmental health. The Council actively promotes cooperation, both within the Arctic and globally, to address the environmental changes facing the region (Arctic Council, 2013), ideally through an ecosystem-based approach which balances conservation and sustainable use of the environment (PAME, 2011).

The *Arctic Biodiversity Assessment's* findings (Meltofte, 2013; Box 1) have served as the impetus for the Arctic Council's programme of work on invasive alien species. In May 2017, the Council adopted the *Arctic Invasive Alien Species (ARIAS) Strategy and Action Plan* (CAFF, 2017). This document is a call to action voiced by Arctic nations;

The Arctic Biodiversity Assessment

The *Arctic Biodiversity Assessment* (Meltofte, 2013) recognises that there are currently few invasive alien species in the Arctic, and underscores that more are expected with climate change and increased human activity. Authors recommended:

"Reducing the threat of invasive alien/non-native species to the Arctic by developing and implementing common measures for early detection and reporting, identifying and blocking pathways of introduction, and sharing best practices and techniques for monitoring, eradication and control. This includes supporting international efforts currently underway, for example those of the International Maritime Organization to effectively treat ballast water to clean and treat ship hulls and drilling rigs. (Recommendation 9)"

Actions for Arctic Biodiversity: Implementing the Actions of the Arctic Biodiversity Assessment 2013–2021 (CAFF, 2015) sets forth two actions to address Arctic invasive alien species:

Action 9.1 (2015-2017): Develop a strategy for the prevention and management of invasive species across the Arctic, including the identification and mitigation of pathways of introduction of invasions. Include involvement of indigenous observing networks, which include invasive and new species reporting, to assist with early detection.

Action 9.2 (2017-2019): Incorporate common protocols for early detection and reporting of non-native invasive species in the Arctic into CAFF's Circumpolar Biodiversity Monitoring Programme (CBMP).

Table 1 Examples of introduction pathways and impacts.

Pathway	Species	Impact(s)
Escape from fur farms	American mink (*Mustela vison*)	High predation on native species in Iceland and Scandinavia (Birnbaum, 2013)
Gardening and land reclamation	Nootka lupine (*Lupinus nootkatensis*)	Successful competition against native plants that has changed the ecological structure and function in Iceland (Magnusson, 2010)
Intentional releases into the natural environment for food	Red king crab (*Paralithodes camtschaticus*)	Effective predation of a wide range of marine species in some Norwegian fjords (Oug, et al., 2011)
Intentional releases into the natural environment for hunting	Raccoon dog (*Nyctereutes procyonoides*)	Effective predation of ground-nesting birds and amphibians, and service as a vector of rabies and other pathogens and parasites in northern Scandinavia (Sutor, et al., 2010; Kowalczyk, 2014; Dahl & Åhlén, 2016)

Table 2 Arctic Invasive Alien Species Strategy and Action Plan priority actions.

Arctic Invasive Alien Species Strategy and Action Plan	
1. Inspire urgent and effective action: Raise awareness of the unique opportunity that the Arctic Council and its partners have to inspire the urgent and effective action necessary to protect the Arctic from invasive alien species.	
1.1	Promote and, as needed, develop targeted communications and outreach initiatives to raise awareness of the urgent need and unique opportunity to protect the Arctic region from the adverse impacts of invasive alien species;
1.2	Encourage Arctic States and non-Arctic States (including Arctic Council Observer States), working collaboratively with Permanent Participants, to implement effective programmes for preventing the introduction and controlling the spread of invasive alien species through domestic actions and/or international agreements and relevant guidelines, such as the International Convention for the Control and Management of Ships' Ballast Water and Sediments, and the IMO *Guidelines for the control and management of ships' biofouling to minimise the transfer of invasive aquatic species* (Biofouling Guidelines);
1.3	Promote and coordinate the Arctic Council's work on invasive alien species with relevant scientific, technical, and policy-making bodies and instruments; and
1.4	Encourage the integration of the outputs of the Arctic Council's work on invasive alien species into international efforts and legal and institutional frameworks, especially planning and coordination mechanisms, including at the national and sub-national levels, where appropriate.
2. Improve the knowledge base for well-informed decision making: Improve the capacity of the Arctic Council and its partners to make well-informed decisions on the needs, priorities, and options for preventing, eradicating, and controlling invasive alien species in the Arctic by improving the knowledge base.	
2.1	Identify and assess: a) the invasive alien species and pathways that pose the greatest risk of biological invasion into, within, and out of Arctic ecosystems; b) the Arctic ecosystems, livelihoods, and cultural resources most vulnerable to biological invasion; and c) the current and projected patterns and trends of introduction and impacts of invasive alien species in the Arctic;
2.2	Produce a series of topic-specific assessments of invasive alien species issues in the Arctic considering scientific, Traditional Local Knowledge (TLK), technical, environmental, economic, socio-cultural, legal, and institutional perspectives;
2.3	Improve the collection of information on the occurrence and impacts of Arctic invasive alien species, taking advantage of new technologies for early detection, and integrate this information into circumpolar, regional, and community-based observing networks, monitoring programmes, (in particular the Circumpolar Biodiversity Monitoring Programme), and associated information systems such as (the Arctic Biodiversity Data Service); and
2.4	Facilitate full, timely, and open sharing of data and other information relevant to Arctic invasive alien species prevention and management through the Arctic Biodiversity Data Service and the CAFF Web portal.
3. Undertake prevention and early detection/rapid response (EDRR) initiatives: Protect Arctic ecosystems and human well-being by instituting prevention and early detection/rapid response programmes for invasive alien species as a matter of priority.	
3.1	Collaborate with industries, such as, tourism, energy, fisheries, mining, and shipping, and other stakeholders, as relevant, to develop and implement a wide range of biosecurity measures for points of entry and along priority pathways to reduce the initial transfer of species;
3.2	Encourage the establishment of new, or strengthen existing, surveillance, monitoring, reporting, and rapid response programmes necessary to ensure EDRR at points of entry. Consideration of TLK and community-based monitoring programmes should be encouraged;
3.3	Encourage the development and sharing of tools to enable EDRR for invasive alien species that may pose a substantial threat to the Arctic;
3.4	Actively facilitate the eradication of invasive alien species from island ecosystems throughout the Arctic as well as the recovery of native island species and habitats that have been impacted by those invasive alien species;
3.5	Develop guidance for the use and transfer of native and alien species to and throughout the Arctic environment, and identify opportunities to foster ecological resistance and resilience to environmental change;
3.6	Collect information on best practices and assess whether there is a need for the International Maritime Organization to develop Arctic specific guidance for minimising the threat posed by ballast water and biofouling as vectors for the transfer of aquatic invasive alien species from shipping; and
3.7	Foster development of the innovative research, tools, and technologies needed to advance invasive alien species prevention and EDRR capacities in the Arctic region, including through support from funding programmes.

it establishes near-term priorities for securing the future of the Arctic. These priority actions (Table 2) span terrestrial, freshwater, and marine ecosystems and take environmental, cultural and economic factors into consideration. Some of the priority actions apply to the Arctic Council as a whole, while others are best addressed at the working group level or through national implementation. The Conservation of Arctic Flora and Fauna (CAFF) and Protection of the Arctic Marine Environment (PAME) working groups of the Arctic Council hope that each Arctic State, working collaboratively with its partners, will integrate the actions from the *ARIAS Strategy and Action Plan* into national plans and employ the priority actions. This would enable the advancement of relevant decisions made under the auspices of other multi-lateral fora and instruments (e.g. the Convention on Biological Diversity and the International Maritime Organization).

The effective implementation of these priority actions will, of course, depend upon securing the resources necessary to implement them as a matter of urgency and upon collaboration with Permanent Participants, non-Arctic States (including Arctic Council Observers), regional and local authorities, industry and all others who live, work, and travel in the Arctic. Recognition by States, authorities and external organisations that collaborating with the Arctic Council provides a collective and highly desirable benefit will also be crucial. CAFF and PAME will coordinate implementation under the overall direction of the Senior Arctic Officials, drawing on other Arctic Council working groups and partners as needed. Progress reports will be submitted by CAFF and PAME to the Senior Arctic Officials and Arctic Council Ministers every two years.

Although only one of the priority actions set forth in the *ARIAS Strategy and Action Plan* (CAFF, 2017) is explicitly focused on islands, all of the action items are relevant to protecting island ecosystems. Invasive alien species issues are inherently context-specific; they change through time and across landscapes. These particular measures will need to be tailored to particular pathways, populations of non-native species, localities, type and scale of impact, and the available resources.

IMPLEMENTING PRIORITY ACTION

ARIAS Strategy and Action Plan priority action 3.4 calls for the Arctic Council and its partners to "actively facilitate the eradication of invasive alien species from island ecosystems throughout the Arctic as well as the recovery of native island species and habitats that have been impacted by those invasive alien species". The ARIAS Strategy and Action Plan Steering Committee identified this item as a priority because:

1. Island species and ecosystems are well documented as being particularly vulnerable to the impacts of invasive alien species (per previous discussion in this paper). Of particular concern are seabird species that have evolved in the absence of persistent, successful nest-site predators such as the commensal rodents.
2. The level of biological invasion on Arctic islands is relatively low. Due to a lack of other confounding variables, the likelihood for native species/ecosystem recovery following the eradication of invasive vertebrates is high.
3. There are already several examples of successful invasive vertebrate eradications from Arctic islands (Croll, et al., 2015; Jones, et al., 2016; Brooke, et al., 2017). Lessons learnt from these initiatives can be readily applied to future efforts.

To date, efforts to eradicate invasive alien species in the Arctic have been undertaken domestically by the jurisdictional governing body. Priority action 3.4 sets a new precedent for invasive alien species management and creates new opportunities for collaboration, funding, and planning across the region.

The United States Arctic Invasive Species Working Group (coordinated by the National Invasive Species Council (NISC) Secretariat: <www.invasivespecies.gov>) is exploring opportunities to collaborate with domestic and international partners to develop and begin to enact an implementation plan for priority action 3.4. As a minimum, this will include measures to:

1. Identify relevant data available in the Arctic island context and make the data available through open-access information systems, including the Threatened Island Database (TIB) and Biodiversity Information Serving Our Nation (BISON) information system.
2. Summarise the available data to generate information on current knowledge and identify gaps in key information (data gaps).
3. Develop and execute a strategy for filling data gaps.
4. Create a prioritisation schema for determining which island eradications will take precedence and why.
5. Using the schema, determine priorities for the eradication of invasive vertebrates from Arctic islands based on available information and with input from the Arctic Council members and other relevant stakeholders.
6. Based on these priorities, develop an implementation plan, including a co-financing strategy, and secure the additional resources necessary to address these priorities.
7. Implement the eradication plan for the priority island(s) identified in step 5.
8. As appropriate, develop and implement a recovery plan for native island species and habitats of concern. The recovery plan should include a monitoring programme to enable early detection and rapid response to any future invasions.

Invasive alien species have only recently become an issue of concern in the Arctic. Relatively few baseline data on species presence and impacts are available in either the continental or island context. In implementing priority action 3.4, there is a need to start with the basics: assembling/collecting baseline data and evaluating the current status and trends of invasive alien species according to island, species and pathway specific parameters. These assessments are necessary to enable governments to set priorities: which islands, where, why, and how? The findings generated by these assessments can be coupled with data on changes in human activity patterns and climate to generate projections of potential future conditions and thus strengthen and expand the programmes of work necessary to minimise the risk of impending impacts to Arctic island ecosystems (see Hendrichsen, et al., 2014; McGeoch, et al., 2016, for general discussion on assessment needs).

Unfortunately, data collection, sharing, and standardisation is a substantial challenge to filling information gaps in the Arctic. To the best of our knowledge, no one has previously assembled data on invasive alien species occurrence on Arctic islands, although some relevant data can be accessed as subsets of data contributed to national and regional biodiversity information systems [e.g. Global Biodiversity Information Facility (GBIF)]. Where information is unavailable via publicly accessible databases or published literature, information will need to be actively solicited from other available sources, including experts in the field, institutional and/or scientific networks, and traditional local knowledge.

Islands, in general, offer stronger benefits to eradication projects given their high biodiversity, high vulnerability and generally lower risks of reinvasion (compared to non-island ecosystems) that tend towards lasting eradication success (Helmstedt, et al., 2016). However, eradication projects and similar conservation initiatives are proportionately more expensive on islands than other geographical areas due to their typically restricted access and lack of infrastructure, a reality exacerbated in the Arctic (Martins, et al., 2006; Donlan, et al., 2014). Limited resources, cross-jurisdictional collaboration, and evolving techniques/technologies define our capacities to carry out eradication projects. This makes it very important to strike the right balance between the biological need for eradication and the feasibility and sustainability of operations when prioritising locations (Saunders, et al., 2011; Martinez-Abrain & Oro, 2013). Defining clear objectives and measures of performance will be vital in order to effectively and efficiently maximise the limited available funding. Consequent restoration efforts, the second half of priority action 3.4, contribute to the need for an innovative, flexible and integrated portfolio of eradication actions and strategic planning tools. Both restoration capabilities and eradication technical abilities have made exponential progress over the last decades, and yet accurate inclusion of economic costs when prioritising project scope remains a challenge due to its complexities and data gaps that require assumptions and estimates (Donlan & Wilcox, 2007; Carrion, et al., 2011; Veitch, et al., 2011).

To date, no comprehensive invasive alien species eradication prioritisation scheme has been developed for Arctic islands. Recent studies on the prioritisation of islands for invasive alien species eradication projects have highlighted and critiqued approaches to the removal of invasive alien species on a given island from multi-taxa and single-species perspectives. Helmstedt, et al. (2016) highlight the importance of including cost analyses and consideration of high-risk options or targeted, logistical options when weighing the risks and benefits of eradication (Game, et al., 2013; Joseph, et al., 2009). Helmstedt, et al. (2016) point to the value of learning from successes and failures, as well as targeting combinations of invasive alien species, and emphasise three main factors when determining the conservation benefit of various portfolios of action: ecological benefit, economic cost and feasibility of each eradication action. In addition, the study outlines the importance of cost calculations across combined portfolios of action in order to determine cost-sharing opportunities.

In the context of the Arctic islands project outlined above, detailed assessments of invasive alien species eradication options, cost-sharing opportunities and logistical feasibility will need to be conducted once the choice of candidate islands has been narrowed down with the view of maximising potential ecological and social benefits. Table 3 provides an overview of relevant prioritisation criteria to be considered during project planning and implementation. These criteria are not listed according to priority. The level of importance will be assigned during the schema development process.

Translating priorities into action on the ground can be challenging, but it is a reasonable goal when local communities, national and local government agencies, and landowners value the benefits that can be realised from the eradication of invasive alien species from islands. A key strategy to successful implementation will be the development of a "top down/bottom up" approach, where policy, regulatory, and financial support is in place, and the local island communities, landowners and agencies begin investing in the work on the ground. Implementation can be realised when the "demand" finds the resources, support and policies to move forward.

Restoration of island ecosystems is only achievable if adequate and robust funding mechanisms are in place. Projects and programmes tend to be expensive with a large upfront investment required, but the financial return on investment can be high (see Walsh, et al., this 2019). With greater demands and competition for government resources, projects tend to be funded one island at a time. Managers typically rely on blending funding from multiple grant programmes and through partnerships with non-governmental organisations, private foundations and/or philanthropy. This partnership approach to funding projects can be inefficient, and the opportunity to investigate partnerships to co-finance and implement programmatic portfolios is being considered (see Stringer, et al., 2019). Adequate financing is critical to ensure long-term sustainability and protection of the investment to respond to new introductions and facilitate active and passive restoration.

CONCLUSION

Invasive alien species impacts in the Arctic region have global implications. Arctic biodiversity is an irreplaceable asset. To envision the Arctic as ecologically, culturally and economically sustainable necessitates a focus on the factors that threaten the region's environment and human well-being. Thus, eradicating invasive alien species from Arctic island ecosystems will have cumulative benefits. If these islands are protected from invasive alien species, they may have a greater ability to resist and be resilient to other potential stressors. The achievements made through the adoption of the *ARIAS Strategy and Action Plan* present a unique opportunity for collaboration, innovation and collective action across the Arctic at all levels of governance, from regional to local community scales. Governments and their partners need to work together to make the eradication of invasive alien species from Arctic islands feasible, reduce the risks of future island invasions through commerce and other pathways by cooperating in prevention and management efforts across all shared ecosystems, and address the various factors that make island ecosystems particularly vulnerable to the adverse impacts of invasive alien species.

ACKNOWLEDGEMENTS

The authors extend their gratitude to the members of the ARIAS Strategy and Action Plan Steering Committee, the United States Arctic Invasive Species Working Group, and the CAFF and PAME Secretariats for the multi-year discussions that have facilitated the work proposed here. This paper draws heavily on the ARIAS Strategy and Action Plan which is a product of the Arctic Council's CAFF and PAME Working Groups. The views expressed in this publication are solely those of the authors and do not necessarily reflect the views of the United States Government, the U.S. Department of the Interior, or the National Invasive Species Council.

Post Script Since completion of this paper, the National Invasive Species Council Secretariat and Island Conservation collaborated in the production of an analysis of available non-native species data and developed a preliminary prioritisation schema for Arctic islands. That report, *Data Matters: informing the eradication of invasive species on islands*, is available on the Council's website <https://www.doi.gov/sites/doi.gov/files/uploads/data_matters_island_conservation_report.pdf> and through Island Conservation (Gregg.howald@islandconservation.org).

Table 3 Preliminary factors for consideration in any prioritisation scheme for the Arctic.

Factor	Considerations
IUCN Red Listed species	This includes migratory bird species and should consider the current and trend status of the IUCN Red Listed species, the threat level by the target invasive, and the IUCN Red Listed species' historical recovery status.
Direct and indirect benefits	This is particularly important in understanding how to maximise project-wide benefits that may span varying islands and island systems, species, or stages in the invasion process. Direct benefits include eliminating the threat or degradation posed by the invasive alien species to targeted native ecosystems or species. Indirect benefits may include eliminating the threat or degradation posed to non-targeted ecosystems and species such as those not listed on the IUCN Red List or in other policy.
Direct and indirect consequences	Eradication projects can have significant negative and unintended impacts to native species from the techniques or technologies used, failure of control measures, or greater disruptions to ecosystem equilibriums from the removal of an established invasive alien species. It is important to assess the possibility and probability of potential consequences specific to the prioritisation scheme's target goals. Where other factors outweigh foreseen consequences, mitigation or prevention activities will need to be considered in overall cost and feasibility planning.
Reinvasion potential	The risks of anthropogenic reinvasion vary between islands depending on which pathways they connect to, their geographical proximity to other land masses such as those within swimming distance, the extent of environmental degradation or negative impacts post eradication that affect the feasibility of reestablishment, among others. This component has significant impacts on the sustainability and projected costs of a project.
Biological and ecological vulnerability and resiliency	Biological and ecological vulnerabilities serve as high conservation value components and contribute to project feasibility. Vulnerabilities include islands that come in contact with pathways and the islands' ecological resiliency capacities to biological invasion and reinvasion which impact additional prevention and restoration initiatives.
Impacts on Arctic inhabitants	This consists of not only the direct and indirect economic impacts that disrupt or limit subsistence living and local economies, but also the cultural/spiritual aspects of Arctic life that depend on natural resource identity and use. These considerations in a prioritisation scheme should make use of Traditional Local Knowledge.
Opportunities for community management	Utilising community management opportunities has the potential to not only cut costs and fill knowledge gaps, but also engage local managers and community members in complementary conservation practices such as early detection and rapid response efforts and restoration projects.
Costs and impacts on economies	This consideration needs to extend beyond the direct monetary losses to include the indirect impacts on economies and labour resources (e.g. reduced yields from natural resources, prevention of future yields, alterations and reductions in ecosystem services, and market/non-market value losses (Colautti, et al., 2006).
Feasibility and technology	Feasibility needs to include both the probability of successful eradication and the sustainability of that success. Technology feasibility/availability will differ between islands, species, and ecosystems and need to be assessed and prioritised per project proposal.
Political will of jurisdiction	Sustained political will plays a significant role in the success of any government funded project. When considering a potential site location, island system, or species, it will be important to assess the political will at each level surrounding the project's target and objectives.
Gaps in knowledge	The Arctic has relatively fewer studies regarding native species, invasive alien species, island vulnerabilities, and future risks of biological invasion that go beyond generalisations on warming climates and increasing pathways. It is important that these data gaps are recognised throughout the prioritisation process and adjusted for, where possible.
Climate change impacts	Climate change impacts the vulnerability and susceptibility for biological invasion, reinvasion, and establishment and should be taken into consideration for the long-term feasibility of an eradication project. Together, these two issues can result in exacerbated impacts to ecosystem function and biodiversity (Mooney & Cleland, 2001; Hellman, et al., 2008; Rahel & Olden, 2008).

Abstract Recent years have seen large increases in the number and size of successful invasive species eradications from islands. There is also a long history of large scale removals on larger land-masses. These programmes for mammals and terrestrial plants follow the same cost-area relationship although spanning 10 orders of magnitude in scale. Eradication can be readily defined in island situations but can be more complex on larger land-masses where uncertainties defining the extent of a population, multiple population centres on the same land-mass and ongoing risks of immigration are commonplace. The term 'complete removal' is proposed to describe removal from an area with ongoing effort to maintain the area as clear, as features in many larger scale mainland programmes. Examples of complete removal to a boundary, in patches and in habitat islands are discussed. While island eradications continue to grow in scale, new legislation such as the lists of Species of European Union Concern will also drive increasing management on larger land-masses. However, these lists include large numbers of species that are already widespread. Methods are needed to prioritise species to reflect both the risks posed and the feasibility of management, including the effects of scale on cost and effectiveness.

Keywords: control, eradication, invasive alien species, non-native species

INTRODUCTION

The removal or eradication of invasive alien species is increasingly used as a conservation tool. New legislation, for example the European Union's Invasive Alien Species Regulation, will also place increasing responsibilities on states to remove or eradicate high risk species. Both of these considerations are driving an increased number of management programmes at increasing scales and there is a need to understand how the costs and constraints change in relation to scale. A large number of published eradications have been based on islands, often at relatively small scales, while a small number of larger programmes have been based on mainland experience. There is a need to pull together these different sources of evidence, to support an assessment across a wider range of scales than can be achieved by considering islands or mainland eradications in isolation.

REMOVAL AT SCALE – ISLANDS AND MAINLAND EXPERIENCE

Recent years have seen a large increase in successful invasive species eradications from islands, as well as significant increases in the size of islands involved. The number of successful eradications continues to increase, and in 2012 the Database of Invasive Species Eradications (<http://diise.islandconservation.org>) recorded 1,182 whole-island introduced invasive animal species eradication projects either completed or underway on 762 individual islands. In terms of scale, recent years have seen a number of large island eradications. Cruz, et al. (2009) describe the eradication of goats from the 584 km^2 Santiago Island in Galapagos; Parkes, et al. (2014) predicted the effort required to remove cats from the 1,680 km^2 Stewart Island in New Zealand, while the current rat removal on South Georgia will cover 3,538 km^2 (Piertney, et al., 2016).

Although the point at which an island becomes a mainland is arbitrary, there is also a long history of invasive mammal removals from larger land masses in Northern Europe (Robertson, et al., 2017). These include muskrat (*Ondatra zibethicus*) eradications from the mainlands of Britain and Ireland in the 1930s; the eradication of the Himalayan porcupine *(Hystrix brachyura*) (1970s) and coypu (*Myocaster coypus*) (1980s) from the British mainland; a variety of American mink (*Neovison vison*) and grey squirrel (*Sciurus carolinensis*) removals from the larger British islands together with the removal of Pallas' squirrel (*Callosciurus erythraeus*) from Flanders on the European mainland (since 2000). Few of the programmes covered more than a fraction of the total land mass, so size was defined as the area over which species sightings occurred and trapping took place. The larger of these species programmes have covered areas of 3,411 km^2 (the two phases of the Hebridean mink programme), 5,219 km^2 (the five separate muskrat eradications) and 19,210 km^2 (coypu) (details and full references given in Robertson, et al. 2017). The ongoing ruddy duck (*Oxyura jamaicensis*) eradication from Europe (Robertson, et al., 2015) covers six states totalling 1,535,509 km^2.

Data on the costs of eradications are available for projects covering ten orders of magnitude of scale. Studies have described the costs of successful mammal eradications from islands (Martins, et al., 2006; Howald, et al., 2007) and larger land-masses (Robertson, et al., 2017), while Rejmánek & Pitcairn (2002) describe costed plant eradications in California. For mammal eradications, those on large land-masses covered significantly larger areas than those reported from islands while successful plant eradications were confined to smaller areas. Data from these different sources, appear to follow the same relationship (Fig. 1) whereby the cost per unit area is reduced by approximately 10% as the area involved doubles (Robertson, et al., 2017). As experience of eradications on larger islands grows, the overlap between island and mainland experiences is increasing (Cruz, et al., 2009; Parkes, et al., 2014; Piertney, et al., 2016).

It is worth recording that two small datasets describe programmes that fall outside this relationship. Rejmánek & Pitcairn (2002) also record three aquatic plant eradications which appeared more expensive than comparably sized terrestrial plant programmes, while the ruddy duck

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 687–691. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

eradication (Robertson, et al., 2015) has been significantly less expensive compared to similarly scaled mammal programmes (Robertson, et al., 2017). More data are needed on the management of other taxa in different environments before firm conclusions can be drawn. These results are based upon currently available methods of eradication. As new technologies, such as gene-drives (Webber, et al., 2015), e-DNA self-resetting (Carter, et al., 2016) and self-reporting traps (Jones, et al., 2015) become available it is likely that these costs will decrease.

Eradication and complete removal

In their classic paper, Bomford & O'Brien (1995) make a clear distinction between eradication and on-going control, presenting these as alternative objectives for management. They also identify three key criteria for successful eradication; that the rate of removal exceeds the rate of increase at all densities; there is no immigration; and all reproductive animals are at risk.

These definitions and criteria have guided many successful eradications and are particularly applicable to islands where the population extent and risks of immigration can be readily assessed. However, at the scales found on larger land masses, these criteria may be more difficult to apply or achieve, for example where the boundaries of a population remain poorly defined, where multiple population centres may occur on the same land mass, or where immigration remains a risk. Despite this, large scale programmes frequently lead to the removal of species from large areas of land. Although not meeting Bomford & O'Brien's (1995) definition of eradication, these situations are also not well described as on-going control as no active management is required across the majority of the area. In these circumstances 'complete removal' may be a better definition of the objectives, sitting between Bomford & O'Brien's (1995) definitions of eradication and on-going control.

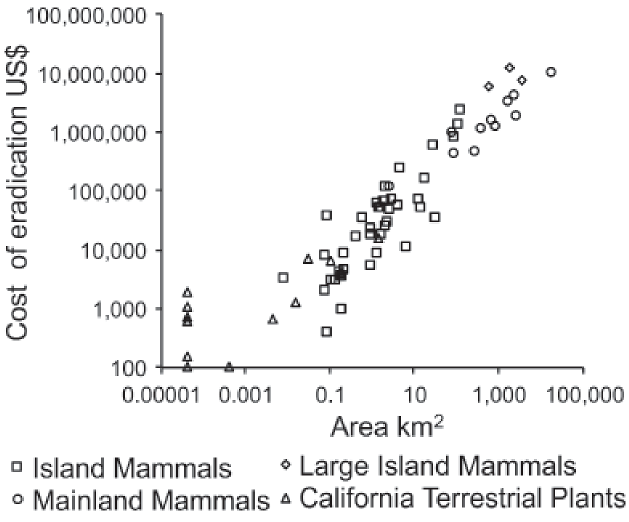

Fig. 1 The relationship between the area (km2) of a successful removal and the total cost (US$). The square symbols represent island mammal eradications reported by Martins, et al., (2006). The circles are for removals of mammals from larger land masses in Northern Europe (Robertson, et al., 2016). The three diamond symbols are recent examples or predictions of large-scale mammal eradications from islands: (Cruz, et al., 2009; Parkes, et al., 2014; Piertney, 2016). Plant eradications from California are triangles (Rejmánek & Pitcairn, 2002). Where the study recorded effort as man-years or man-days, total cost is estimated based on US$50k per man-year (Rejmánek & Pitcairn, 2002; Parkes, et al., 2014; Robertson, et al., 2016).

Eradication, the complete removal from an area, with no immediate prospect of recolonisation from neighbouring areas.

Complete Removal from an area but with ongoing effort to maintain the area as clear.

On-going Control within an area to reduce abundance, associated damage and the risk of spread.

Based on this definition, complete removal has been applied in a number of forms.

1 - Complete removal to a boundary

One objective of large scale programmes can include complete removal of a species up to a boundary across which the risk of reinvasion remains. Control along the boundary, or in a neighbouring buffer zone, can reduce the risk of reinvasion and help keep the main area clear. The nature of the boundary may vary, including fences (Saunders & Norton, 2001), landscape barriers such as water bodies or mountains (Schuchert, et al., 2014), or bottlenecks through which invading animals must move (Roy, et al., 2015). These boundaries can be permanent features of the management, requiring ongoing inputs (Saunders & Norton, 2001), or may be part of a phased programme to clear a larger area (Yamada & Sugimura, 2004; Bryce, et al., 2011; Robertson, et al., 2015; Russell, et al., 2015). If the aim is the removal of the species from a large area, but the funds or resources are insufficient for the simultaneous management of the entire population, then removal to a boundary is likely to feature.

The North American ruddy duck was introduced to the UK in the late 1940s, and its subsequent spread into Europe threatens the native white-headed duck (*Oxyura leucocephalus*) through hybridisation. The plan to eradicate the ruddy duck from Europe involves coordinated management across the continent. As the UK was the original source of this population and contained the majority of the birds, it was the focus of initial control (Robertson, et al., 2015). However, once the UK no longer contained breeding birds (currently it is thought only a few males remain), the English Channel became a boundary between a cleared area and the remaining continental populations. Control of the remaining European birds is ongoing, in the meantime the UK maintains surveillance and, if required, control along this boundary to maintain its cleared status.

In the UK, the native red squirrel (*Sciurus vulgaris*) is threatened by the ongoing spread of the invasive grey squirrel (*S. carolinensis*). This is mediated by the spread of a poxvirus by the asymptomatic greys which is typically fatal to the reds (Rushton, et al., 2000). The island of Anglesey on the north coast of Wales contained a small relict population of the native reds although greys were spreading onto the island. A control programme removed the greys (Schuchert, et al., 2014), allowing the reds to spread and recolonise the entire island. Anglesey is separated from mainland Wales by a narrow tidal channel, crossed by two bridges. There is evidence that grey squirrels can cross this boundary and the risk of recolonisation remains. To reduce this risk and maintain the island as grey squirrel-free, management has included a surveillance and rapid response programme to pick up incursions (Shuttleworth, et al., 2016), trapping to reduce the density of greys on the mainland side of the boundary, and a plan to extend the area of complete removal to clear greys from the North Wales coast up to a more distant boundary formed by a geographic bottleneck where the mountains meet the coast.

The American mink (*Neovison vison*) spread through the Western Isles of Scotland following its escape from fur farms in the 1950s. Its spread threatened internationally important populations of ground nesting birds as well as local economic activities such as salmon fishing. The decision was taken to aim for the eradication of this species from the archipelago but logistic and funding constraints, combined with the need to gain experience, led to a phased programme. In the first phase, mink were completely removed from the Uists, the southernmost islands of the chain (Roy, et al., 2015; Faulkner, et al., 2017). A buffer zone was maintained (South Harris) between this cleared area and the remaining mink population on the main island (Lewis) to the north. This buffer included a narrow, island strewn channel between the Uists and South Harris. Trapping on these 'stepping stone' islands together with South Harris itself provided an effective barrier to recolonisation. Once the Uists' work had provided confidence that eradication was feasible, a second phase extended mink control north to cover the remainder of the archipelago (Lambin, et al., 2014).

2 - Complete removal from patches

In some cases the primary objective of management may be the reduction of the impact of an invasive species with no prospect to eradicate. In many cases this constitutes ongoing control rather than complete removal (Bomford & O'Brien, 1995), although in some circumstances it can lead to complete removal. For this to occur, two criteria must be met, the species must be controlled at a rate sufficient to remove all of the resident animals in an area, and the scale of control should be such that the risk of recolonisation is so low in the centre of the controlled area that the central area is effectively maintained clear. The prospects of this occurring are scale-dependent, with the cleared area forming a larger proportion of the total as scale increases.

This approach has been used in New Zealand with the creation of 'mainland islands', areas maintained predator-free through the use of fencing combined with continuing control (Saunders & Norton 2001; Gillies, et al., 2003). The same results can be achieved without fencing, for example in Mauritius where the introduced small Asian mongoose (*Urva auropunctata*) (Patou, et al., 2009) is a major threat to the continued survival of a range of native bird species (Bunbury, et al., 2008). The mongoose is widely spread across the island, inhabiting a range of habitats, while the native birds are largely confined to remaining patches of good quality native forest. Control of the mongoose has been carried out in a number of these forest areas to create 'mongoose free' patches within the wider mongoose distribution. A network of box traps has been in place since 1989 and maintains a year-round effort to remove mongoose. As the size of the trapped area increases, the number of animals captured per unit area decreases (Fig. 2). Areas less than 5 km in extent continue to catch high numbers of mongoose per unit area, presumably because they face constant recolonisation pressure from neighbouring habitats. However, in larger areas, particularly those over 10 km^2 in area, mongoose catch per unit area drops dramatically. This is consistent with catching animals in a boundary area, with the proportion of the area maintained as mongoose-free increasing as the total area trapped increases. Achieving this requires ongoing effort, but complete removal provides many of the benefits of eradication, and has been a key element of efforts to conserve a suite of species endemic to the island. These include the Mauritius kestrel (*Falco punctatus*), the pink pigeon (*Nesoenas mayeri*), the echo parakeet (*Psittacula eques*) and a number of passerines such as the Mauritius black bulbul (*Hypsipetes olivaceus)*, and Mauritius fody (*Foudia rubra)*. Only through intensive trapping to maintain these predator-free patches, combined with a captive breeding and release programme, disease management and supplementary feeding, have these species managed to persist.

3 – Complete removal from habitat islands

Islands as blocks of land surrounded by water are widely recognised, but isolated blocks of habitat within a matrix of other land uses share many of the same characteristics. When invasive alien species are confined to discrete habitats within this matrix, they can be considered as inhabiting 'habitat islands'. In these cases, limited rates of species movement or colonisation between habitat islands may produce isolated populations, with particular opportunities for management within large land masses.

The monk parakeet (*Myiopsitta monachus*) has established a number of discrete populations in different European cities (Munoz & Real, 2006; Rodríguez-Pastor, et al., 2012). Although an attractive species widely kept as a pet, in the wild this species builds large communal nests on tall trees or man-made structures such as electricity infrastructure or radio masts. The large size and volume of nest material can lead to electrical short-outs and fire risks, with consequent economic costs (Avery, et al., 2002). The discrete nature of its current distribution, with isolated populations including London, Amsterdam and a variety of Spanish cities suggests that different populations have resulted from separate releases rather than natural spread from a single point of release. The management of this species reflects this, with some regions attempting the complete removal of isolated populations (Parrott, 2013).

The introduced Pallas' squirrel (*Callosciurus erythraeus*) also has a highly fragmented distribution within Europe, suggesting a number of separate introductions rather than spread from a single point of release. A rapid response in Flanders, Belgium removed a population whose distribution was constrained to a suburban setting in a small community surrounded by farmland (Adriaens, et al., 2015). In effect this species was present on a habitat island which aided its removal.

The current removal of rats from South Georgia (Piertney, et al., 2016) uses a similar approach. Glaciers on the island separate a number of discrete rat populations, which appear to be genetically isolated (Robertson & Gemmell, 2004). This allows the complete removal of discrete populations as steps to achieve the larger goal of island wide eradication.

These examples illustrate the potential for effective removal of isolated populations to be undertaken within larger land masses, using the principles applied to island

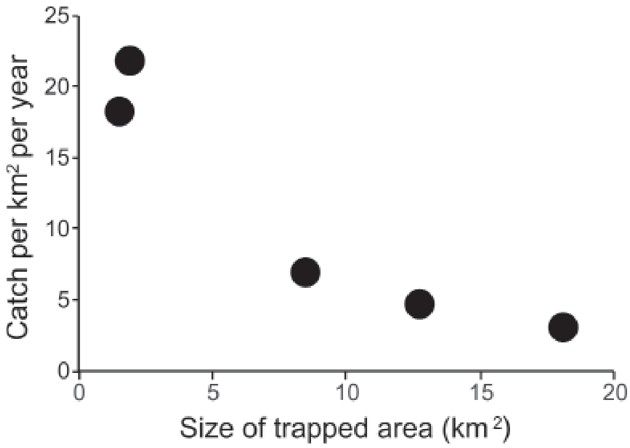

Fig. 2 The density of mongoose removed by trapping in five conservation areas in Mauritius. The control areas were surrounded by habitat containing mongoose populations.

eradications. However, as species establish and spread these discrete populations will become less pronounced. Identifying whether the distribution of a species represents a number of discrete clusters will have important implications for management, for example the decision to consider complete removal or on-going control. Spatial analysis of distributional data can be used to indicate the presence of discrete populations of a species. A range of spatial and spatio-temporal clustering algorithms (Velázquez, et al., 2016) can detect spatial point patterns and may be useful to differentiate clusters as they form.

EFFECTIVENESS AND SCALE

We used published accounts to assess the costs of removal at different scales. Doing so requires dealing with a number of biases. Firstly, it is commonly recognised that the published literature preferentially records success (Dwan, et al., 2008). For example, the successful coypu eradication in the UK is well documented (Gosling & Baker, 1987; Baker & Clarke, 1988; Gosling, et al., 1988; Gosling & Baker, 1989; Baker, 2006); the failed UK attempt to eradicate the American mink is barely recorded (Sheail, 2004) although it took place on a similar scale. Other failures are likely to have gone unrecorded. A publicly available database of island eradications is available (Keitt, et al., 2011), it would be useful to extend this to also include details of eradications on larger land masses. More importantly, the literature only records attempts, there is very little information on those situations where no action was taken, either through inaction or a judgement that it was not worthwhile. Inaction remains the most common response to invasive species. The successful island eradications are based on only a tiny proportion of the world islands, while the number of attempted eradications of alien species in Europe (Genovesi, 2005) is a similarly small proportion of the 20,000 species thought to have established.

If we are to make more objective decisions, we need to decide if, and when, management is appropriate in both island and mainland situations. Prioritisation methods have been applied to islands to identify those where management may be most beneficial (Harris, et al., 2012; Dawson, et al., 2015). Booy, et al. 2017 describe a method to assess the feasibility of eradication which incorporates the consideration of scale. If, as seems likely but has yet to be convincingly demonstrated, the prospects for successful eradication or complete removal decrease as a species spreads, then these methods offer a route to assess at what scale eradication or complete removal may no longer be a realistic outcome.

The application of methods to assess the feasibility of management is a critical need. The current EU invasive alien species regulations include the listing of species considered to be of 'Union Concern' and place reporting and management obligations on member states in which they occur. The selection of species for listing is largely based on established methods of risk assessment (Roy, et al., 2014), identifying species which pose a risk without similarly considering the feasibility of management. This focus on risk can result in the listing of species for which there are few realistic prospects for management. For example, of the 79 species currently listed or under consideration as Species of Union Concern, over half are already present in at least five member states. To date there are no successful examples of species eradication or complete removal in Europe when a species has already spread to this number of countries, although these may occur in future. Listing species based on risk assessment alone, without considering the scale and feasibility of management, risks committing resources into the on-going management of already widespread species, rather than the more productive routes of prevention and rapid response.

CONCLUSIONS

The experience of island eradications continues to grow, and to be applied at increasing scales. Alongside this, new legislation will drive increasing management on larger land masses. As island eradications grow in scale they will face many of the challenges experienced on larger land-masses, such as problems defining populations, multiple population centres on the same land mass, ongoing risks of immigration and the need for interim objectives. We suggest the term 'complete removal' to reflect the situation regularly encountered on larger land masses where a species may be removed from an area but with the need for an ongoing effort to maintain the area clear given the risk of reinvasion. The literature contains examples of successful eradications or complete removals in island and mainland situations covering 10 orders of magnitude. These island and mainland programmes appear to follow the same cost-area relationship. They also demonstrate an advantage of scale, with the costs per unit area of control reduced as the area of control increases. On larger land masses, such as the EU, care is needed to focus species listing on species where prevention, eradication or complete removal are realistic outcomes rather than committing member states to the on-going control of already widespread species. Methods of prioritisation which balance both risk and the feasibility of management, including the effects of scale on cost and effectiveness, are needed to guide future actions.

Strategic environmental assessment for invasive species management on inhabited islands

J.C. Russell[1] and C.N. Taylor[2]

[1]School of Biological Sciences and Department of Statistics, University of Auckland, Private Bag 92019, Auckland, New Zealand. <j.russell@auckland.ac.nz>. [2]Taylor Baines & Associates, PO Box 8620, Riccarton, Christchurch, New Zealand.

Abstract Over the past decade the challenges of managing invasive species on inhabited islands have clearly become limiting factors to scaling-up the area of invasive species eradications. Step-change is required to unleash the conservation and restoration potential of biodiversity on inhabited islands around the globe and avoid the pitfalls previous attempts to eradicate invasive species on inhabited islands have fallen into. Strategic environmental assessment (SEA) is a systematic decision support process, aiming to ensure that environmental and other sustainability aspects are considered effectively throughout policy, plan and programme making. Within the framework of SEAs, on target islands eradication planners could implement a number of tools including stakeholder engagement, social impact assessment and economic cost-benefit analysis alongside existing environmental impact assessment. Such a suite of assessments captures the immediate impacts of an eradication operation on a range of values, alongside predicted long-term changes in these tightly coupled socio-ecological systems. In this paper we outline what SEA is, and then contrast invasive species management attempts occurring outside an SEA framework on two similar but also contrasting UNESCO World Heritage islands; Lord Howe Island, Australia and Fernando de Noronha, Brazil. We then demonstrate how an SEA approach to invasive species management would assist planning in New Zealand to eradicate introduced mammalian predators from two large offshore islands in New Zealand; Aotea (Great Barrier Island) and Rakiura (Stewart Island). We conclude with future prospects for applying SEA to invasive species management on inhabited islands.

Keywords: eradication, mammals, New Zealand, social impact assessment, World Heritage

INTRODUCTION

Over the past decade the challenges of managing invasive species on inhabited islands have clearly become limiting factors to scaling-up the area of invasive species eradications on islands (Oppel, et al., 2011; Glen, et al., 2013). This is particularly the case for eradication of small mammalian predators, where step-change in technology (e.g. use of helicopters for aerial delivery of toxin; Howald, et al., 2007) coupled with ongoing incremental advances (e.g. non-target mitigation; Hanson, et al., 2015) mean very large islands are now potential targets of whole-island small mammal eradication, but there has not been a commensurate increase in the knowledge around engaging with resident communities (Russell, et al., 2018). Scaling-up eradications to larger islands is also confounded by additional complexities such as mixed land-tenure and land-use (Holmes, et al., 2015) on larger islands, further complicating the suite of appropriate methods for social engagement and technical implementation.

There are many reasons why there should be an increased emphasis on inhabited islands as targets for biodiversity conservation. Most uninhabited islands are small and, although the number of islands from which invasive species have been eradicated is impressive (e.g. Jones, et al., 2016), as a percentage island land area the total is still low (Russell, et al., 2016a). Some endangered species can only be conserved on large islands (PCE, 2017), while climate change increases the long-term risk profile for small islands as resilient conservation sites (Courchamp, et al., 2014). In the tropics, even small islands can be inhabited (Russell & Holmes, 2015), and small island developing states (SIDS) are particularly poorly represented in invasive mammal eradication statistics (Russell, et al., 2017a). Eradication of invasive mammals on inhabited islands also brings about many other benefits beyond biodiversity conservation, including benefits to agriculture, economies, public health and culture (Russell, et al., 2017a).

To date approaches to community engagement in anticipation of mammal eradication on inhabited islands have been designed and led mainly by biologists with a particular set of values and priorities (e.g. Bell, 2019). They have tended to be ad hoc and have not always drawn upon existing scholarship in community engagement. A new step-change is required to unleash the conservation and restoration potential of biodiversity on inhabited islands around the globe and avoid the pitfalls previous attempts to eradicate invasive species on inhabited islands have fallen in to. In this paper we outline the potential for strategic environmental assessment to enable more consistent assessment of options and engagement with island communities in the context of invasive mammal eradication. We then provide two contrasting illustrative examples of approaches to invasive predator management on two similar UNESCO World Heritage island sites, followed by examples from the two largest inhabited offshore islands of New Zealand. We conclude with recommendations for implementing strategic environmental assessment during planning for invasive species management. We emphasise that much of the scholarship we present here is built upon reflection over the past decade on attempts to eradicate invasive mammals from inhabited islands. These lessons come from the benefit of hindsight and could not be anticipated in advance, so they should not be taken as reflecting poorly on those who initially invested themselves in advocating for invasive mammal eradication. Our purpose is to suggest a way towards better processes and improved outcomes from eradications on inhabited islands.

Strategic Environmental Assessment

Strategic environmental assessment (SEA) is a widely accepted approach to applying impact assessment to policies, plans and programmes, contributing to the planning processes, decision making and the ongoing management of change (Tetlow & Hanusch, 2012). Sustainability assessment is another approach often linked to SEA (Morgan 2012). SEA has been described as "analytical and participatory approaches that aim to integrate environmental considerations into policies,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 692–697. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

plans and programmes and evaluate the inter linkages with economic and social considerations" (OECD, 2006). Applications of SEA include spatial planning, sector planning (e.g. fisheries, energy) and catchment planning (Tetlow & Hanusch, 2012; Taylor & Mackay, 2016).

Importantly, SEA provides an over-arching framework of a collection of tools rather than a single, fixed and prescriptive approach. Such an approach is therefore analogous to best practice in technical implementation of eradications on islands (Keitt, et al., 2015), where just as islands differ ecologically, it is also recognised they differ socially. Thus, in any particular case variations with regards to best, or complete, practice will still take place. Its application is an ongoing adaptive and iterative process which adds value to and builds capacity in existing systems (e.g. island human communities). The sorts of tools that can be considered as contributing to the SEA toolbox for island eradications include:

- Community and stakeholder engagement techniques
- Social profiles/baselines and social impact assessments (SIA)
- Health impact assessments
- Cost benefit analyses
- Ecological baselines and impact assessments (EIA)
- Technical feasibility studies
- Livelihoods analyses
- Social marketing/environmental education
- Environmental and social monitoring
- Institutional analyses and change management (includes ongoing biosecurity planning).

As a toolbox, SEA has been around since about the early 1990s when it developed from a growing realisation that local and project-specific applications of environmental impact assessment are insufficient when environmentally damaging decisions are being made at a more strategic level. SEA has not been widely applied in the context of wildlife management (Taylor, et al., 2004). However, in some countries SEA-like frameworks have been implemented in all but name (e.g. the Resource Management Act in New Zealand provides for the application of SEA and the development of policies and plans for the purposes of natural resource management). Strategic environmental assessment is widely accepted internationally as a critical tool in development planning (e.g. by the World Bank and OECD), where the focus is on impact analysis through to institutional assessment. Strategic environmental assessment is accepted in international development as a way to incorporate environmental considerations across all levels of strategic decision-making including plans, programmes, and policies, setting the context for environmental and social impacts assessments of development projects.

In the context of wildlife management on inhabited islands, we adopt the definition of Russell, et al. (2018) for an inhabited island. Namely that "inhabitation on an island incorporates the basic infrastructure to enable a community to function socially and economically, such as any of schools, churches, community buildings or general shared spaces, alongside enterprises delivering goods and services, and opportunities for residents to pursue a range of livelihood opportunities in the public and private sectors". However, we hasten to add that even when an island is uninhabited, a social framework process may still be required during wildlife management planning where stakeholders and others with vested interests in the island can be identified.

Poor or inconsistent planning is well known in other sectors to delay project completion (Flyvbjerg, 2014). To avoid this problem, we consider wildlife management on islands, and particularly eradication of invasive species, should be treated in the same way as any large-scale, multi-component development project, whereby SEA is a valuable unifying framework that draws together a collection of tools. Many of the tools under SEA are already becoming increasingly applied when planning invasive species management, such as social profiling (Russell, et al., 2018), social impact assessment (Crowley, et al., 2017b), and participatory processes (McEntee & Johnson, 2016). Other tools, such as EIA and economic cost-benefit analyses, can work under the umbrella of SEA for specific eradication projects, once the strategic framework is in place. In particular, eradication practitioners globally should adopt a best practice approach when working with communities on inhabited islands, as they already do for technical best practice when planning the operational elements of eradications on islands (Keitt, et al., 2015).

Most importantly, SEA provides the policy tool by which the role of invasive species eradication as a conservation intervention can cascade throughout all levels of the decision-making process on islands, including deliberative and more participatory approaches (Sims, 2012). This more comprehensive approach applies not just to decisions about wildlife management, but around sustainability of the environment and the livelihoods of human communities on islands. We see this as critical to avoid the pitfalls that previous eradication propositions on inhabited islands haven fallen into – namely where invasive species eradication is considered only as a technical solution to a wildlife management problem on a project by project basis (isolated from other island issues and strategies), and where the support for eradication is seen as merely needing to gain a public consensus through democratic process.

UNESCO WORLD HERITAGE ISLANDS

Many island groups are listed as UNESCO World Heritage sites based on their cultural and natural heritage values. A subset of the islands listed for natural heritage values are also inhabited. In this section we explore the contrasting experiences of enabling introduced small mammal predator management on two similar inhabited UNESCO World Heritage islands where such predator management has been proposed; Fernando de Noronha, Brazil and Lord Howe Island, Australia. These are not the only UNESCO World Heritage islands where predator management takes place. Predator management is also undertaken on Fraser Island, Australia but within the context of a suite of different social and environmental issues related to dingo management (Allen, et al., 2018), and has also been considered on Gough Island (Varnham, et al., 2011), and undertaken on islands in the Galapagos (Carrion, et al., 2011) and Ogasawara Islands (Hashimoto, 2010).

Fernando de Noronha

Fernando de Noronha and Atol das Rocas Reserves in Brazil was assigned UNESCO World Heritage status in 2001. Fernando de Noronha is an archipelago, comprising the primary island of the same name and 20 secondary islands and islets, lying 345 km north east of Brazil in the tropical Atlantic Ocean. The inhabited centre of the island is classified as an Environmental Protection Area (APA), while the uninhabited forested outer areas of the island are part of the Marine National Park (PARNAMAR). Both areas are environmentally administered at the federal level by ICMBio, but socio-politically administered at the state level by neighbouring Pernambuco state on the continent. The resident population of Fernando de Noronha is estimated at around 3,000 people (IBGE 2016). Tourism is the major enterprise on Fernando de Noronha (de Oliveira, 2003), and an estimated 500 tourists arrive and depart each day. This has led the state government to impose a daily tourist tax for environmental protection <http://www.ilhadenoronha.com.br/ailha/taxadepreservacao_em_noronha.php>. However, it is only the regulation of visitor numbers and not proceeds of the tax which contribute directly to environmental protection.

Today the major invasive species on Fernando de Noronha are cats (*Felis catus*), black (*Rattus rattus*) and brown rats (*R. norvegicus*), and the introduced tegu (*Salvator merianae*) lizard (Abrahão, et al., 2019). In Brazil, invasive species are not widely acknowledged as a threat to biodiversity (Bellard & Jeschke, 2016), and any management of invasive species on Fernando de Noronha typically reflects a public health and continental mind set. Wildlife is managed only in the context of vectors of disease (Magalhães, et al., 2017) while cats are managed as companion animals with strict laws administered from the governing Pernambuco state which do not permit lethal control of cats unless their own welfare is suffering (Dias, et al., 2017). The tegu is a CITES listed native species from continental South America, which is also likely to be having severe predatory impacts on the island fauna (Abrahão, et al., 2019).

Management of invasive species on Fernando de Noronha lacks an island conservation context which acknowledges the severe impact such species are having on the biodiversity of the island, and does not engage in lethal control (Russell, et al., 2016b). These biodiversity impacts are not able to be considered alongside other social and economic issues on Fernando de Noronha, as independent levels and agencies of government are in charge of each separately. Strategic environmental assessment would allow proposals for the management of invasive species on Fernando de Noronha to be placed within their broader social context, where invasive species can be considered both as public health pests and companion animals. Impact assessments of invasive species on both the environment and society are absent but could be contemporaneously created. The island's environmental aesthetic (e.g. beaches) is known to be the main driver of tourism, and generates considerable wealth each year, but it is unknown what role the island's biota (e.g. unique endemic species) play in tourism. Strategic environmental assessment would allow the costs of invasive species on the wider economy to be properly calculated, alongside the potential added value to tourism from invasive species management if not eradication. It would play a role in assessing institutional preparedness for embarking on invasive species management and incorporating invasive species management in wider environmental issues such as pollution and island development. In doing so this would ensure that invasive species management was not marginalised against other critical development issues on the island such as poverty and unemployment.

Lord Howe Island

Lord Howe Island, in Australia, was inscribed UNESCO World Heritage status in 1982. Lord Howe Island is an archipelago, comprising the primary island of the same name and 27 secondary islands and islets, 600 km east of Australia in the Tasman Sea. The island is administered as part of the state of New South Wales and for legal purposes is regarded as an unincorporated area administered by the Lord Howe Island Board which reports to the New South Wales Minister for Environment and Heritage. The resident population of the island is around 350 people. Tourism is the primary enterprise on Lord Howe Island but the Kentia palm (*Howea forsteriana*) industry also contributes to the local economy (Gillespie & Bennett, 2017).

The major invasive species on Lord Howe Island are black rats and mice (*Mus musculus*) (Wilkinson & Priddell, 2011). Eradication of rodents from Lord Howe Island would accrue both biodiversity (Hutton, et al., 2007) and economic benefits (Gillespie & Bennett, 2017). It would specifically facilitate reintroduction of the critically endangered Lord Howe Island stick insect (*Dryococelus australis*) (Hutton, et al., 2007) from its last remaining wild habitat on nearby tiny, precipitous Ball's Pyramid. Eradication of the rats and mice on Lord Howe Island was first proposed in 2001 followed by a series of technical feasibility studies (Saunders & Brown, 2001, Parkes, et al., 2003). Planning commenced in 2006 (Wilkinson & Priddell, 2011) and a draft eradication plan was published in 2009 (LHI Board, 2009). Whereas a number of other eradications of invasive species have occurred on islands belonging to Australia (Priddell, et al., 2011), the eradication of rodents on Lord Howe Island would be the first to take place on an inhabited island, particularly in the strict sense of our more comprehensive definition of inhabitation (i.e. communities and facilities). However, the original proposal to eradicate rodents from Lord Howe Island was met with prolonged resistance by elements of the island community.

Management of invasive species on Lord Howe Island is undertaken in an island conservation context which acknowledges the severe impact such species are having on the biodiversity and economy of the island and engages in lethal control. Nonetheless, on Lord Howe Island resistance to rodent eradication was prolonged from a lack of application of social tools (Russell, et al., 2018), although at the time Lord Howe Island was one of the first inhabited islands where rodent eradication was being actively pursued. Ultimately, a number of tools from SEA have now been applied independently, including an environmental impact assessment (LHI Board, 2016), economic cost-benefit analysis (Gillespie & Bennett, 2017), and human health risk assessment (O'Kane, 2017) Strategic environmental assessment would have allowed the planning of rodent eradication on Lord Howe Island to take place using the most appropriate tools for engaging with a resident community that had unanticipated levels of hostility towards the overall proposal. Tools from an SEA framework would have helped identify the various underlying threads of the resistance to rodent eradication in a community that was already accepting of lethal rodent control for the same values at those proposing rodent eradication. Whereas it was initially believed providing more evidential information on the need for eradication and the expected biodiversity benefits alone would be sufficient to gain support for rodent eradication (Wilkinson & Priddell, 2011), this is now known to play only a small role in invasive species planning (Crowley, et al., 2017a), and SEA would have provided tools for a greater participatory process in the rodent eradication planning on Lord Howe Island.

Summary

Although Fernando de Noronha and Lord Howe Island are very similar in geography, they share only a few consistencies in governance and structure, e.g. on both islands the government remains the land-owner and residents are all lease-holders. Otherwise, the generally vast differences in cultures and governance (Reis & Hayward, 2013) mean that planning for invasive species management must be considered in very different contexts on each island. On Fernando de Noronha SEA would have fostered the consideration of invasive species impacts within wider environmental and societal issues, whereas on Lord Howe Island SEA would have provided guidance on the appropriate tools for community engagement to move beyond rodent control to eradication. Thus, the over-arching framework of SEA would have been applied differently on each island to reflect their different contexts and experiences.

NEW ZEALAND ISLANDS

New Zealand has led the world in invasive mammal eradications, with about one third of its islands having been cleared of all invasive mammals (Towns, et al., 2013). These successes have spurred the country to propose the Predator Free New Zealand ambition to eradicate stoats (*Mustela erminea*), rats and brushtail possums (*Trichosurus vulpecula*) from the entirety of the archipelago by 2050 (Russell, et al., 2015). A necessary stepping stone to this goal would entail removing invasive mammals from the large offshore islands of Aotea (Great Barrier Island) and Rakiura (Stewart Island), which would immediately raise the amount of offshore island predator-free land area from 10% to 50%. Discussions and limited planning for invasive mammalian predator eradication from both islands have taken place but using different methods to understand the wider context of, and barriers to, invasive mammal eradication.

Aotea

Aotea comprises a main island of 27,761 ha and numerous surrounding islands and islets, located 17 km north-east from the northern North Island of New Zealand. The island falls within the rohe (tribal boundaries) of Ngati Rehua and has about 800 residents. Seventy percent of the land is owned by the New Zealand Government and is administered by the Department of Conservation. Invasive mammalian predators include cats, black rats, Pacific rats (*R. exulans*) and mice. Mustelids, brushtail possums and hedgehogs (*Erinaceus europaeus*) are notably absent. Large predator control projects at the sub-island level currently occur at Windy Hill Sanctuary (770 ha) and Glenfern Sanctuary (230 ha), and invasive mammals have been removed from numerous surrounding offshore islands (Clout & Russell 2006). A number of bird species are currently at risk of island extirpation including red-crowned parakeets (*Cyanoramphus novaezelandiae*) and tomtits (*Petroica macrocephala*), and the last remaining kokako (*Callaeas wilsoni*) were removed in 1994 to nearby Hauturu. Whole-island eradication of feral cats and rodents was first proposed in 2003, but was met with prolonged resistance by elements of the island community (Ogden & Gilbert, 2011).

A number of tools from SEA have been applied independently on Aotea to better understand the position of the local community towards invasive mammalian predator eradication. In 2015 a participatory process was initiated in the community to understand community perspectives and aspirations towards the overall ecology of the island (McEntee & Johnson, 2015; McEntee & Johnson, 2016). This participatory process identified that the community's perspective on invasive mammal eradication could not be disassociated from their broader economic and social aspirations, and that any investment in invasive mammal eradication had to be part of a broader investment in the community itself. It also identified underlying conflicts in the community such as the tension between the value of isolation versus the desire to increase tourism, and between the desire to control invasive predators versus the value of a toxin-free environment.

A social profiling exercise was also undertaken in 2015 alongside an assessment of the community's attitudes to invasive species management (Aley, 2016; Russell, et al., 2018). This exercise found that there was a higher level of uncertainty with respect to supporting eradication than found on other neighbouring islands, but the social profile of Aotea was not markedly dissimilar to other neighbouring islands in the Hauraki Gulf, although all the islands were markedly different from a corresponding sample in neighbouring Auckland city. This suggested overall that the community's position on invasive mammal eradication was potentially driven by unique recent experiences and exposure to ideas, rather than anything in its social profile, although there did appear to be an overriding island archetype for all the islands in the study, even though one had already had invasive rats eradicated from it (Russell, et al., 2018).

Rakiura

Rakiura comprises a main island of 174,600 ha and numerous surrounding islands and islets, located 27 km south from the southern South Island of New Zealand. The island falls within the rohe of Ngai Tahu and has about 450 residents. Eighty-five percent of the land is owned by the New Zealand Government and is administered by the Department of Conservation. Invasive mammalian predators include cats, black rats, brown rats, Pacific rats, brushtail possums and hedgehogs. Mustelids and mice are notably absent. Large predator control projects at the sub-island level currently occur at Mamaku Point Conservation Reserve (172 ha; previously Dancing Star Conservation Estate), and invasive mammals have been removed from numerous surrounding offshore islands (Clout & Russell, 2006). Although a number of endangered bird species rare on the main islands of New Zealand are abundant on Stewart Island, the last remaining kakapo (*Strigops habroptilus*) were removed in 1992 to nearby offshore Whenua Hou. Whole-island eradication of feral cats and rodents was first proposed in 2008 (Beaven, 2008), but was also met with local resistance.

Rakiura is another case where a number of tools from SEA have been applied independently in an ad hoc manner, not preceded by any attempt to better understand the position of the local community towards invasive mammalian predator eradication. In 2013 a technical feasibility study for removing all invasive mammal predators from Rakiura was undertaken (Bell & Bramley, 2013). This technical feasibility study found that the eradication of invasive mammalian predators from Rakiura was not possible with today's technology, but a sub-island level project around Halfmoon Bay would be feasible. Subsequently a sub-island level project (4,800 ha) consisting of a predator-proof fence protecting the northern peninsula at Halfmoon Bay was proposed as an interim step to achieving a predator-free Rakiura, including technical reports on the predator-proof fence design (Bell, 2014a) and predator eradication methodology (Bell, 2014b). The report on the fence design emphasised the necessity of a predator-proof fence in order to achieve invasive mammalian predator eradication on the peninsula, while the report on predator eradication methodology presented a suite of options for the community to be consulted upon.

In 2014, an economic cost-benefit assessment of invasive mammalian predator eradication for both Rakiura and Halfmoon Bay was also undertaken (Morgan & Simmons, 2014). This report found that eradication was unlikely to have a net positive economic gain from tourism alone but became positive with the addition of ecosystem service valuation. The report also emphasised that anticipated economic and social benefits from invasive mammal eradication may not necessarily eventuate unless the community had a plan and processes in place to capitalise upon them. Despite the substantial investment in technical scoping and community lobbying for a predator-free Rakiura and the Halfmoon Bay project, there remains a level of resistance to both projects on the island along with multiple local proposals and efforts towards enhanced biodiversity (Russell, et al. 2017b).

Summary

The human communities on both Aotea and Rakiura exist in a similar cultural space, and the islands have remarkably similar ecological histories of bird loss, despite being at opposite latitudes of New Zealand. However, both islands illustrate the importance of drawing on the full set of tools available in SEA to build a comprehensive understanding of the perceived and real barriers to implementing an invasive species eradication programme. On Aotea, an SEA approach would have brought the technical and economic aspects of predator eradication into the community discussion earlier, alongside the social elements. When done properly this could have reduced uncertainty in the technical aspects of the proposed eradication, and addressed broader livelihood elements, particularly with respect to the economy, which are important issues on the island. In contrast, on Rakiura an SEA approach would have identified much earlier in the planning process the importance of including social assessment alongside technical and economic cost-benefit assessment, and drawn all three threads together simultaneously to identify that the most immediate barriers to predator eradication on Rakiura, or even in Halfmoon Bay, reflect existing political structures and economic development issues on the island.

DISCUSSION

In this paper we have outlined the process of SEA and how it might specifically be applied to wildlife management, with an emphasis on invasive species management and eradication on inhabited islands. We have reflected on lessons learnt from case studies on four inhabited islands around the world where invasive species are the primary threat to biodiversity, while also impacting on other elements of island livelihoods. Strategic environmental assessment captures a broad suite of tools, including EIA and SIA. Not all of the tools which are a part of SEA may need to be implemented on every island, and SEA allows the application of more context-specific tools such as SIA, and subsequent community engagement and collaborative planning. Importantly, SEA is not a single, linear or one-off process. As stated at the outset, it is an ongoing adaptive and iterative process which adds value to and builds capacity in existing systems. For eradications on inhabited islands the target system is the island community itself, including both human and non-human organisms. This should come as no surprise as it is now readily accepted that environments with humans in them must be managed as joint socio-ecological systems (González, et al., 2008).

We encourage eradication project managers to identify at the outset which SEA tools should be applied in any given project (e.g. Crandall et al. 2018), and to implement those tools in a consistent manner across projects. Governments should also develop a standardised planning and reporting process for invasive species eradication programmes. However, it is important to note that SEA is not a panacea to the challenges faced by practitioners wishing to implement invasive species eradication programmes on islands. Strategic environmental assessment can still be prone to biases either towards values or technical evidence in decision-making processes (Kørnøv & Thissen, 2000). In some cases, whole-island eradication may simply not be an optimal nor achievable goal, due to technical, ecological social, economic or political barriers (Russell, et al., 2015). This does not mean eradication should not remain an aspirational goal (e.g. Predator Free New Zealand), but that in the meantime focus is directed to conservation interventions which maximise return-on-investment in the broadest sense, e.g. invasive species management at the sub-island level.

The application of SEA in a conservation context has the added benefit of bringing wildlife management and invasive species eradication more strongly into the ambit of a broader application of SEA to island development. This would enable the wider benefits of invasive species eradication to be realised, such as on public health (de Wit, et al., 2017) and in primary industry (Nimmo-Bell, 2009). It would also allow the benefits to be incorporated into the international Sustainable Development Goals, such as reduced inequalities through the more equitable distribution of resources for invasive species eradication across developed and developing island nations. For instance, in small island developing states (Russell, et al., 2017a), which are predominantly tropical and home to unique biodiversity not found elsewhere and at risk from invasive species such as mammalian predators (Russell & Holmes, 2015). Undertaking an SEA approach to invasive species eradication on islands will ultimately ensure the longevity of eradications on islands, and alongside enabling eradications on islands in the first instance, will have immediate benefits in the implementation and maintenance of biosecurity on islands (e.g. Russell, et al., 2017a).

ACKNOWLEDGEMENTS

Towards a guidance document for invasive species planning and management on islands

A. Tye

International Union for Conservation of Nature, COI Blue Tower 3rd floor, Rue de l'Institut, Ebène, Mauritius. Present address: 2 School Lane, King's Ripton PE28 2NL, UK. <alantye@gmail.com>.

Abstract In 2012 a process was initiated to produce a guidance document for invasive species management on islands, as an objective of a regional invasive species project in the Western Indian Ocean (WIO) islands, implemented by IUCN. The consultative process for producing the document began with requests and discussions via regional and global island and invasives email distribution lists. Initial responses revealed a consensus on the need for a guidance document for programmatic planning. A draft was therefore constructed around existing Pacific regional guidelines and a draft manual that had initially been written for the WIO, with new supplementary sections suggested by respondents. The new draft was discussed and revised in workshops at two international conferences. The document is now organised into three main sections: the first on how to use it, the second a checklist of the essential components of a comprehensive island invasives programme (to ensure nothing is overlooked when planning), and the third providing detailed guidance on the planning and decision-making processes. The document is intended to provide a comprehensive framework and procedural guide for invasive species planning on islands. Further consultations took place by email, and a later draft was tested by a number of users writing various kinds of invasive species strategy and action plan. Publication will be in English, French (both published 2018) and Spanish (scheduled for 2019).

Keywords: best practice, consultative planning, NBSAP, networks, NISSAP, prioritisation

INTRODUCTION

The intentional and unintentional movement by people of organisms around the world, many of which become invasive in the areas to which they are introduced, is an international problem of particular concern to islands. The effective management of invasive species on islands therefore requires comprehensive and coordinated action by international agencies, governments, NGOs, the private sector and local communities. Small islands and developing states do not have the resources to tackle all invasive threats by themselves, and in some regions collaborative regional plans and strategies have been developed to promote coordinated planning and action between islands and nations and also to guide international agencies in providing assistance to them. Many countries have also developed National Invasive Species Strategies and Action Plans (NISSAPs), as have a number of individual islands (for brevity, all such plans are herein termed NISSAPs). The Convention on Biological Diversity recognises invasive species as a serious threat, including in its Aichi Target 9, and encourages countries to include plans for managing invasive species in their National Biodiversity Strategies and Action Plans (NBSAPs). However, the NBSAPs and NISSAPs of different islands and island countries vary greatly in their comprehensiveness in dealing with invasive species problems (Doherty & Boudjelas, 2010; Boudjelas, in press).

The Inva'Ziles Project, implemented by IUCN from 2012 to 2018, provided assistance to the islands of the western Indian Ocean (WIO) region in managing biological invasions. One of the project's objectives was to develop guidance for islands and island nations to help them prevent and manage the spread of invasive species and reduce their impacts on biodiversity and people's livelihoods. This paper describes the process leading to the production of a guidance document specifically for invasive species planning on islands worldwide. It explains the purpose of the document and outlines progress towards its publication, including input from the 3rd Island Invasives conference in Dundee, July 2017.

FIRST STEPS

The Inva'Ziles project began with a broad interpretation of its commitment to produce a guidance document for invasives management on islands, by compiling a first draft of a manual attempting to cover the whole range of actions necessary for an invasive species programme, in the following chapters:

INTRODUCTION

- Importance of biological diversity
- Significance of biological invasion as a disruption of biodiversity

BIOLOGICAL INVASION AS A PROCESS

ELEMENTS OF AN INVASIVES SPECIES STRATEGY

- Regional coordination and exchange
- Risk Assessment
- Prevention without quarantine
- Pathways of introduction
- Early detection and rapid response
- Management of established invasions

MONITORING

CAPACITY

- Institutions
- Awareness
- Information
- Conventions

IMPLEMENTATION OF INVASIVES SPECIES MANAGEMENT

- Policies, laws and regulations
- Institutions and capacity
- Roles and responsibilities of the public
- International and regional responsibilities

GLOBAL CHANGE AND INVASION

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 698–702. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

While all these topics are important, there are good resources already available to help planners and managers with many of these activities, including project design, border biosecurity, methods of controlling various species of invasive animal, plant and other organisms, raising awareness, etc. Examples include the guidelines and toolkits of the Global Invasive Species Programme (www.issg.org/gisp_guidelines_toolkits.htm) on marine biofouling (Jackson, 2008), marine pest management (Hilliard, 2005), legal and institutional frameworks (Shine, et al., 2000; Shine, 2008), best prevention and management practice (Preston, et al., 2000; Wittenberg & Cock, 2001), and economic analysis (Emerton & Howard, 2008) along with their accompanying training courses (www.issg.org/gisp_training_coursematerials.htm). There are also many excellent materials developed in individual regions, such as the rodent and cat eradication resource kits for the Pacific (Pacific Invasives Initiative, 2011) and UK (GB Non-native Species Secretariat, 2017), as well as the Pacific kits for invasive plant (Pacific Invasives Initiative, 2015) and ant (New Zealand MFAT, 2016) management and their accompanying training courses. It would be impossible within a single document to improve on all of these and others. Further, it was considered doubtful whether general explanations of biological invasions and their impacts on biodiversity would be necessary for the intended primary users of the document: invasive species planners, managers and researchers on islands. The introductory material covering these topics and the discursive style adopted in the first Inva'Ziles draft limited the amount and clarity of the guidance provided; for example, the draft did not give clear guidance on the steps to be taken when planning an invasives programme, nor on how to prioritise when faced with many problems and limited financial and human resources. It was felt that a short document with a clear purpose and direct guidance would be more useful and used than something longer and more discursive.

It was therefore decided to carry out consultation in order to find out what kind of guidance invasive species workers themselves thought they needed most, so as to be able to focus the planned document more precisely on priority gaps in available resources.

CONSULTATION AND REDRAFTING

Given the Inva'Ziles Project's primary responsibility to provide assistance to the WIO region, an initial consultation was carried out by e-mailing a simple questionnaire to the c. 325 members of the Western Indian Ocean Network on Invasive Species (WIONIS), asking what kind of guidance they felt was most needed. It was essential to give respondents an idea of what might be possible for the project to produce within the limitations of its timespan and budget, so, to encourage realistic answers three possibilities were suggested: a manual-style document resembling the first draft produced by Inva'Ziles, something focused more precisely on the planning and decision-making processes, using the example of the *Guidelines for Invasive Species Management in the Pacific* (SPREP, 2009: hereafter termed the 'Pacific *Guidelines*'), or something else.

This was followed by a similar worldwide consultation using the following global and regional e-mail distribution lists: aliens-l (1,400 subscribers, global), islands-l (360, global), carib-ias (310, Caribbean), the Pacific Invasives Initiative list (1,210), and the Pacific Invasives Partnership (c. 40). In addition, the same request was sent to specifically compiled lists of known contacts in the Atlantic and Mediterranean islands (c. 20 people).

These consultations generated responses from invasive species planners, scientists and managers, including experts in all major island biomes, marine and terrestrial (all contributors up to the submission date of the present article are named in the Acknowledgments). Of the 43 respondents who indicated a clear preference for the kind of document they would like to see developed, two wanted an operations manual for field management and 41 preferred guidance on planning, with no-one suggesting any other kind of document. These choices, taken together with written comments from many other respondents, indicated a consensus that specific guidance on programmatic planning was scarce and lacking in detail, and that this represented a particular resource gap. The Pacific *Guidelines* have been widely adopted and used in that region, and many respondents felt that an updated and internationalised version of this would be highly appropriate for other island regions.

The decision was therefore made to produce a document addressing this need for planning guidance, taking the Pacific *Guidelines* as a model, updating and hopefully improving it, and at the same time endeavouring to make the document as useful and relevant as possible to islands worldwide. A skeleton was then produced by adapting the text of the Pacific *Guidelines* for a global set of users, and adding ideas for new sections suggested by the drafting team, questionnaire respondents and others. The new sections were then partially populated by adapting text from the Inva'Ziles first draft manual.

To expand the consultation process, we used opportunities created by international and regional meetings to obtain further input. Workshops were therefore organised at the IUCN 'World Conservation Congress' (WCC) in Hawai'i, September 2016, and the 3rd 'Island Invasives' conference (3II), Dundee, July 2017. The first of these meetings attracted (as expected) a broad cross-section of conservationists, while the second drew a substantially different group, consisting primarily of invasive species management practitioners and researchers. Both meetings generated contributions from people working on a wide range of aspects of the invasives threat to islands, from all parts of the world.

At the WCC, two events were organised with the objective of obtaining input. First, the IUCN held a major introductory event on '*Islands at risk: meeting the global challenge of Invasive Alien Species*', at which three initial presentations (one on the guidance document) were followed by work-groups on the three topics. The guidance work-group attracted some 30 people, of whom 14 offered to make additional contributions later, as the drafts developed. The second WCC event was a roundtable discussion organised by the Pacific Invasives Partnership, which attracted about 20 people, most of whom had not attended the first working session. At both of these sessions, input was obtained not only for the global guidance document, but also for a planned revision of the Pacific *Guidelines*, led by the Pacific Invasives Partnership.

Comments and ideas received at the WCC were incorporated into a second draft, which included supplementary sections solicited meanwhile from volunteer experts on particular topics. During this process it became clear that guidance on two areas in particular was desired: the planning process itself, including prioritisation and decision-making, and how to increase support for invasives management among politicians, their electorates (the public), and local communities experiencing problems caused by invasives. As a result, these two areas grew to constitute the largest supplementary sections.

At the 3II, the IUCN gave an introductory presentation in plenary to explain the purpose of a working session on the guidelines that evening. Some 50 people came to the evening session (approximately 15% of the conference attendees), which was organised into three work-groups covering different sections of the draft, namely: planning and decision-making; awareness, support and capacity; research and practical management. Twenty of those who attended offered to contribute further.

The steps towards producing this document are illustrated in Fig. 1, and the location or geographical interest of the identified contributors summarised in Table 1. At the time of writing this paper, we were in the process of incorporating comments from the 3IIsland A major outcome from 3II was confirmation from practitioners that the fundamental need for this document was genuine and widespread, and also that guidance on how to use the document should be given clearly within.

THE CURRENT DRAFT

The aim thus became to provide a comprehensive framework and procedural guide for anyone planning an invasives programme on islands, including international and regional agencies, conservation NGOs, relevant government agencies (agriculture, biosecurity, environment …), conservation managers, research planners, and anyone else who has to find, plan and prioritise funds and resources for invasives management.

The latest and final draft met the target limit of 48 pages plus covers (the Pacific *Guidelines* comprises 24 pages including covers), has now been organised into three main sections (plus a "Resources" section). The first of the main sections explains the purpose of the document, how to use it, and who the intended users are. The second section is a checklist of the essential components of a comprehensive island invasives programme, to ensure nothing is overlooked when planning (this part still resembles the Pacific *Guidelines*, which consists mainly of such a checklist). The third section describes in detail how to conduct the processes mentioned by many people as being particularly problematic, especially how to plan, how to prioritise, how to make decisions, and how to increase collaboration, support and involvement by different target groups ranging from local communities to senior policy- and decision-makers. Throughout, there are links to additional resources on each topic.

The document provides decision-making guidance at both programmatic planning and field project planning levels, including how to prioritise, how to choose management goals, and how to win political and community support for the actions planned. It should help international agencies to identify their niche for invasives work on islands and to identify island priority needs that match their agency's expertise. It will help national and local agencies and managers to identify and prioritise actions within their jurisdiction, design a NISSAP, benefit from the experience of other countries and organizations, and justify projects to decision-makers and donors. Content of the three main sections is organised as follows:

INTRODUCTORY MATERIAL

- Purpose of the document, intended users, how to use
- Background

THE GUIDELINES CHECKLIST

- Foundations (planning, decisions, support, capacity, legal)
- Information (baseline, monitoring, prioritisation, research)
- Management (borders, established invaders, restoration)

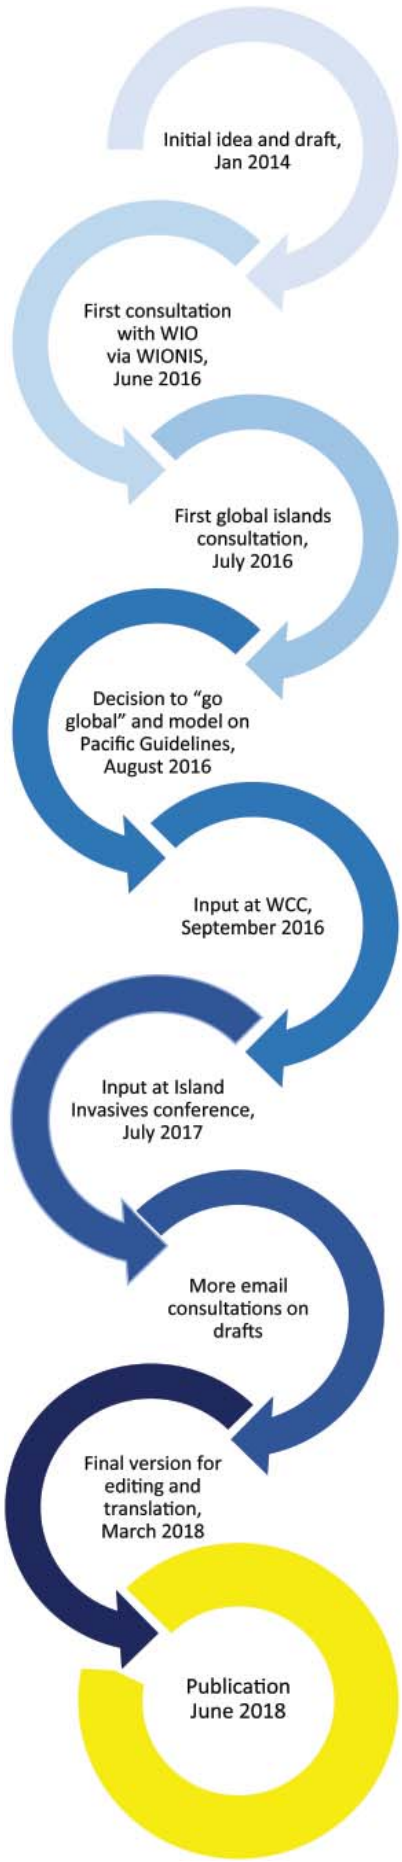

Fig. 1 Timeline of the process of producing the guidance document.

HOW TO PLAN

- Getting people involved, raising support for the plan, mutual help networks
- Programme planning, NISSAPs and others
- Prioritising, hard decisions, decision tools, risk analysis
- Neglected areas
- Planning for global change
- Project planning, other decision tools

The identification of these priority areas for guidance has largely been determined by the views of the respondents. These priorities differ somewhat from the critical areas for action identified almost 20 years ago in the Pacific, when the following were considered to need special attention (SPREP, 2000):

- Shortage and inaccessibility of information on invasive species and best management practice
- **Lack of awareness of the impacts of invasive species**
- **Insufficient networking, coordination and collaboration**
- Inadequate legislation, regulations, cross-sectoral policies, and enforcement
- Shortage of trained personnel, and inadequate facilities
- **Insufficient funding.**

The three items in bold are closely related to the current priority needs identified by our recent consultations. The differences reflect both the fact that some of the other areas, particularly best management practices, have since been addressed by resources specially designed to assist with them, but also the fact that our new document is aimed at perceived needs for guidance itself, rather than at other kinds of need (e.g. adequate facilities, trained personnel, laws etc.).

FINAL STEPS

The final draft was circulated once more to the core group of committed contributors (ultimately just over 100 people contributed) as well as to all of the e-mail distribution lists cited above. Special contributions were solicited from experts on particular themes. The later drafts were tested in a number of planning processes, including for the first NISSAP of the Comoro Islands in mid-2018. The English and French versions were published in print and online in mid-2018 and the Spanish version published online in early 2019.

ACKNOWLEDGEMENTS

The Inva'Ziles Project (official title *Preparation and testing of a comprehensive model for preventing and managing the spread of invasive species on island ecosystems*) was implemented by the International Union for Conservation of Nature (IUCN), funded by the European Union and hosted by the Indian Ocean Commission. Geoffrey Howard and Olivier Tyack (IUCN) drew up the initial concept and first draft of the guidance document. Kosi Latu (SPREP) kindly gave permission to use the Pacific *Guidelines* as a model. Kevin Smith, Olivier Hasinger (IUCN) and David Moverley (SPREP) organised working sessions at the 2016 'World Conservation Congress', and Kevin, together with Souad Boudjelas (Pacific Invasives Initiative) and Jill Key (GB Non-Native Species Secretariat), also organised the session at the 3rd 'Island Invasives' conference; they have all provided invaluable support and contributions throughout. Dick Veitch encouraged me to write this article for the current proceedings, Katharina Lapin (IUCN) constructed Fig. 1, and Olivier Hasinger and Kevin Smith reviewed a draft. The following had contributed to drafts by the date of submission of this article by providing texts, commenting on versions, suggesting areas of concern, or in other ways (this list does not include people who contributed at conferences but did not leave their details): Ademola Ajagbe, Katy Beaver, Alex Bond, Elsa Bonnard, Olaf Booy, Rafael Borroto, Souad Boudjelas, Nancy Bunbury, Earl Campbell, Dario Capizzi, Juli Caujapé-Castells, Alison Copeland, Ana Costa, Franck Courchamp, Phil Cowan, Steve Cranwell, Cathleen Cybèle, Curt Daehler, Maria Cristina Duarte, Julia Dunn, Rui Bento Elias, Marko Filipovic, Julian Fitter, Frauke Fleischer-Dogley, Jason Goldberg, Ines Gómez, Viliami Hakaumotu, Sjurdur Hammer, Olivier Hasinger, Ben Hoffmann, Geoffrey Howard, Stephanie Hudin, Jason Jack, Patricia Jaramillo, Marie-May Jeremie-Muzungaile, Gabe Johnson, Chris Kaiser-Bunbury, Springer Kaye, Inti Keith, John Kelly, Jill Key, Michael Kiehn, Cynthia Kolar, Christoph Kueffer, Janice Lord, Ian MacDonald, Gwen Maggs, Christy Martin, Kelly Martinou, John Mauremootoo, Mathilde Meheut, Tommy Melo, Jean-Yves Meyer, Joel Miles, Aileen Mill, James Millett, Nitya Mohanty, Craig Morley, David Moverley, Bradley Myer, Rachel Neville, Ray Nias, Kimberley O'Connor, Warea Orapa, Shyama Pagad, Julián Pérez, John Pinel, Bruce Potter, Parmenanda Ragen, Frida Razafinaivo, Tim Riding, Gérard Rocamora, James Russell, Susana Saavedra, Adrian Schiavini, Richard Selman, Nirmal Shah, Andy Sheppard, Greg Sherley, Junko Shimura, Didier Slachmuylders, Kevin Smith, Antonio Soares, Yohann Soubeyran, Vikash Tatayah, Anna Traveset, Olivier Tyack, Magdalena Vicens,

Table 1 Islands and island regions represented by the 96 identified contributors so far (each contributor assigned to only one category). OIT signifies overseas island territories of any kind, irrespective of their political status; n = no. of contributors.

Islands	**n**	**Islands**	**n**	**Islands**	**n**

Chapter 4: Abstracts

These abstracts are for papers which were presented at the conference, either as oral presentations or poster papers, but for which the authors have chosen not to prepare and publish a full written paper.
These abstracts are given in the alphabetical order of the prime author of the paper with the address of only that first author included.

Mexico's progress and commitment to comprehensive island restoration

A. Aguirre-Muñoz, F. Méndez-Sánchez, L. Luna-Mendoza, A. Ortiz-Alcaraz, J. Hernández-Montoya, Y. Bedolla-Guzmán, M. Latofski-Robles, E. Rojas-Mayoral, N. Silva-Estudillo, F. Torres-García, M. Félix-Lizárraga, A. Fabila-Blanco, A. Hernández-Ríos, E. Bravo-Hernández, F. Solís-Carlos, C. Jáuregui-García and D. Munguía-Cajigas

Grupo de Ecología y Conservación de Islas, A.C., Avenida Moctezuma 836 Zona Centro, Ensenada, Baja California 22800 Mexico. <alfonso.aguirre@islas.org.mx>

For the past 18 years, Mexico has taken bold steps to systematically eradicate invasive mammals. Mexico´s 4,111 islands host 8.3% of the country's plants and land vertebrates. They harbour one in three seabirds worldwide, placing Mexico as the third most diverse country. Invasive mammals have had a big toll on Mexico's biodiversity, with 17 out of 21 confirmed vertebrate extinctions occurring on islands. The Mexican conservation organisation Grupo de Ecología y Conservación de Islas (GECI), in collaboration with Mexico's federal government, and a wide network of national and international donors, has been leading the National Programme for Island Restoration that has grown in scope. The first eradications on small islands fostered trust amongst partners, setting the foundations for complex eradications on bigger islands requiring innovation, capacity development, and research. Island biosecurity is now a priority for long-term tangible results. This programme evolved to be truly comprehensive, including post-eradication restoration to strengthen island resilience, and the social construction of a cultural approach integrating interests from conservation and local fishing communities. Results to date include: (1) eradication of 58 populations of invasive mammals from 37 islands; (2) publication of both a National Island and Invasive Species Strategy, identifying conservation priorities; (3) ongoing active restoration of seabird colonies and native plant communities; (4) original applied research and ad hoc infrastructure and equipment to support restoration; (5) legal protection of all Mexican islands; (6) assessing the effects of climate change on islands' biodiversity and human populations; and (7) formation of in-house specialists through postgraduate studies in collaboration with research institutes and universities from Mexico and elsewhere. As for the future, we foresee two priorities: (1) remove invasive mammals from all Mexican islands by 2030; and (2) promote the creation of an "International Islands Institute" that could operate under a wide international collaboration and interdisciplinary approach.

The Pacific invasives partnership – a model for regional collaboration on invasive alien species

P.C. Andreozzi, R. Griffiths, D. Moverley, J. Wainiqolo, R. Nias, S. Boudjelas, D. Stewart, S. Cranwell, M. Smith and P. Cowan

U.S. Department of Agriculture, Animal and Plant Health Inspection Service, Washington DC, USA. <Phillip.C.Andreozzi@aphis.usda.gov>

Invasive Alien Species (IAS) are a fundamental challenge facing Pacific Island Countries and Territories (PICTS), impacting economies, habitats, food security, biodiversity, livelihoods and quality of life. These negative and substantial impacts are being acknowledged by PICTs leaders as well as on the international stage. As the inter-relatedness of IAS and other fundamental challenges such as climate resilience, oceans and sustainability are understood and acknowledged, strategies to integrate IAS and biosecurity concepts into international efforts will require invasive species expertise and guidance. The Pacific Invasives Partnership (PIP) is a group created by the Pacific Roundtable for the Conservation of Nature that has evolved into a broad advocate for IAS outreach and an incubator for collaborative IAS efforts in the Pacific. PIP comprises volunteer IAS experts from regional, national, NGO and international groups that work in two or more PICTS and want to advance IAS issues. By taking a "rising tide floats all boats" approach, PIP members work to raise the profile and understanding of IAS as a fundamental, underpinning issue to PICT economies, environments and future sustainability. PIP successes over the past five years include reports and briefing materials prepared for the Pacific Islands Forum Leaders meeting, provision of advice and assistance for Pacific invasive species Global Environment Facility projects, leading and supporting regional and sub-regional projects on regional biosecurity, invasive ant and rodent eradication and prevention, and the successful raising of the IAS profile at various international fora. PIP is a successful model of regional collaboration on invasive alien species and could be used as a model for similar efforts in other island regions of the world.

A review of monitoring of biodiversity responses to island invasive species eradications

J. Bird, J. Shaw, R. Alderman and R. Fuller

Centre for Biodiversity & Conservation Science, University of Queensland, School of Biological Sciences, University of Queensland, St Lucia, Queensland 4072 Australia. <jez.bird@uq.edu.au>

A recent review examined the benefits from invasive species eradications on islands worldwide. While the review concluded that island eradications are overwhelmingly beneficial for native biodiversity, a response to eradication was only demonstrated for 22 of the 532 islands treated. While many studies advocate monitoring, there appears to be a gap, either between eradication effort and monitoring effort, or between monitoring and analysing/reporting responses. We focussed on regions of the Pacific, Australia and the Caribbean to document the level of monitoring on islands where eradications have taken place. We collated published and unpublished literature and spoke to key practitioners in the region to investigate targets for monitoring, duration and frequency of monitoring, and the ability of implemented monitoring work to detect responses. We also investigated drivers of monitoring such as type of funder or implementing organisation behind the eradication operation. The study's findings highlight apparent biases in monitoring effort, they provide a benchmark of current monitoring effort, and open the debate on when and where monitoring should be undertaken and how best to develop optimal monitoring strategies.

A review of seabird recovery on Lundy Island, England, over a decade following the eradication of brown and black rats

H. Booker, D. Appleton, D. Bullock, R. MacDonald, E. Bell, D. Price, P. Slader, T. Frayling, A. Taylor and S. Havery

Species and Habitats, Royal Society for the Protection of Birds, RSPB, Headquarters, the Lodge, Sandy, Bedfordshire SG19 2DL, UK. <Helen.Booker@rspb.org.uk>

Lundy, a 450 ha island situated 19 km off the Devon coast in the UK's Bristol Channel, is internationally important for its marine life and its waters were established as the UK's first Marine Nature Reserve in 1971. Lundy is home to eleven seabird species, including Manx shearwater (*Puffinus puffinus*), for which the UK has a global responsibility and Atlantic puffin (*Fratercula arctica*), a globally threatened species. Steep declines in Lundy's seabird populations, with puffins nearing extinction and low numbers of Manx shearwaters, led to the establishment of the Seabird Recovery Project in 2001. The project aimed to improve the conditions for these burrow-nesting seabirds through the eradication of brown and black rats. From 2002–2004 a ground-based operation was undertaken, and in 2006 Lundy was officially declared rat-free. The seabird populations of Lundy have been well studied with detailed regular data spanning the last 35 years. Over the last decade, as a result of rat removal, seabird numbers on the island have doubled and storm petrels have colonised. By 2013, the breeding population of Manx shearwaters increased more than ten-fold to an estimated 3,451 pairs. In 2004, the puffin population on Lundy fell to an all-time low with only five individuals, but in 2013, more than 80 individuals were recorded. Here we discuss the observed seabird responses to the eradication and present the most recent results of the monitoring surveys from 2017. These impressive results highlight the importance of and need for effective biosecurity to reduce the risk of re-incursion of rats. Lundy is a popular tourist destination with a working farm; therefore, the regular transportation of cargo remains a high biosecurity risk. A revised biosecurity and incursion response plan is now being finalised.

Eradicating invasive ants in conservation areas

C.L. Boser

The Nature Conservancy, 532 E Main St, Suite 200 Ventura, California 93001, USA. <cboser@tnc.org>

Established invasive invertebrates, such as Argentine ants (*Linepithema humile*), can have long-term and cascading adverse ecological impacts for native communities. In Mediterranean ecosystems, they out-compete most native ant species and harm plants such that they interfere with pollination, reducing seed set. In 2013–2016 we developed and carried out a unique treatment protocol on four Argentine ant infestations on Santa Cruz Island, California, totalling 410 ha. We used polyacrylamide beads, hydrated with 6 ppm thiamethoxam and 25% sucrose water distributed at a rate of 148 litres per hectare via helicopter and hopper. We treated the four infestation areas 14 times, for total cost of US$1,400 per ha. Two monitoring strategies used lures and visual searching on 74 ha in 2013–2015, with costs at US$2,200 and US$500 per ha. The less costly, targeted strategy revealed one spot population totalling 0.3 ha. This population was located at the edge of a treatment site, possibly indicting that the 50 m buffer added to that delimited infestation was insufficient. Follow up treatments were conducted on that site and Argentine ants were not detected in subsequent monitoring rounds. Monitoring will continue 2016–2020 throughout all four treatment areas, aided by a fine-scale model of probability of detection and probability of persistence by vegetation type, and detection dogs. Packaged with patience and persistence, these treatment and monitoring protocols show promise as an eradication tool. Preliminary data indicate that the treatment may also be effective in eradication programmes for other invasive ant species.

Big island, small invader: eradicating invasive fish on a national scale

M. Brazier

National Fisheries, Environment Agency, Bridge End Depot, Causeway Road, Kendal, Cumbria, North West, UK. <matt.brazier@environment-agency.gov.uk>

Topmouth gudgeon (*Pseudorasbora parva*) is an invasive non-native cyprinid from Asia. Listed as a Species of Union Concern under the EU Invasive Alien Species Regulations, it is considered one of the most potentially damaging non-native fish species to invade Western Europe. Introduced to Great Britain (GB) in 1984, evidence indicated that if topmouth gudgeon established in GB, the impacts on our native species and habitats could be severe. The threats were clear, and the case for action robust. However, in 1980s and 1990s GB authorities lacked a coherent invasive species strategy, regulatory powers were ineffective, there was no focused expertise or capacity and the tools and techniques necessary to control such a tenacious invasive species had not been developed or adopted. Topmouth gudgeon spread inexorably across England and Wales, until 2004. By 2004, with seven populations identified, the authorities were no closer to a solution. However, using an innovative biocide-based approach, a local Environment Agency team successfully eradicated topmouth gudgeon from a fishery in the Lake District. This led to a number of small scale, ad hoc eradications, but as confirmed populations climbed to 14, sustainable removal of the species from GB was not considered feasible. In 2011, supported by the GB Invasive Species Strategy, the Environment Agency utilised their growing expertise and capacity to develop a specialist team and equipment and implemented a Water Framework Directive National Programme; their ambitious objective: total eradication of topmouth gudgeon from GB by 2018. Scaling up from small scale, localised eradication to a national landscape scale programme to eradicate an aquatic invasive species was unprecedented and presented significant strategic, legal, operational, economic and political challenges. This paper documents that 12-year journey, highlighting the challenges, discussing how they were overcome, the lessons learnt, and considers the future potential and direction of this work.

Population growth of seabirds after the eradication of introduced mammals

R. Buxton and M. Brooke

Department of Fish, Wildlife, and Conservation Biology, Colorado State University, 1474 Campus Delivery, Fort Collins, CO 80523, USA. <rachel.buxton@colostate.edu>

Eradication of introduced mammals to restore island ecosystems has become increasingly common, with more than 1,000 successful projects around the world. Various benefits for native fauna have been documented, including reduced predation and positive demographic response. However, evidence that these eradications lead to increases in populations of seabirds, which are important island ecosystem engineers, is sparse. The limited amount of monitoring is partly because of seabirds' long life cycle, meaning that several years or even decades may elapse before populations respond to eradication. Drawing on data from across the world, we assemble population growth rates (lambda, λ) of 181 seabird populations of 69 species following successful eradication projects. After successful eradication, the median growth rate was 1.12 and populations with positive growth ($\lambda > 1$; n = 151) greatly outnumbered those in decline ($\lambda < 1$; n = 23) and those that exhibited no change ($\lambda = 1$; n =7). Population growth was faster at newly-established colonies compared to those already established, and in the first few years after eradication before the species' age of first breeding. Because λ was higher before first-time breeders are recruiting back into the colony, this suggests that immigration is important for colony growth. Population growth was also faster among gulls and terns compared to other seabird groups and when several invasive mammals were eradicated together in the course of the restoration project. This reflects the relative lack of philopatry among gulls and terns and reinforces current best practice – the removal of all invasive mammals where feasible. These results may help prioritise sites for future eradication projects and determine where active seabird population management is required after eradication.

Assessment of the possible effects of biological control agents of *Lantana camara* and *Chromolaena odorata* in Davao City, Mindanao, Philippines

C. Canlas, C. Gever, P. Rosialda, Ma. N. Quibod, P. Buenavente, N. Barbecho, C. Layusa and M. Day

Biology Department, Adamson University, 9666 Dona Cipriana Street, Gat-Mendoza, Brgy. Vitalez. <canlascristine@ymail.com>

Invasive plants have an impact on global biodiversity and ecosystem function, and their management is a complex and formidable task. Two of these invasive plant species, *Lantana camara* and *Chromolaena odorata*, are found in the Philippines. *Lantana camara* has the ability to suppress the growth of and outcompete neighbouring plants. *Chromolaena odorata* causes serious agricultural and economical damage and causes fire hazards during dry season. In addition, both species have been reported to poison livestock. One of the known global management strategies to control invasive plants is the introduction of biological control agents. These natural enemies of the invasive plants reduce population density and impacts of the invasive plants, resulting in the balance of the nature in their invasion. Through secondary data sources, interviews, and field validation (e.g. microhabitat searches, sweep netting, opportunistic sampling, photo-documentation), we investigated whether the biocontrol agents previously released by the Philippine Coconut Authority (PCA) in their Davao Research Center to control these invasive plants are still present and are affecting their respective host weeds. We confirm the presence of the biocontrol agent of *L. camara*, *Uroplata girardi*, which was introduced in 1985, and *Cecidochares connexa*, a biocontrol agent of *C. odorata* released in 2003. Four other biocontrol agents were found to affect *L. camara*. Signs of damage (e.g. stem galls in *C. odorata,* and leaf mines in *L. camara*) signify that these biocontrol agents have successfully established outside of their release site in Davao. Further investigating the extent of the spread of these biocontrol agents in the Philippines and their damage to the two weeds will contribute to the management of invasive plant species in the country.

Black rat eradication from Linosa Island: work in progress

M. Cecchetti, G. Dell'Omo and B. Massa

University of Exeter, Environment and Sustainability Institute, College of Life and Environmental Science, Penryn Campus, Cornwall UK; and Berta maris, Linosa. <mc703@exeter.ac.uk>

The black rat (*Rattus rattus*) is one of the most successful colonising mammals and one of the 100 world's worst invasive species. It is a generalist and opportunistic predator, particularly of seabird eggs and chicks on islands where it has been transported by humans on ships. The Life project "Pelagic Birds: Conservation of the main European population of *Calonectris diomedea* and other pelagic birds on Pelagic Islands" on Linosa Island involves the eradication of black rats, since it is considered the major cause of Scopoli's shearwater breeding failure. From 15 May to 10 October 2013, a preliminary phase was carried out to determine the abundance and the distribution of black rats and house mice (*Mus musculus*) through captures. In four sessions of captures in eight different representative habitats, a total of 197 rats and 247 mice have been captured. In the same year rats impacted negatively the 34% of the 400 shearwater nests monitored, having a similar impact on eggs and chicks. On February 2016 we set 2,700 rodenticide stations all around the island. Then, the rodenticide was replaced in April, June, October and November, with positive results. The rat take of baits has decreased significantly. In November, an average of 86% of baits were left in the stations, indicating a strong decrease of the rat population. Continuing the action and the distribution of rodenticide is essential in order to reach the eradication of this aggressive predator by the end of the year.

Effects of cat, rat, and human predation on Scopoli's shearwater (*Calonectris diomedea*) breeding success and nest-site occupancy on Linosa Island

M. Cecchetti, L. Nelli, B. Massa and G. Dell'Omo

University of Exeter, Environment and Sustainability Institute, College of Life and Environmental Science, Penryn Campus, Cornwall, UK; and Berta maris, Linosa. <mc703@exeter.ac.uk>

Biodiversity on islands is seriously threatened by invasive species, that have been voluntarily or accidentally introduced by humans. Seabirds, especially small and medium ground-nesting Procellariiformes, are particularly vulnerable to introduced predators which can negatively affect breeding success and nest occupancy. Linosa is a small Mediterranean island where thousands of Scopoli's shearwaters (*Calonectris diomedea*) breed each year. Their survival is endangered by the presence of 400 inhabitants, 300 free-roaming cats (*Felis catus*), and a conspicuous population of rats (*Rattus rattus*). Our study aims at evaluating the effects of cat, rat and human predation on the shearwaters' breeding success and the effects of breeding failure on nest-site occupancy. From 2013 to 2016 we monitored shearwater nests and collected data on burrow occupancy, egg deposition, egg hatching, and chick fledging taking notes of cases of failure. Nest characteristics were also measured. Overall, the shearwater breeding success was 65% and predation by mammals was the major cause of breeding failure (19%). We analysed the effects of cat and rat predation and poaching on the nest occupancy in the following year, using generalised linear mixed effect models. We also analysed if nest characteristics (depth and diameter) and nest position, in terms of distance from houses, roads, trails and coastline, were related to the probability of predation by cats, rats and poaching. Egg-poaching had a negative effect on the occupancy of the following year, whereas predation upon eggs by rats and predation upon chicks by cats had a minor effect. We also found that the nest position didn't affect the probability of predation by rats and cats and egg poaching. However, increasing in cavity depth reduces the probability of cat predation.

Invasive plants: what can be done about this continuing threat to biodiversity?

C. Clubbe

Conservation Science, Royal Botanic Gardens Kew, Richmond, Surrey TW9 3AE, UK. <c.clubbe@kew.org>

Human intervention has led to plants being moved around the world for centuries. This practice has been both unintentional and intentional. Unintentional when seeds and/or vegetative propagules were transported vicariously alongside other materials being moved. Intentional when desirable and useful plants were moved around the world, often linked with colonialisation, arguably the fore-runner of today's globalisation. Many of these plants became naturalised only locally or required careful nurturing to survive in their new habitats. However, some of these plant species found their new environments highly conducive to spread. Removed from controlling factors such as pests and herbivores, they became established over significant areas posing a serious threat to native biodiversity. Invasive species are now recognised as a major driver of biodiversity loss globally, with particularly severe impacts on islands. We have reviewed six global invasive species databases to determine the number of invasive plants globally. Taxonomic reconciliation has demonstrated that 6,075 vascular plant species are currently documented as invasive. The first part of this talk will review this in its historical context and consider the implications of the continuing increase in the number and spread of invasive plant species globally. The second part of the talk will review work by Kew's UK Overseas Territories team on invasive plants. The UK Overseas Territories support the most significant UK biodiversity in terms of unique species and habitats. This biodiversity is under severe threat from invasive species. We have been identifying and mapping invasive plants, and developing actions plans for their control. The talk will include examples from St Helena, Ascension, Falkland Islands and British Virgin Islands. Wider implications from this work for dealing with this global threat will be considered.

Partnerships in the restoration of tropical Pacific islands

S. Cranwell

Birdlife International, GPO Box 18332, Suva, Fiji. <steve.cranwell@birdlife.org>

The eradication of invasive alien species from islands is a highly effective conservation action for the recovery of declining and threatened native species. Among the characteristics necessary for the success of these operations and the sustainability of the conservation outcomes is a range of technical expertise, cultural and political support, and financial and organisational capacity. In the tropical Pacific, civil society organisations including the BirdLife Partnership have taken a lead in implementing invasive vertebrate eradications, and despite capacity limitations have successfully delivered operations for 40 sites in five countries since 2007. The scale and complexity of these eradications have increased over time, from focusing on single target species on individual islands to simultaneously addressing multiple invasives and islands. This growing experience has highlighted the strengths of locally based civil society organisations, particularly in addressing the cultural and political issues associated with vertebrate eradications, but also the essential role of partnerships in supporting their technical preparation and financing. The operations to date have benefited multiple threatened species. However, if invasive species management is to fulfil it's potential to reduce biodiversity loss on Pacific islands, political support and local capacity must increase, particularly for biosecurity. Stronger partnerships between governments and non-governmental organisations are also necessary, both to engage local communities and to meet the specialised technical preparations and significant financing needs, so that the challenges of island restoration are met with a response of the requisite pace and scale.

Vespapp: citizen science to detect the invasive species *Vespa velutina*

M. del Mar Leza, A. Marqués, C. Herrera, M. Ángel Miranda, M. Ruiz, A. Pou and C. Guerrero

University of Balearic Island, Palma of Majorca, Balearic Island, Spain. <mar.leza@uib.es>

The yellow-legged hornet (*Vespa velutina*) is an Asian native species recorded across Europe, including mainland Spain, since 2004. Its first detection in Majorca (Balearic Islands; Spain) took place by researchers at the Laboratory of Zoology in collaboration with local beekeepers in October 2015. This invasive species has an important impact on biodiversity, apiculture and human health. Adult wasps are predators of bees, therefore contributing to the loss of honeybee colonies. For efficient actions to minimise the harms of the invasive species, early detections are crucial. Thus, civic collaboration may offer an important source of information to determine the presence and distribution of *V. velutina.* Current technological advances offer the opportunity for citizens to become active participants of the scientific research (citizen science). Vespapp is a software, either as a cell phone app or a website, which aims to identify any suspicious observation (hornets and nests) by sending a picture to a global database. The received information is subsequently confirmed or discarded by an expert panel. In case of a positive identification, an action protocol is implemented including the placement of traps, nest removal and monitoring the area. Since the Vespapp launch in June of 2016, the app has been downloaded 1436 times, has received more than 450 photos and 31 of them have been positive in the Balearic Island and the Iberian Peninsula. These results have enabled detection and removal of a total of nine nests during 2016, which is of great importance in controlling the expansion of the *V. velutina* considering the early stage of invasion in the Balearic Islands.

Wild ginger, a beautiful menace to island ecosystems – can a natural solution be found?

D. Djeddour, N. Maczey and C. Pratt

CABI Bakeham Lane, Egham, Surrey TW20 9TY, UK. <d.djeddour@cabi.org>

Kahili or wild ginger, (*Hedychium gardnerianum* (Zingiberaceae)) poses a serious threat to many unique island ecosystems worldwide including: the Federated States of Micronesia, Cook Islands, French Polynesia, Hawaii, New Zealand, La Réunion, the Macaronesian Archipelago and Jamaica. Introduced from the foothills of the Himalayas for its ornamental/commercial value, kahili has escaped cultivation and to become an aggressive coloniser in its introduced, sub-tropical range. Adaptable to a wide range of habitats, from native wetlands and riparian areas through to forest understorey, road verges and scrubland, wild ginger forms large, herbaceous, shade tolerant monocultures which outcompete native vegetation. It has the potential to prevent regeneration of native forests and cause wide scale ecosystem collapse and biodiversity loss. Wild ginger forms deep rhizome beds, reproduces vegetatively as well as through seed and is spreading unchecked across extensive and rugged terrain, which make chemical and mechanical control largely ineffectual. Classical biological control is widely believed to be the only long-term solution for this intractable invader. A biocontrol initiative for kahili ginger was initiated by CABI in 2008 for Hawaiian and New Zealand stakeholders. Surveys in the native range identified a number of damaging and limiting natural enemies which continue to be evaluated for specificity in the UK. The progress, prioritised agents and future prospects are further described.

Is poisoning rodents a health hazard?

J. Doube

SAAS-MedSTAR, SA Health (and Australian Antarctic Division), 5 Taylors Lane,
Strathalbyn, SA 5255, Australia. <james.doube@sa.gov.au>

As large-scale island eradication projects expand, it is inevitable that aerial baiting will occur on inhabited islands. However, when anticoagulant bait is to be spread all around living areas, community concerns about the safety of such projects are likely and understandable. Health monitoring of bait handling personnel on the largest island aerial baiting projects (including Macquarie Island and South Georgia), has shown no significant poisoning. Given the exposure of these individuals is orders of magnitude beyond that of community members, such monitoring can provide reassurance to far less exposed individuals. Additionally, lessons can be learnt on how to manage the community perceptions of these issues for critical conservation projects.

When our enemy is our friend: new approaches to managing alien vegetation in Seychelles catchment forest

K. Fleischmann, S. Massy, M. Schmutz, B. Seraphine and J. Millett

University of Seychelles, P.O. Box 1348, Anse Royale, Mahé, Seychelles. <kfleisch@bluewin.ch>

Invasive alien plants are one of the major causes of biodiversity loss with impacts on ecosystems such as alterations of biogeochemical and hydrological cycles. The Seychelles' forest is dominated by non-native vegetation arising from plantation agriculture often referred to as novel ecosystems. Under some circumstances native vegetation shows signs of recovery, particularly in low light conditions that occur under a forest canopy dominated by exotic species. Conversely, high light conditions arising from forest disturbance benefit invasive exotic species especially vines such as *Merremia peltata* which outcompete native vegetation. The Ecosystem Based Adaptation in the Seychelles project aims to enhance water-catchment management formulating recommendations for vegetation rehabilitation and establishing post-rehabilitation monitoring. The project will rehabilitate 600 ha of forest, an ambitious target that requires forestry management capacity development, policy development and community support to ensure long-term protection and management of catchment forest. Catchment vegetation quality was assessed using plant endemism, species diversity and forest rejuvenation indices. Sampling was conducted by transects and permanent monitoring plots in 10 intensive monitoring sites in water catchments. The project also deployed drone monitoring and light level monitoring using images taken with a fish eye lens. Rehabilitation has been implemented first on sites with high vegetation quality indices where management is expected to assist natural regeneration. Management has focused on removal of exotic saplings and under-canopy shrubs leaving a forest canopy dominated by exotic species including *Tabebuia pallida* and *Falcataria moluccana* intact. This counterintuitive approach is expected to maintain the shade conditions and the microclimate that will benefit native species over non-native species and facilitate the regeneration of palm dominated native forest. Initial indications are that closed canopy forest rehabilitation and community supported protection of forests from disturbance are important management measures for these novel ecosystems and hence for water catchments.

Eleonora's falcon (*Falco eleonorae*) benefiting from cat eradication – the case of Andros, Greece

J. Fric, T. Dimalexis, V. Goritsas, A. Evangelidis and I. Nikolaou

Nature Conservation Consultants Ltd., Chalandri, GR-15231 Greece. <jakobfric@n2c.gr>

Three colonies of Eleonora's falcon (*Falco eleonorae*) on the island of Andros (Cyclades, Greece) have been monitored since 2006. On two of these colonies, presence of rats has been recorded at least since 2006, while the third colony was invaded by rats in 2011. The latter provided a unique situation to study the short-term impacts of rats on the breeding performance of the Eleonora's falcon. On the newly rat-infested islet within a single year the number of active nests, the breeding success and the total number of fledglings were reduced by 47%, 23% and 58% respectively. Rat eradication operations were successfully carried out on all three islets in 2012 and 2014. At all colonies the breeding performance improved immediately. At the colony where rats were present for only one breeding season (2011), all breeding parameters recovered to pre-invasion levels within the rat eradication year. In all colonies, vegetation degradation resulting from rat foraging had consequently led to lower nesting site quality for falcons. Therefore, rat eradications were followed by construction of artificial nests which further improved the breeding habitat. In the years following the eradications 14–25% of active nests were artificial and the breeding success in artificial nests was in general higher than in natural nests. The rat eradication operations in combination with the construction of artificial nests on the islets of Andros indicate the benefits of these management measures on the breeding performance of the Eleonora's falcon and highlight the importance of immediate response to rat infestation. The conservation measures were implemented as part of the LIFE Nature project ANDROSSPA (LIFE10 NAT/GR/000637).

A review of 12 years of rat eradication operations for the conservation of priority island nesting birds in Greece

J. Fric and A. Evangelidis

Nature Conservation Consultants Ltd., Chalandri, GR-15231, Greece. <jakobfric@n2c.gr>

Since 2005, rat eradication operations have been carried out on a total of 41 uninhabited islets and islands in the Aegean Sea in Greece ranging in size from less than 1 ha up to almost 300 ha with the total area exceeding 1,050 ha. The initial eradication methodology was developed with the support of the Royal Society for the Protection of Birds and further optimised through implementation of consecutive eradication operations. The operations were carried out on 16 different groups of islets and islands with the aim of improving the breeding habitat of a significant proportion of island nesting bird species of conservation concern, including Eleonora's falcon (*Falco eleonorae*), Mediterranean shag (*Phalacrocorax aristotelis desmarestii*), Audouin's gull (*Larus audouinii*), yelkouan shearwater (*Puffinus yelkouan*), Scopoli's shearwater (*Calonectris diomedea diomedea*) and European storm-petrel (*Hydrobates pelagicus*). While the most recent eradication operations are still underway, previous operations have successfully removed all rats, eliminating egg and chick predation, as well as, degradation of bird nesting habitats. All rat eradication operations were carried out using brodifacoum-based bait, deployed mainly through placement of bait stations in association with hand broadcast. No significant negative impacts on non-target species due to baiting have been recorded. All rat eradication operations have been carried out through six different LIFE projects co-financed by the European Commission.

Improving nesting habitats for the Eleonora's falcon and seabirds

J. Fric, A. Evangelidis, T. Dimalexis, N. Tsiopelas, S. Xirouchakis, C. Kassara and S. Giokas

Nature Conservation Consultants Ltd., Chalandri, GR-15231 Greece. <jakobfric@n2c.gr>

Rat invasion is considered a major environmental issue regarding the Aegean islands (Greece), which are characterised by a rich biodiversity of faunistic and floristic taxa of high conservation concern. One of the most emblematic bird species at national level, Eleonora's falcon (*Falco eleonorae*), is severely affected by rat invasion. The Aegean islands constitute the core of its breeding range, holding more than 80% of the species' breeding population. In the framework of the LIFE Nature project "LIFE ElClimA" (LIFE13 NAT/GR/000909), rat eradication operations take place at two uninhabited island complexes, hosting approximately 6% of the species' national population, as well as important colonies of other priority seabird species that are also affected by rat predation, namely the yelkouan shearwater (*Puffinus yelkouan*) and Scopoli's shearwater (*Calonecrtis diomedea*). Removing rats from a total area of 705 ha is the largest rat eradication operation ever attempted in the country. Rodenticide baits have been primarily deployed in bait stations to minimise primary poisoning risk to non-target species, e.g. partridges (*Alectoris chukar*) and rabbits (*Oryctolagus cuniculus*), as well as their predators such as Bonelli's eagles (*Aquila fasciata*) and long-legged buzzards (*Buteo rufinus*), which could be deprived of their food source. After several months of regular baiting, bait consumption is minimal and the eradication operations are considered to be at their final stage. Close cooperation with regional and local stakeholders throughout the field operations aims to ensure optimal involvement of local communities and authorities as well as minimal risk of future rat reinvasion. The rat eradication operations implemented in the framework of the current project are expected to contribute to the preservation of the high ecological value of the two island complexes in general and, in particular, to the improvement of the nesting habitat and conservation status of important bird species in the area.

Broadening the context of invasive species eradications

P. Genovesi

ISPRA and IUCN SSC ISSG, Via V. Brancati 48, Rome, ROMA 00144, Italy. <piero.genovesi@isprambiente.it>

Our ability to eradicate harmful organisms has greatly progressed in the last decades, and available information shows that currently this management tool not only is one of the most effective conservation weapons, but also that it permits protection of human livelihood. In conservation we tend to refer to eradications as the total and permanent removal of an invasive species' population by means of a time-limited campaign; this term is more often used for eradications carried out on islands, where some general rules apply, such as that all individuals need to be vulnerable to the removal methods, and that there should be no risk of reinvasions. However, there is a growing number of interventions that go beyond this definition. Eradications can now target multiple species, and campaigns carried out in densely inhabited regions need to address significant risks of reinvasions through long term surveillance and rapid response efforts. Furthermore, there have been eradications carried out at much larger scales than small islands, such as those implemented for human or animal health purposes (e.g. smallpox or the rinderpest virus eradicated from the globe), or of eradications in mainland areas, requiring complex geographical planning, and that may set context specific objectives such as management to zero density in key areas through permanent control efforts. To fully exploit the potential of invasive species control for conservation, it is important to adapt the lessons learnt in islands eradications, rethinking the paradigms of this conservation tool to the new challenges that need to be met, as also highlighted by the Honolulu Challenge on Invasive Alien Species adopted in 2016. The New Zealand Predator Free 2050 campaign, planning to eradicate several key invasives at an unprecedented scale, is indeed a milestone in this direction, providing a basis for broadening the global vision of invasive species management.

Recovery of Santa Luzia Nature Reserve and translocation of the globally endangered Raso lark

P. Geraldes, T. Melo, P. Oliveira and V. Paiva

Marine Program, Sociedade Portuguesa Estudo das Aves, Av Columbano Bordalo Pinheiro, 87, 3º, Lisbon, 1070-062 Portugal. <pedro.geraldes@spea.pt>

The inhabited island of Santa Luzia is a priority KBA located in Cabo Verde. It holds the entire world population of the Critically Endangered Raso lark (*Alauda razae*) and the most important colony of Cabo Verde shearwater (*Calonectris edwardsii*). Since 2013 SPEA, Biosfera1 and RSPB have developed a feasibility study for habitat recovery of Santa Luzia, including an operational plan for cat (*Felis catus*) eradication and several baseline studies on the local species, both native and alien. The current project aims to translocate part of the population of Raso larks to the nearby island to increase the resilience of the population to long periods of droughts that have been increasing with global climatic changes. The feral cat population, estimated at 126 animals (95% CI 87.5 – 189) individuals, has strong negative impacts on several species of fauna on the island and will have to be removed to increase the chances of success of the re-introduction of Raso larks. Mice (*Mus musculus*) are also present, but at very low densities. Abundance index was calculated throughout the year and peaked at 0.06 and 0.067 captures/trap/night in February and March respectively (mean abundance index throughout the year 0.026). Recent data on the cat diet shows high levels of reptile predation and was found to change markedly depending on annual conditions. In 2010 mice were 79.6% of prey species identified in cat diet, while in 2013 and 2014 cats preyed mostly upon reptiles (91.67% of scats and >70% of prey item biomass). The project will rely strongly on local staff and will involve local communities in order to build local capacity and to increase awareness of the problems caused by IAS on islands. We aim to achieve sustainable protection of the habitats and threatened biodiversity of Raso, Branco and Santa Luzia marine protected areas.

Setting-up a predator-free area on a Macaronesian island using a pest-proof fence

P. Geraldes, T. Pipa, N. Oliveira, C. Silva and S. Hervías

Marine Program, Sociedade Portuguesa Estudo das Aves, Av Columbano Bordalo Pinheiro, 87, 3º, Lisbon, 1070-062 Portugal. <pedro.geraldes@spea.pt>

The island of Corvo, with an area of 17.1 km^2, is the smallest, westernmost and least populated of the nine islands of the Azorean Archipelago; 41% of the island is classified as a Special Area for Conservation and Special Protection Area thus included in the Natura 2000 Network and classified as UNESCO's Biosphere Reserve. Azorean settlers brought a number of associated threats to the local fauna and flora, such as the introduction of invasive mammals (rats (*Rattus* spp.), mice (*Mus musculus*), cats (*Felis catus*), goats (*Capra hircus*) and sheep (*Ovis aries*)), which jeopardize the breeding populations of seabirds. The archipelago still remains of critical importance for the conservation of several petrel species, namely Cory's shearwater (*Calonectris borealis*), little shearwater (*Puffinus lherminieri*) and Madeiran storm-petrel (*Hydrobates castro*). From 2009 to 2012, with funds from the EU LIFE program, a 100% pest proof fence 800 m long was built on Corvo, Azores. This solution was adopted to create a safe nesting area of 3 ha for shearwaters and petrels breeding in the island and subject to high predator pressure from feral cats, dogs (*Canis familiaris*), black-rats (*Rattus rattus*) and mice. Following the closure of the area, all predators were removed and biosecurity procedures were adopted. The vegetation cover inside the fenced area was cleared of alien plants and native flora was abundantly replanted to recover the natural habitats. Acoustic and visual luring methods for prospecting seabirds were employed, and for three consecutive years small groups of juveniles Cory's shearwaters were translocated to the area. The fence withstood hurricane type winds and very frequent harsh weather conditions for long periods of time with minor maintenance necessary. After four years the fence demonstrated to be a feasible solution for adequate areas and the first breeding pairs of seabirds were recorded inside the area during the 2016 breeding season.

Green iguana (*Iguana iguana*) monitoring and control efforts on Grand Cayman

J. Haakonsson, F. Rivera-Milan and E. Radford

Cayman Islands Department of the Environment, Terrestrial Resources Unit, PO Box 10202, 580 North Sound Road, Grand Cayman KY1-1002,Cayman Islands. <jane.haakonsson@gov.ky>

Effective control management of invasive alien species (IAS) is limited by our understanding of population dynamics. Monitoring and modelling are essential components of control management. The green iguana (*Iguana iguana*) is overabundant on Grand Cayman (estimated density ± SE = 41.363 ± 16.813), and this can cause significant economic losses (e.g., damage to roads and agricultural crops), pose serious health and safety hazards (e.g., diseases and accidents), and trigger negative ecological interactions with endemics (e.g., hybridisation with the Sister Island rock iguana (*Cyclura nubila caymanensis*)). Therefore, control management is a priority for the Cayman Islands Department of the Environment (DOE). In this poster, we provide information about green iguana population surveys conducted on Grand Cayman in August 2014, 2015 and 2016. With the abundance estimates derived from these surveys, we conducted a model-based assessment of population response to sustained removal effort. Although the green iguana is exposed to human-induced mortality (e.g. hunting at private property, depredation by feral cats (*Felis catus*) and dogs (*Canis familiaris*), and road kills), the population increased at an annual rate of 60% between 2014 and 2015 and 98% between 2015 and 2016 (not including hatchlings). Herein, we present the results from experimental culls organised by the DOE in June 2016 in which 18,838 green iguanas were removed mainly from western Grand Cayman. Bounty hunter groups and skilled hunters under contract both averaged about 100 iguanas killed per day. Removal effort, technique used and crippling loss (i.e., shot but not retrieved) were among the variables quantified, which also included biological data to establish a baseline understanding of green iguana population dynamics and response to control management. Applying basic concepts of harvest theory and decision analysis, the DOE and USFWS are developing cost effective strategies going forward.

Predicting the potential habitat of the invasive coral vine (*Antigonon leptopus*) using remote sensing and species distribution modelling

E. Haber, M. Eppinga, M. Ferreira dos Santos, M. Rietkerk and M. Wassen

Copernicus Institute for Sustainable Development, Utrecht University, P.O. Box 80115, Utrecht, 3508 TC, The Netherlands. <e.a.haber@uu.nl>

The spread of invasive plant species often outpaces the capacity to manage the invasions. Remote sensing can be used to map the distribution of invasive plant species at a snapshot in time, but it is difficult to predict the future distribution without incorporating the habitat preferences of the invasive species. Habitat suitability modelling is predictive, but often suffers from an insufficient number of training points. In this study we combine vegetation classification models based on remotely sensed imagery with habitat suitability models to predict the potential distribution of an invasive vine, *Antigonon leptopus* (Polygonaceae), on two neighbouring Caribbean islands, St. Eustatius and Saba. A Support Vector Machines (SVM) classification was produced for two WorldView-2 images of St. Eustatius (images acquired on 8 February 2011 and 24 August 2014) to produce maps of presence/absence of the vine. Pixels from the SVM classifications where *A. leptopus* was present in both years were used as the dependent variable in the species distribution model for St. Eustatius. The independent variables tested for the species distribution model were slope, elevation, soil hardness, soil moisture, drainage area, distance to nearest building, and distance to nearest road. The results suggest that the potential for *A. leptopus* invasion can be readily assessed for other islands in the Lesser Antilles. We illustrate this potential for the neighbouring island of Saba, revealing that the expansion of *A. leptopus* may approach that of St. Eustatius if no preventive actions are taken.

The diet of 'Viking mice' on Nólsoy, Faroe Islands

S. Hammer and J. Russell

University of Glasgow, 3R 51 Taylors Lane, Dundee, DD2 1AP UK. <sjurdur@hotmail.com>

Burrowing seabirds can be very vulnerable to rodents. Although there is abundant evidence for the negative impact of rats, there is some recent evidence that mice (*Mus musculus*) can also have a detrimental effect on seabird populations. Introduced by Vikings, mice are the only rodent on Nólsoy in the Faroe Islands, which also hosts one the largest European storm-petrel colonies in the world. Using stomach dissections and stable isotope analysis we examined for evidence of storm petrel consumption (eggs or chicks) in mice on Nólsoy. The findings may have implications for rodent management on Nólsoy and other Ramsar sites in the Faroe Islands.

Seabird restoration and advances towards the eradication of feral cats on Guadalupe Island, Mexico

J.C. Hernández-Montoya, L. Luna-Mendoza, A. Aguirre-Muñoz, F. Méndez-Sánchez, A. Duarte-Canizales, E. Rojas-Mayoral, S. Hall, Z. Peña-Moreno, S. Figueroa-Flores, D. Cosio-Muriel and M. Latofski-Robles

Director de Proyecto Isla Guadalupe, Grupo de Ecología y Conservación de Islas, A.C., Moctezuma 836, Centro, Ensenada, Baja California 22800, Mexico. <julio.montoya@islas.org.mx>

Guadalupe Island (24,172 ha; 1,298 m) is located in the Pacific Ocean, 260 km off the Baja California Peninsula. It is inhabited (ca. 150 people) and is part of a Biosphere Reserve, managed by Mexico's National Commission for Natural Protected Areas (CONANP) in collaboration with Grupo de Ecología y Conservación de Islas, A.C, a professionalised Mexican NGO. Guadalupe has 223 vascular plant species (12% endemic), and hosts 139 taxa of birds, including seven endemic races, six of which are considered extinct. Goats (*Capra hircus*), cats (*Felis catus*) and house mice (*Mus musculus*) were introduced by the end of 19th century. Now a goat-free island, the feral cat is the most serious threat to biodiversity, especially to surface- and burrow-nesting birds. The island hosts the most important breeding colony of Laysan albatross (*Phoebastria immutabilis*) in the Eastern Pacific. Upon its colonisation in 1983, albatross adults and chicks have been subject to severe predation by feral cats. To protect the albatross population, since 2003 we have done cat control around the breeding area, now improved by the construction of a 700 m exclusion fence that protects 65 ha. Thanks to these efforts, the number of breeding pairs has increased exponentially, with more than 400 to date. With a long-term vision and the support from the National Fish and Wildlife Foundation (NFWF) and the Alliance WWF-Fundación Carlos Slim, as of March 2017 we have moved from cat control to eradication. Timeframe for the eradication campaign will be 4.5 years. The methods will involve hunting, trapping (leg-hold traps) and detection dogs. Since the island is inhabited, biosecurity measures are crucial since the eradication's start. The achievement of the eradication will benefit native and endemic seabirds and landbirds–especially those endangered–preventing their extinction.

From island studies to mainland management

S. Hudin

Natural Areas Conservancies Federation, 6 rue Jeanne d"Arc, Orléans, 45000 France.
<stephanie.hudin@reseau-cen.org>

Islands have been the first and foremost natural habitats impacted by alien invasive species. With some delay, mainland ecosystems are going through the same effects. Difficulties to manage and mitigate the effects of AI on indigenous species are even greater, and the task to define a strategy more complex, on the continent. The numerous studies and reports have helped taking the challenge up in some territories, and in France, it was decided to plan and organise efforts at the hydrological scale of the great river, the Loire. Since 2002, exchanges between on-field managers and stakeholders have permitted the creation of a network that has emerged as an example, as it edited a first interregional strategy of management of alien species. The flow of information, the common edition of documents and supports for the management were the first on the to-do list. Now, as Europe has announced its first 37-long list of priority species, the Loire working group is revising its third version of a prioritised list and editing a first mapping of more than 60 species. Most of these species came or were helped by the connected water system of the large river and its tributaries. As an interconnected habitat system within the continent, the Loire basin can be compared to an island and as such has a lot to inform the managers from the island alien invasives techniques used to eradicate the species. The creation of an atlas helps visualise which species should be targeted for such efforts, and where to start. So, the achievement of more than 15 years is only the start.

Differential effects of human impact and habitat type on exotic and native species diversity on oceanic islands

W. Jesse, J. Ellers, J. Behm and M. Helmus

Ecological Science - Animal Ecology, Vrije Universiteit Amsterdam, De Boelelaan 1085,
1081HV Amsterdam, The Netherlands. <w.a.m.jesse@vu.nl>

Human land use is considered one of the main drivers of species compositional change. While some species experience population decline as a result of human activities, others optimally exploit human-impacted environments. We hypothesised that such contrasting responses could in part be attributable to species' native or exotic origin. Our objective was to assess the effect of human impact, defined as the addition of man-made substrates, on the taxonomic and functional composition of exotic and native reptile assemblages of two anthropogenically impacted Caribbean islands. We extensively surveyed insular reptile communities and recorded species abundance and richness data. Functional traits were obtained from literature and used to construct functional diversity metrics for every sampled community. Of the composite environmental variation among 114 sample plots, 46% could be reduced onto two PCA axes, resulting in a habitat structure axis (29%) as well as a human impact axis (17%). PCA axes were subsequently regressed against various taxonomic and functional abundance and diversity indices. Habitat structure and human impact independently affect abundance and diversity indices across both islands. The direction of these effects largely depends on exotic or native origin. Exotic species are never found in forest habitat, whereas native abundances peak in tropical forest. Exotic abundances are primarily affected by human impact levels while native abundances show no significant association. Exotic species occur in higher numbers on St Martin, which is likely due to regional shipping intensity rather than within-island factors. Furthermore, on St Martin, exotic species significantly increase functional trait diversity by occupying unique functional niche space in impacted environments. However, we found no indication of environmental filtering of functional trait values as a result of human impact, rather habitat structural change seems to shift community trait values towards beneficial levels for survival in non-forested environments.

Genetic pest management technologies to control invasive rodents

D. Kanavy and D. Threadgill

Molecular and Cellular Medicine, Texas A&M University, Texas A&M Health Science Center,
Joe H. Reynolds Medical Bldg. Rm. 440, College State, TX 77840, USA. <kanavy@tamhsc.edu>

Many strategies exist to manage invasive pests on islands, ranging from poison to trapping, with varying degrees of success. Genetic technologies are increasingly being applied to insect pests, but so far, not to vertebrates. We are implementing a genetic strategy to eradicate invasive mouse populations as another tool for pest control. *Mus musculus*, the common house mouse, is one of the most widespread invasive species. Mice threaten human health, agriculture, and biodiversity on many islands, particularly seabirds. Seabirds are endangered indirectly through competition for resources or predators being attracted by the mice or directly with mice attacking chicks and eggs. Rodenticides are the most common method of eradicating mice, but their use leads to poisoning of non-target species and has limited efficacy against mice. An approach that could eliminate non-target species impact would be to engineer daughterless mice linked to a gene drive system for self-sustained propagation. For this project, we have investigated exploiting a naturally occurring gene drive, the t-complex. Using the t^{w2} haplotype of the t-complex, we observed the t^{w2} haplotype being transmitted to offspring with a transmission distortion ratio of 95.3%. The daughterless phenotype is being accomplished by inserting the *Sry* gene (male sex-determining gene) into an autosome containing the t^{w2} haplotype via CRISPR/Cas9 gene editing. The presence of *Sry* will induce testis formation, regardless of the sex chromosomes naturally inherited. When *Sry* is inserted into the t-complex, the desired gene will spread through the population, eliminating female offspring. This model system will support studies to evaluate the effectiveness of crashing an invasive population without adversely affecting other species. While still in the beginning stages, this is a novel idea and once this method has been perfected, it will open the way to use this genetic strategy for the eradication of other invasive mammal species.

A new look at Galapagos fouling communities

I. Keith, J. Carlton and G. Ruiz

Marine Biology, Charles Darwin Foundation, Av. Charles Darwin, Puerto Ayora, Santa Cruz, Galapagos Islands, Puerto Ayora, Ecuador. <inti.keith@fcdarwin.org.ec>

The maritime history of the Galapagos Islands begins in 1535 with the accidental discovery of the archipelago. For the past 500 years the islands have endured a significant amount of terrestrial plant and animal introductions and, to some extent, freshwater invasions; however, the number of marine introductions reported has been significantly lower. Research has been conducted looking at the fouling communities of the Galapagos Marine Reserve (GMR) to provide a clearer picture of the true scale of marine non-native species present in ports and harbours of the GMR. Settlement plates were deployed for three and 14 months on floating docks on the Islands of Santa Cruz and San Cristobal. As a result, numerous new records of introduced species of hydroids, polychaete worms, bryozoans, and ascidians, amongst other taxa, have been documented for the Galapagos. The continued increase of marine traffic from many sources to the Galapagos Islands concomitantly increases the risk of arrival of non-native species to this region. While research on terrestrial invasive species is well established, research on marine invasive species and their impacts in the GMR has been less investigated. The Charles Darwin Foundation (CDF), the Galapagos National Park Directorate (GNPD) and the Galapagos Biosecurity Agency (ABG) have been working together to improve the marine biosecurity standards for the GMR, and some clear advances are now in place. A synthesis of marine biosecurity based on prevention, early detection and management of marine non-native species is presented and potential management strategies discussed.

Planning processes for eradication of mice on Gough Island

J. Kelly, K. Springer, C. Stringer, A. Schofield and T. Glass

Species and Habitats, Royal Society for the Protection of Birds, RSPB, Headquarters, the Lodge, Sandy, Bedfordshire SG19 2DL, UK. <John.Kelly@rspb.org.uk>

Gough Island, part of the remote Tristan da Cunha group in the South Atlantic, is considered one of the most important seabird islands on the planet. A UK Overseas Territory and World Heritage Site, Gough supports millions of breeding seabirds and the UK's only Critically Endangered bird species, the Tristan albatross and Gough bunting. Invasive house mice (*Mus musculus*) were introduced in the 1800s and prey on hundreds of thousands of chicks each year. It has been predicted that the Tristan albatross faces extinction within c. 30 years unless the mice are eradicated. Led by the RSPB and the Government of Tristan da Cunha, the Gough Island Restoration Programme aims to eradicate mice from Gough Island using aerial baiting containing anticoagulant toxin; a methodology established during previous island eradications. Now in the operational planning phase, the programme aims for mouse eradication on Gough in 2019. Applications for various approvals are required and a captive bird management programme designed to protect land birds vulnerable to secondary poisoning. As well, robust operational planning and detailed logistical planning need to be completed. Situated around 2,800 km from Cape Town, South Africa, Gough Island presents challenges including its remoteness, terrain, weather and cave systems. Long lead in times for planning are required, reflecting the scale and complexity of logistics and regulatory requirements.

Perils of saving the smallest for the last: lessons learnt about sequencing eradications on Santa Cruz Island, CA

J. Knapp, C. Boser, J. Randall, E. O'Byrne and S.A. Morrison

The Nature Conservancy, 532 E. Main Street, Suite 200, Ventura, California, USA. <jknapp@tnc.org>

The biota of many islands have been damaged by invasive species, but in a growing number of cases island invaders have been successfully eradicated. Many eradication projects target vertebrate species whose size and harmful effects make them particularly conspicuous. Unfortunately, smaller and less conspicuous invaders, including invertebrates and plants, may be overlooked before or following successful eradications, and their continued presence can limit the attainment of some of the management goals that may have motivated the earlier eradications. For example, vegetation recovery that often follows removal of herbivores can make eradication of remaining invaders more difficult. Vertebrate eradications can result in the release of perceived "secondary" invaders, which can compromise the benefits of the initial eradication. We review the suite of eradications that have occurred or are underway on Santa Cruz Island, USA, which have focused on plant, invertebrate, avian, and mammalian taxa. We discuss the biological impacts of – including the long-term management challenges created by – decisions regarding which taxa were eradicated when. We recommend that prior to undertaking any eradication all invasive species and the resources they threaten be evaluated with regard to how the sequence of eradications may positively or negatively affect any eradication efforts that may follow.

Citizens' attitude towards the removal of grey squirrels in Italy: what support do we need?

V. La Morgia, D. Paoloni, P. Aragno and P. Genovesi

Institute for Environmental Protection and Research – ISPRA, Ozzano Emilia (BO), Via Ca" Fornacetta 9, Ozzano Emilia (BO), 40064 Italy. <valentina.lamorgia@isprambiente.it>

Grey squirrels (*Sciurus carolinensis*) were introduced in Umbria, Central Italy, in 2000. Since then, they have successfully occupied a range of about 50 km^2. The LIFE U-SAVEREDS Project now aims to eradicate this isolated population, but the squirrel distribution is centred on the city of Perugia and animals are particularly abundant in public urban parks and private house gardens. Thus, part of the public opinion opposes the project activities. For this reason, the overall management strategy involves both direct (capture and euthanasia) and indirect (capture and surgical sterilisation) removal of the animals. Further, a Decision Support System including the evaluation of social issues was specifically developed. It identified spatial intervention priorities and it allowed the start-up of grey squirrel management in areas where the overall social context was favourable. At the same time, we implemented a targeted information campaign to increase the population's knowledge on the issue of invasive alien species and, most important, to actively involve citizens in the Project. As a consequence, several citizens agreed to collaborate on the eradication campaign. Following the intervention in different management units, characterised by a different acceptance level of the eradication campaign, we now evaluate how the citizens' collaboration affected the outcome of Project activities. The percentage of accessible land (ranging from 84 to 21%) for each management unit was quantified through mapping and modelling in GIS environment, and was compared to the outcome of direct removal of the animals. In 2016, 470 animals were removed, and preliminary results suggest that the spatial configuration of accessible lands also plays an important role in the eradication. Considering both social and technical issues, simulations were finally implemented to assess the success probability of the eradication campaign at local scales.

Computer modelling of complex interstitial spaces to protect endemic island lizards from invasive mice

Z. Lennon, H. Wittmer and N. Nelson

School of Biological Sciences, Victoria University Wellington, Wellington, New Zealand. <zoe.lennon@vuw.ac.nz>

New Zealand is home to a large diversity of endemic lizards, with 42 gecko (Diplodactylidae) and 55 skink (Scincidae) taxa, ~ 84% of which are classified as Threatened or At Risk. Habitat destruction and invasive mammalian predators are responsible for much of this decline. Endemic lizard species are afforded legal protection in New Zealand, meaning that when populations are threatened by human activity such as road construction, individual animals must be salvaged and moved to a safe location (mitigation translocation). Mitigation translocations of lizards in New Zealand often involve habitat enhancement, for instance building new rock pile habitat. However, there is little research to show if habitat enhancement actually has the intended effect of providing better habitat for lizards, or if there might be undesirable side effects such as creating habitat for invasive predators like mice (*Mus musculus*). I describe a novel technique using a computer game physics engine (Unity, PhysX) to investigate the best rock pile design to protect translocated skinks while hindering the movement of mice. I achieve this by measuring the interstitial spaces in virtual rock piles to determine which compositions (sizes, shapes of constituent rocks) will maximise spaces skinks are able to fit through while minimising spaces mice are able to fit through, enabling skinks to avoid predation by mice. My virtual approach to this problem allows me to model complex spaces which were unable to be measured using previous, physical techniques. Predictions from modelling are confirmed using data from computed tomography (CT) scans of real rock piles. The design that results from this research will be tested in a real mitigation translocation to determine whether skinks have higher survival in my rock pile designs. This research will inform understanding of invasive predator/prey interactions and conservation of species threatened by invasive mammals.

An integrated physical control method on *Spartina alterniflora*

J. Li, C. Zhao and X. Zhao

Chinese Research Academy of Environmental Sciences, Beijing, China. <lijsh@craes.org.cn>

Spartina alterniflora is a noxious invasive plant due to its ecological impact. An integrated method of mowing plus shading (MS) was conducted for control of *Spartina alterniflora* in Guangxi, China. Plant height, node number, node length, basal stem diameter, aboveground biomass and population density of this weed were used to compare the effectiveness of mowing and MS. Results showed that all characters of *S. alterniflora* were significantly decreased by mowing plus shading ($P<0.\ 05$), and only node number, plant height and aboveground biomass were suppressed by mowing alone. It was indicated that clonal growth and sexual reproduction of *S. alterniflora* were absolutely inhibited by mowing plus shading in the whole growth season. We also found the restraining effect of mowing plus shading was positively correlated with shading degree. The light transmittances of single layer shading net, double layers shading net and triple layers shading net were 15.27%, 2.29% and 0.31%, respectively, and rhizome survival rate were 3.68%, 2.09% and 1.70% in November respectively. Above-ground parts were all dead in November before mowing plus single layer shading treatment, while they were all dead at July in mowing plus double layers shading treatment and mowing plus triple layers shading treatment. In the future, mowing plus shading may be used as an effective method of controlling *S. alterniflora*.

Predicting the risk of plant invasion on islands: the case of *Miconia calvescens* in the Marquesas, French Polynesia (South Pacific)

M. Libeau, R. Pouteau, R. Taputuarai and J.-Y. Meyer

Délégation à la Recherche, Government of French Polynesia, B.P. 20981, 98713 Papeete, Tahiti, French Polynesia. <mel.libeau@gmail.com>

Miconia calvescens (Melastomataceae), a small tree native to Central and South American rainforests, is a dominant plant invader in the Society Islands (French Polynesia), Hawaii, New Caledonia, and tropical Australia, thus listed as one of the world's 100 worst invasive species. This fast growing, early reproducing and prolific seed producer (small fleshy fruits dispersed by birds over long distances) with a long-lasting soil seed bank (several decades) was first detected 20 years ago in the Marquesas (French Polynesia), a remote archipelago with a unique and endangered native flora (48% of endemism and 145 threatened species). Despite some eradication efforts, several new outbreaks have been located in the last few years on the largest island of Nuku Hiva. In this alarming context, it is urgently needed to determine the potential distribution of the species in order to assess the risk of invasion and refine the areas for further surveys and control. Species distribution models (SDMs) are numerical tools that project species distribution from the combination of species occurrences with environmental variables. Fitting an SDM on the basis of Marquesas populations to predict the future of *Miconia* over the archipelago would violate the equilibrium assumption behind SDMs. Moreover, projecting the environmental envelope occupied by the species in its native range would ignore inherent characteristics of island ecosystems (e.g. low species richness, low functional redundancy, competitive release, vacant niches, restricted and specialised habitats) that leave them much more vulnerable than continents to biological invasions. As a result, the environmental distribution of *Miconia* across the similarly-sized high-elevation islands of the Society and the Hawaiian archipelagos was projected over the Marquesas. The different SDMs agree that *Miconia* will spread over a large area of native lowland rainforest and montane cloud forest in Nuku Hiva unless appropriate control strategies are rapidly adopted.

The secret life in Switzerland of an island pest, the house mouse

A. Lindholm and B. König

Department of Evolutionary Biology and Environmental Studies, University of Zurich, Winterthurerstrasse 190 CH-8057 Zurich, Switzerland. <anna.lindholm@ieu.uzh.ch>

House mice (*Mus musculus*) can have harmful effects on island biota, and are frequently the targets of eradication efforts. The success of eradication strategies will be influenced by how well the biology of the house mouse is understood. We have carried out a long-term study of a free-living population of wild house mice in Switzerland, following mice in the population from cradle to grave (or disappearance). Adult mice are chipped and a system of antennas installed at the entrances to nests have allowed us to monitor the movements of house mice and observe their social lives in unprecedented detail. House mice live in large but fairly closed social groups of males and females, sharing several nests. Competition between males and between females has led to dramatic reproductive skews in both sexes and high rates of infanticide, despite *ad libitum* food availability. Multiple paternity within litters is common. Cooperation between breeding females within a social group also occurs, in communal nursing of all pups present in the same nest. Population density has increased over time, giving rise to larger group sizes. How this increase in social tolerance is achieved is unclear. Furthermore, population size recovered rapidly from an epidemic that killed ca 30% of adults. We are currently focused on understanding factors influencing reproductive suppression, dispersal likelihood, social tolerance and cooperation between females, including genetic influences, such as the t haplotype. Our studies may be useful in predicting the outcome of interventions to house mouse populations.

Catalysing conservation of islands through collaboration: a North American perspective

A. Little, A. Aguirre-Muñoz, G. Seutin, L. Wein, P. Nantel, H. Berlanga, F. Méndez-Sánchez, J. Putnam, E. Iñigo-Elías and G. Howald

U.S. Fish and Wildlife Service, 1901 Spinnaker Drive, Ventura, CA 93001, USA. <annie_little@fws.gov>

The countries of North America are inextricably linked through shared species, habitats, and ecosystems. Over the last several decades, significant efforts have been made to protect and restore unique island ecosystems within the three nations. Many of the significant advances have been through bi and trilateral collaboration. In recognition of the value of cross border collaboration, in 2014, the governments of Canada, United States and Mexico signed an agreement to protect fragile island ecosystems and their imperilled species. This agreement, endorsed under the scope of the Trilateral Committee for Wildlife and Ecosystem Conservation and Management, strengthens the on-going collaboration between the three nations on the conservation and restoration of island ecosystems and their adjacent coastal and marine environments. Through coordinated efforts, government and NGO partners are accelerating investment in island conservation programmes across North America with a focus on invasive species, biosecurity, restoration, and regulatory processes. Activities include prioritisation of invasive species on a continental scale, sharing of expertise and technology, strengthening institutional capacities, and leveraging (shared) funding and support. These partnerships have accelerated conservation outcomes across North America, including the eradication of invasive species in Canada, protection of rare species and ecosystems in the United States, and a systematic and comprehensive programme to conserve and restore islands in Mexico.

The value of monitoring and the price of uncertainty in the management of an invasive population

E. McHenry, X. Lambin, T. Cornulier and D. Elston

School of Biological Sciences, Zoology Building, University of Aberdeen, Tillydrone Ave, Aberdeen, UK. <*ewan.mchenry@abdn.ac.uk*>

Improving decision-making regarding resource allocation for the control of invasive populations often requires monitoring to obtain information on the state of the population. The cost incurred by monitoring detracts from the resources available for direct control, and so, for monitoring to be feasible, the information gained must have greater value to management than the costs of obtaining it. We aim to provide generalisable recommendations on the use of monitoring data to inform the management of invasive species. Here we present a simulation study inspired by the control of invasive American mink in Scotland. Mink populations exhibit seasonal dynamics with highly dispersive juvenile and intrasexually territorial adult life stages. Control effort was simulated to be dependent on season and perceived variation in the abundance of settled adults. Imperfect monitoring can result in false positive or negative detections of adults, allowing the value of reducing uncertainty by increasing monitoring effort to be explicitly considered in terms of its impact on the invasive population and unplanned overspending of effort budgets. The modelling framework allows the relative value of monitoring effort to be assessed for different control strategies. Future work will utilise large-scale mink control data and surveys of a threatened endemic prey species, the water vole, to estimate the level of mink control required for a high probability of persistence of water vole metapopulations. This will inform future simulation work identifying the balances between monitoring and intervention that maximise the probability of favourable conservation outcomes for fixed cost.

Invasive arthropods of ecological, agricultural and health importance recently introduced in the Balearic Islands (Spain)

M. A. Miranda, C. Barceló, D. Borràs, A. González, M. Leza and C. Paredes-Esquivel

Biology, University of the Balearic Islands, Cra. Valldemossa km 7,5, Palma de Mallorca, Balearic Islands 07122 Spain. <ma.miranda@uib.es>

The Balearic Islands archipelago (Mallorca, Menorca, Ibiza and Formentera) is located in the western part of the Mediterranean Sea. Like other places in the area, the Balearic Islands are exposed to the introduction of several highly invasive species, some of them even world-wide distributed. In fact, the Balearic Islands have a long record of introduced species including different taxa of animals. Here we focus on those invasive arthropod species that were introduced during the last decade and have high impact on ecosystems, agriculture and human health. We present a description of the current situation of the incursion, spread and impact of the tomato leafminer (*Tuta absoluta*, Gelechiidae); the red palm weevil (*Rhynchophorus ferrugineus*, Curculionidae); the Asian tiger mosquito (*Aedes albopictus*, Culicidae) and the Asian hornet (*Vespa velutina*, Vespidae). We conducted an analysis of the path of entry of the different species to the Balearic Islands, considering means of transport including commodities and human transportation. We also analysed the current impact of the presence of the above-mentioned species on agriculture (i.e. increase use of insecticides), landscape (i.e. palm trees destruction), human health (i.e. vector-borne diseases) and ecosystems (i.e. impact on bee population). Results indicate that some invasive species, such as *T. absoluta* could be effectively managed by farmers after a period of adaptation of control procedures to the new pest. The impact on landscape by species such as the red palm weevil has notably increased since its introduction and its expansion is currently uncontrolled. Species such as the Asian tiger mosquito have changed the perception of citizens on the risk of vector-borne diseases, due to the current expansion and its possible implication on arbovirus transmission. Finally, the recent detection of the Asian hornet, has deeply increased concern about the role of bees as an essential component of ecosystems.

Using key-informant surveys to reliably and rapidly estimate the distributions of multiple insular invasive species

N.P. Mohanty, G.J. Measey, A. Sachin, G. Selvaraj and K. Vasudevan

Centre of Excellence for Invasion Biology, Department of Botany and Zoology, Stellenbosch University, Stellenbosch, South Africa. <nitya.mohanty@gmail.com>

Knowledge of invasive species' distributions is critical to manage established populations. Distribution at large spatial scales can be rapidly estimated through public surveys, though reliability of such information must be tested. We gathered detection/non-detection data for the Indian bullfrog (*Hoplobatrachus tigerinus*), the common myna (*Acridotheres tristis*), the house sparrow (*Passer domesticus*), and the giant African snail (*Achatina fulica*) through interviews in 91 sites on inhabited islands of the Andaman Archipelago. We interviewed 855 key informants comprising farmers, plantation workers, and aquaculturists, from January to March and September to December 2015. Additionally, we obtained detection/non-detection data for the Indian bullfrog (75 sites), the common myna (65 sites), the house sparrow (39 sites), and the giant African snail (29 sites) through systematic visual encounter surveys and opportunistic records. We corrected the informant data for false positive detections in an occupancy framework and estimated the distribution of the four species. The Indian bullfrog occurred on all islands, except Baratang, Long, and Little Andaman Islands. The giant African snail was ubiquitous, occurring on all islands. The distribution of the common myna was most likely influenced by roads, while ports might be significant for the house sparrow invasion. The findings substantiate the efficacy of public surveys in generating rapid distribution information on multiple invasive species simultaneously.

Time germination response to temperature and light conditions in *Ulex*

Z. Negrín Pérez, D. Da Re, M. Bernardos and B. Garrido

La Laguna University, San Cristóbal de La Laguna, Tenerife, Canary Islands, Spain. <znegrinp@ull.es>

The Canary Islands are widely recognised as an outstanding biodiversity hotspot worldwide. Biological invasion, together with wildfire, are two of the main factors of biodiversity loss in the islands, due to low habitat diversity, their simplified trophic webs and the high rates of endemism. *Ulex europaeus* is an invasive species, which is in the early period of its naturalisation, but it is already affecting two of the richest ecosystems of the island: laurel and pine forests. Previous studies were focused on shade and post-fire conditions as key factors in the growth of young plants, while less attention was oriented to factors linked to seeds germination. The goals of this study are to understand the role of light exposure and temperature shocks in *U. europaeus* germination, and to highlight the optimal conditions. In this study, seeds experienced three different light exposures (total darkness, 70% shade and full light) with eight different temperature ranges (from 30º to 130º C). Then seeds were exposed to temperature shocks for 1, 5 and 10 minutes. The results of DCA and standard statistical analysis show that light exposure has a low relationship with seed germination. Significant differences were found between temperature and time germination: a short exposure to temperatures between 40º to 70 ºC has a positive effect on the germination of *U. europaeus*, although higher temperatures inhibit germination. These results enable a greater understanding of the relationships of *U. europaeus* and environmental conditions of fire zones, but further studies that take into consideration the role of litter and ashes are needed also.

Rat eradication from Berlengas Island, Portugal

N. Oliveira, P. Geraldes, I. Fagundes, P. Oliveira and J. Andrade

Marine Conservation Department, Sociedade Portuguesa Estudo das Aves, Av Columbano Bordalo Pinheiro, 87, 3º, Lisbon, 1070-062 Portugal. <nuno.oliveira@spea.pt>

The Berlengas Archipelago, six miles off the coast of Portugal, is composed of a main island of 95 ha and five small islets. It holds the only colony of Cory's shearwaters (*Calonectris borealis*) on continental Portugal, and the largest Portuguese colonies of shag (*Phalacrocorax aristotelis*) and yellow-legged gull (*Larus michaellis*). A breeding population of Madeiran storm-petrel (*Hydrobates castro*) of unknown size also breeds on the nearby islets. The native vegetation includes three endemic species of conservation concern. The presence of IAS in Berlengas (black rat, *Rattus rattus*) is considered to have a significant impact on several seabird species and on the island vegetation. It is also thought to prevent colonisation of the main island by prospecting Madeiran storm-petrels that are often recorded there. Within the scope of an EU funded LIFE programme, a full rat eradication started in 2014, and is still underway, to restore the local ecosystem. A grid of 1,000 closed baiting stations (25 m x 25 m) was used with cereal pellets containing the anticoagulant brodifacoum. Special care was taken to prevent secondary poisoning of non-target species, and a full assessment of the invasive alien species populations was made before any control action started. Species abundance, local distribution, inter-annual abundance variation, and genetic characterisation was determined prior to the baiting operations that started on September 2016. The last confirmed rat sign was registered at the end of October during the weekly monitoring surveys. After December 2016, the remaining toxic baits were removed from the baiting stations and non-toxic scented baits were used to detect any remaining signs of rat activity. The operational phase is expected to last at least two years after the first baiting station was set and we expect that after the eradication the subsequent recovery by seabirds and native plants will make a substantial conservation contribution at European level.

Response of an open feral cat population to an intensive control programme for improving the critically endangered Fatu Hiva monarch conservation strategy

P. Palmas, R. Gouyet, T. Ghestemme, A. Matohi, E. Terorohauepa, I. Tauapaohu, C. Blanvillain, J. Zito, D. Beaune and E. Vidal

Institut Méditerranéen de Biodiversité et d'Ecologie marine et continentale (IMBE), Aix Marseille Université, CNRS, IRD, Avignon Université, Centre IRD de Nouméa, BPA5, 98848 Nouméa cedex, Nouvelle-Ca, Nouméa, New Caledonia. <palmas.pauline@gmail.com>

The Fatu Hiva monarch (*Pomarea whitneyi*) is an endemic terrestrial bird of Fatu Hiva Island (Marquesas, French Polynesia) red-listed by IUCN as Critically Endangered since 2000. Recent decline of the remaining populations is particularly alarming with 30 individuals currently remaining while 275 were still present 10 years ago. Introduced predators have been identified as the main cause of extirpation, especially ship rat (*Rattus rattus*), introduced in the 1980s and feral cats (*Felis catus*) that reatly impact the remaining population at all bird demographic stages (chicks at nest, fledging chicks, and adults). An intensive feral cat culling programme has therefore been progressively implemented over the past five years by SOP-Manu (Birdlife representative in FP) on a 290 ha controlled area to secure part of the Fatu Hiva monarch population. By using data from 43,845 trap-nights and > 189,000 camera-trap images we evaluated the effects of this intensive cat control on feral cat abundance in the treated area (three different indices: abundance index, minimum number of individuals and individual capture histories using the spatially explicit capture–recapture (SECR) model to calculate densities). In parallel, we fitted cats with GPS collars to (i) understand the recolonisation process from the untreated adjacent areas and (ii) assess the risk due to domestic and stray cats from the nearby village. These results will help to refine and optimise feral cat control strategy in this large, mountainous and inhabited island where eradication could be considered, although difficult. The protected and treated area includes 25 of the 30 remaining individuals whose only three breeding pairs of this species are on the verge of extinction.

Feral cats threaten the outstanding endemic fauna of the New Caledonia biodiversity hotspot: implications for feral cat management strategy

P. Palmas, H. Jourdan, E. Bonnaud, F. Rigault, L. Debar, H. De Méringo, E. Bourguet, R. Adjouhgniope and E. Vidal.

Institut Méditerranéen de Biodiversité et d'Ecologie marine et continentale (IMBE), Aix Marseille Université, CNRS, IRD, Avignon Université, Centre IRD de Nouméa, BPA5, 98848 Nouméa cedex, Nouvelle-Ca, Nouméa, New Caledonia. <palmas.pauline@gmail.com>

Among invasive species, feral cats (*Felis catus*) are one of the most successful and harmful predator species leading to dramatic loss of biodiversity on the world's islands. Effective feral cat management (eradications, controls) on numerous islands generally resulted in positive effects for native biodiversity conservation. The lack of feral cat diet study in the New Caledonia archipelago was an obstacle (i) to assess the importance of feral cat issues and (ii) to provide relevant guidelines for feral cat population management to mitigate their impacts. Our study aims to evaluate feral cat threats to the outstanding biodiversity at this major biodiversity hotspot in order to provide recommendations to prioritise management and preservation of native biodiversity. We investigated feral cat predation by analysing 5,300 cat scats sampled at 14 selected representative sites giving an accurate picture of the four main natural habitats. Feral cats prey upon at least 43 vertebrate species, 20 of which are IUCN Red List threatened species. New Caledonia is the home of 30.8% of IUCN threatened species preyed on by feral cats, while representing only 0.12% of the total area of islands (including Australia). Thus, this study increases at least by 44.4% the number of IUCN threatened species vulnerable and preyed upon by feral cats across islands worldwide. Threatened vertebrate species preyed on by feral cats are skinks, flying foxes and petrels, and their predation mainly occur in humid forest and maquis mosaic sites. The results of this study prompted feral cats to be listed among the top-five priority species for future management in New Caledonia. We therefore recommend that future actions be prioritised based upon the most critical species situations (most impacted and endangered native species, i.e. skinks, flying foxes, seabirds), and targeting first some geographic areas of manageable size already offering some management facilities and support.

Scaling up invasive plant management for ecosystem restoration in Mauritius: successes and challenges

S. Pandoo, P. Ragen, B. Vishnuduth, Z. Jhumka and J. Mauremootoo

InSpiral Pathways, 23 Southside, Congresbury, Bristol, Avon BS495BS, UK. <seewajee.pandoo@undp.org>

Objectives: To document progress made in the last 30 years in restoration of Mauritian terrestrial ecosystems with a primary focus on the invasive plant management component. Methodology: Invasive plant management activities and results have not been systematically monitored so much of the evidence for management effectiveness is anecdotal. As part of the UNDP-GEF PAN Project (Expanding coverage and strengthening management effectiveness of the protected area network on the island of Mauritius) practitioners' knowledge of plant restoration practices undertaken to date has been synthesised in a 'Good Practice Guide for Native Forest Restoration in Mauritius'. This synthesis has allowed us to take stock of management effectiveness. Results: The area under restoration in mainland Mauritius has increased from < 10 ha in the 1980s to almost 100 ha from the 1990s to the 2000s to nearly 500 ha today. Per hectare weeding costs in real terms have been reduced by more than half during this period, principally by moving away from pure manual weeding to an approach that involves a mixture of manual and chemical approaches, and more effective implementation arrangements. There are certain common practices in invasive plant management but there are also site and species-specific weeding approaches, and initiatives that could be scaled up such as utilising weed biomass as a cost-recovery option, and using mulching as a weed suppression technique. Conclusions: Much progress has been made at both the site level and nationally for the country's entire PA estate. The Good Practice Guide will help disseminate this knowledge among new and existing practitioners as a contribution to management effectiveness.

Implementing an early detection programme on Catalina Island: prioritising landscaped grasses

J. Parish

Catalina Island Conservancy, PO BOX 2739, Avalon, California 90704, USA. <jparish@catalinaconservancy.org>

Invasive species pose a significant threat to native plant species by increasing the risk of wildland fires, displacing native species, and altering native habitat. Recent trends in Southern California landscaping have increased the demand for drought resistant grasses, and often these are non-native species. Catalina Island Conservancy's Catalina Habitat Improvement and Restoration Program's invasive plant project developed an early detection and rapid response project, the Avalon Grasses Initiative, in 2016 to address recent introductions of three highly invasive grass species installed in landscaping. The Avalon Grasses Initiative implements "target-based" early detection methodology created by previous research and early detection efforts conducted on mainland California. Roadside surveys detect populations and staff walks through the community going door to door to request permission to remove target species and offer native plants as replacement. Initial surveys detected 30 populations of *Cortaderia selloana*, *Pennisetum setaceum*, and *Stipa tenuissima*. Control and survey efforts are on-going, but more than 1,000 plants have already been removed and replaced with native Catalina Island plant species grown in the Conservancy's native plant nursery.

Challenges and opportunities for lethal and non-lethal management of non-native ungulates on islands: feral pigs, goats and cows

D. Parrott, G. Massei, R. Ridley, J. Sandon, M. Lambert, D. Cowan and M. Sutton-Croft

National Wildlife Management Centre, Animal & Plant Health Agency, Sand Hutton, York, YO41 1LZ, UK. <dave.parrott@apha.gsi.gov.uk>

The National Wildlife Management Centre (NWMC), which is part of the UK Government's Animal and Plant Health Agency (APHA), has supported and delivered the management of non-native species including commensal rodents and ungulates on a variety of islands across the world. The NWMC utilises a range of both lethal and non-lethal approaches in these projects. We will present two ungulate case studies highlighting the merits and limitations of each of these approaches. This includes NWMC's recent work to reduce the population of feral goats on Great and Little Tobago in the British Virgin Islands. NWMC worked with the RSPB and the National Parks Trust of the Virgin Islands to directly reduce this population through humane culling and trained locally-based staff to increase their capacity to deliver similar projects in the future. Although this project proceeded as intended, lethal control is not suitable in all situations. We have found that although it can deliver rapid reductions in populations in the short term, and is often the best option where complete eradication is the aim of the management intervention, it may be unfeasible or be unacceptable due to its impact on the environment and on animal welfare. Fertility control is increasingly being considered as an alternative long-term solution to reduce population sizes of problematic species. This non-lethal method can offer a humane, publicly acceptable method to reduce population sizes. Recent advances in research and development have led to the registration of novel fertility control agents for wildlife. Species-specific systems to deliver baits containing oral contraceptives to target species are now available. In addition, the development of new software and mathematical models has allowed researchers to make predictions of the effects of fertility control on population size. In our second case study, we present experimental data on the efficacy of fertility control agents on model wildlife species and illustrate examples of species-specific bait delivery systems.

Diet of introduced black rats (*Rattus rattus*) on Christmas Island: setting the scene with stomach and stable isotope analysis

C. Pink, D. Algar and P. Green

Evolution and Ecology, Latrobe University, P.O. Box 867, Christmas Island, Western Australia 6798, Australia. <caitlyn.pink@environment.gov.au>

The black rat (*Rattus rattus*) is an introduced and invasive rodent, negatively affecting endemic species on many islands worldwide. Black rats have existed on Christmas Island for more than 100 years, and feral cats (*Felis catus*), also on the island, are poised for imminent eradication. The risk of meso-predator release needs to be considered, and a combination of stomach and stable isotope analyses of rats was used to determine potential impacts on native fauna should such a release occur. Samples of rat stomach, muscle and fur, along with baseline and consumer reference groups were collected in plateau forest and coastal terrace for stable isotope analysis during the wet and dry season of 2015/16. Stomach analysis revealed an omnivorous diet, with reproductive parts (flowers, fruits and small seeds) of plants significantly dominating the invertebrate component. One reptile was found in a single gut, the introduced blind snake (*Indothyphlops bramini*) but no birds were detected in stomach contents. Stable isotope analysis showed an omnivorous to predatory role compared with stomach analysis, but no association with nesting seabird sources. The effect of habitat and season did not result in major diet shifts, with rats consuming items that primarily followed the C3 pathway. Omnivory was predominant in plateau forest and carnivory dominated the coastal terraces, while trophic niche width broadened on the coastal terraces. Homogeneity of diet across habitat and season suggests persistent plant and invertebrate resources may satisfy nutritional requirements through opportunity or necessity year-round. Little evidence of significant dietary overlap was shown with feral cats based on stomach data from previous diet studies. Further investigation into the diets and relative abundance of rats over time is required to reliably gauge their impacts on vulnerable species and communities on Christmas Island, to justify future rat control actions in the wake of feral cat eradication.

The prospects for biological control of *Rubus niveus* in the Galapagos Islands

K. Pollard, D. Kurose, A. Buddie and C. Ellison

Invasive Species Management, CABI-UK, Bakeham Lane, Egham, Surrey TW20 9TY, UK. <k.pollard@cabi.org>

Following its introduction for its sweet edible fruit in the 1970s, *Rubus niveus,* native to Indochina, has become one of the worst invasive weeds on the Galapagos archipelago. It invades open vegetation, scrub and forests where it can grow to 4 m in height and form dense, impenetrable thickets. As a result, *R. niveus* can out-compete native flora and decrease biodiversity; the endemic *Scalesia pedunculata* forest on Santa Cruz Island is currently threatened by *R. niveus*. It is also a serious problem for agricultural land where it increases the cost of weed control and may render land unsuitable for cultivation. Current control methods are based on mechanical removal followed by chemical control. However, due to the long-lived seed bank and rapid growth of *R. niveus*, this has to be repeated, which is both labour intensive and costly. Classical biological control using coevolved, host-specific natural enemies from the native range of an invasive species can be an economic and self-sustaining method of weed control. It is important to select natural enemies for further evaluation that are best-adapted to populations of *R. niveus* on the Galapagos Islands. The results of on-going molecular research undertaken to determine which area in the native range the archipelago biotype originated from, will be presented. In addition, the results of a desk-based analysis and preliminary natural enemy surveys in India and China, which have revealed a suite of insects and fungal pathogens that target *R. niveus*, will be discussed.

A tool for biodiversity conservation within Chile: renewed interest in island eradications sparked by successful European rabbit (*Oryctolagus cuniculus*) eradication

M. Pott, E. Hagen, P. Martínez and M. Díaz

2100 Delaware Avenue, Suite 1, Santa Cruz, California 95060, USA. <mpott@islandconservation.org>

Choros Island (301 ha) and Chañaral Island (517 ha) are the two largest islands which make up the Humboldt Penguin National Reserve (RNPH), in northern Chile, within Chile's National Protected Areas System (SNASPE) designed to protect the rich resources of the Humboldt Current. The European rabbit (*Oryctolagus cuniculus*) was introduced to both islands in the mid-20th Century, triggering erosion and negative impacts on native vegetation and two seabird species endemic to the Humboldt Current: the Humboldt penguin (*Spheniscus humboldti*) and the Peruvian diving petrel (*Pelecanoides garnotii*). Island Conservation and CONAF (Corporación Nacional Forestal; Chile's National Forestry Corporation and RNPH manager) initiated the eradication of European rabbits from Choros Island in 2013 – the first eradication of invasive species from a Chilean island in a decade. The project was successfully confirmed in 2014, prompting the partnership to pursue ecological restoration of Chanaral Island in 2015, beginning with the removal of invasive rabbits. Utilising lessons learnt from work on Choros Island, the eradication on Chañaral Island was initiated in 2016 and is currently in a monitoring phase. The opportunity to remove all invasive vertebrates from the entirety of a protected area – RNPH – has built confidence in planning, implementation and monitoring among government officials and local stakeholders (ecotourism operators) and has facilitated increased momentum in Chile for island biodiversity conservation through the eradication of invasive species. As a result, CONAF seeks to achieve greater biodiversity conservation within other islands in the SNASPE, such as the Juan Fernández Archipelago National Park (PNAJF), representing unique ecosystems severely affected by multiple invasive vertebrates.

Finders keepers? Discovering and securing the rare species rediscovered in weeded restoration plots

P. Ragen, S. Pandoo, V. Bachraz, Z. Jhumka and J. Mauremootoo

InSpiral Pathways, 23 Southside, Congresbury, Bristol, Avon BS495BS, UK. <parmananda.ragen@gmail.com>

Objectives: To document the role of the expansion of weeded areas in increasing the discovery of threatened plants and how this process can be integrated into systematic plant species recovery programmes. Methodology: Mauritius hosts some of the most threatened plant species in the world. More than 80% of its remaining 273 endemic plant species are considered to be threatened. The expansion in weeded areas in recent years has resulted in a number of species rediscoveries and increases in the known wild populations for other species. Written and verbal records of species rediscovery from different agencies are consolidated. Results: Results are summarised by numbers of species and number of individuals rediscovered, location of these discoveries and the fate of the discovered individuals. Some rediscovered individuals have been successfully utilised for their germplasm for propagation and subsequent reintroduction. However, in most cases, this process has not been systematic. Conclusions: Finding previously unrecorded species and populations is clearly a positive thing. However, there are challenges. Weeding, although essential for the long-term health of Mauritian native forest, can cause short-term negative effects for rare plants and other threatened taxa. Therefore, it is important to develop weeding approaches that take the requirements of rare plants into account, for example leaving certain exotic species which act as substrates to epiphytic plants, and gradually removing species in the vicinity of rare plants so that they are not exposed to a sudden change in micro-climate. These actions have been implemented in certain instances but have been neglected in others, chiefly because of the lack of knowledge of labourers who are not trained to recognise rare native plants. Rediscovery does not mean that the species concerned are 'out of the woods' so it must be considered to be a part of an overall rare species recovery plan.

Impacts and control of invasive species: trading off actions

M. Roberts, W. Cresswell and N. Hanley

James Hutton Institute, Craigiebuckler, Aberdeen, Scotland. <Michaela.Roberts@hutton.ac.uk>

Environmental conservation is chronically underfunded, as a result of both an absolute shortfall in funding, and poor funding prioritisation. Control of impacts of invasive species on native ecosystems is recognised as of high global conservation priority, but also requires significant economic investment. Improving prioritisation of invasive species control options, and identifying alternative funding sources, would therefore greatly improve efficiency in mitigating degradation caused by invasive species. We incorporate ecological, economic, and social considerations to prioritise options for control of invasive grazing species on Bonaire, Caribbean Netherlands. We estimate impacts of control of terrestrial invasive species on the dry-forest, and on the coral reef, linked by changes in terrestrial sedimentation rates. To address absolute shortfalls in funding, we estimate willingness of SCUBA divers to pay for terrestrial invasive species control. We find significant negative relationships of donkey density with vegetation ground cover; and a significant positive relationship of ground cover on the watershed with coral cover at depths below 10m. Using these models we estimate the impacts on coral cover of strategies to control grazing, including fencing and eradication. Cost curves for each strategy indicated that fencing of watersheds to exclude grazers presented the most cost effective solution within a 50-year time frame. We conducted choice experiments with SCUBA divers to estimate willingness to pay for control of terrestrial invasive species, where this would improve reef health. Willingness to pay exceeded the total costs of both fencing and eradication. We illustrate that control of terrestrial invasive species can lead to benefits in both terrestrial and marine ecosystems, and that funding for such projects may be possible via marine stakeholders. The combination of both terrestrial and marine considerations into invasive species control can greatly improve efficiency, while ensuring funding is allocated to address all threats to ecosystems under direct use.

Incorporating interaction networks into conservation: Tasmania as a case study

A. Rogers, J. Shaw and S. Kark

Biological Sciences, University of Queensland, St Lucia, Queensland 4072, Australia. <a.munro.rogers@gmail.com>

Quantifying the direct impacts of invasive species requires time and resources which are not always available. In systems with limited information, qualitative interaction networks provide a method in which to explore the potential interactions between species at the community level. In Tasmania, hollow-breeding bird communities have been invaded by five hollow-nesting birds and one hollow-using, predatory marsupial, contributing to the decline in populations of several threatened species. While some interactions between native and invasive species on the island have been well documented, little information exists on the impact of most invasive species across the island. The aim of this research is to develop a model which quantifies the likely competitive interactions between hollow-breeding species across Tasmania in order to determine the potential impacts of unstudied invasive species. Hollow-breeding communities are an ideal community in which to study competitive interactions because there is direct competition between species over shared resources and it is possible to include all species in the community. Here we use species traits to model individual species breeding niche space, and use a metric of niche overlap between species to build qualitative networks representing potential competitive interactions for entire hollow-breeding communities. This method highlights known impacts of established invasive species and can be used to model the potential interactions of alien species present but not yet established.

Invasive plants of the Caribbean: application of herbarium collections to protect a regional biodiversity hotspot

J. Rojas-Sandoval, P. Acevedo-Rodríguez, M. Datiles, S. Dube, H. Diaz-Soltero, L. Charles, G. Richards, M. Angel Duenas, D. Simpson, E. Ventosa-Febles, J. Ackerman, F. Areces-Berazain, M. Caraballo-Ortiz, A. Carvajal-Vélez, J. Chabert-Llompart, S. Kaufman, J. Thompson and J. Vélez-Gavilán

Compendium Office, CABI, Nosworthy Way, Wallingford, Oxfordshire OX10 6RP, UK. <julirs07@gmail.com>

The Caribbean Islands represents a biodiversity hotspot with over 650 Critically Endangered or Endangered species. Collation and dissemination of knowledge is a requisite to address the problem of invasive species, a major driving force of species extinction with many other serious socio-economic impacts. This poster describes how, building on the keystone work, 'Catalogue of seed plants of the West Indies' and analysis of over 14,300 georeferenced herbarium accessions at the Smithsonian Institution, a project has collated data on over 570 invasive plant species prioritised from 1,879 plants identified as exotic to the region. Expert authors were selected to compile datasheets on each species from records in the herbarium and in scientific journal articles and authoritative databases. The datasheets were peer reviewed and submitted to CABI for final style edits and publication in the Invasive Species Compendium (ISC), a scientific knowledgebase with global coverage and reach. As of February 2017, 253 of 417 completed datasheets have been published. Inclusion in the ISC provides an Open Access platform for comparison with other taxa and geographic regions within a sustainable programme where information will be updated. Data are collated and presented with particular focus on risk assessment, management of pathways, public awareness, policy development, identification, detection, and options for control. Future work will include in-country gap analyses through consultation and comparison with locally compiled invasive species lists.

Can large database mining inform invasive non-native species management on islands?

L. Ruffino and T. Cornulier

University of Aberdeen, Aberdeen, AB24 3UU, UK. <Lise.Ruffino@jncc.gov.uk>

Global databases, including the IUCN Red List database, the Global Invasive Species Database, and the Threatened Island Biodiversity Database represent invaluable assets for investigating global patterns of extinction risk in insular vertebrates and target priority islands and species for conservation or eradication management. In view of the growing number of studies mining these databases to inform global conservation priorities, we ask two key questions: 1) what questions can these data most effectively address or not address; and 2) are the recommendations issued useful to practitioners and policy makers? Here, we critically assess the quality of the evidence used for quantifying global impacts of invasive non-native species on island vertebrates, and the methodology used in analyses of large publicly-available datasets. We provide recommendations on how to overcome limitations identified in the data, their processing and reporting, and suggest perspectives to address critical knowledge gaps.

Management of numerous introduced plants on Matiu (Somes Island), Wellington, New Zealand

P. Russell and S. Weaver

Scarhead House, Glenfarg, Perth, PH2 9QG UK. <peter@aotearoabiodiversity.co.nz>

Matiu (Somes Island) is a 24.9 ha island in Wellington Harbour, New Zealand. The island has been free of introduced wild mammals since the late 1980s and provides a valuable opportunity to restore coastal forest ecosystems, including biota now rare or extinct on the mainland. Despite being only c. 2.5 km from the mainland, experience to date suggests invasion by invasive plants from the mainland is generally unlikely, although this situation may change in future. Restoration planting began in 1981. Major efforts to manage numerous plants known to threaten the restoration and protection of the island's native biodiversity ("weeds") began in 1998 and were initially somewhat ad hoc. Due partly to the retention of skilled personnel the island's weed management strategy has been refined greatly since 2007, including: enhancing biosecurity procedures pertaining to weeds; developing a thorough, systematic and regular approach to surveying; considering *all* introduced plants and implementing a precautionary approach (erring on the side of controlling plants that *may* be a threat, especially if rare and easy to kill); upskilling personnel; more strategically dividing volunteer, staff and contract labour and prioritising control work (including placing greater emphasis on early detection and nascent foci); and increasing the diversity of the island's native vegetation to enhance its resistance to weed invasion. Of 129 plants of concern to date, 73 (57%) are rated as posing a very high, high or moderate threat and 53 (73%) of those are now considered rare, possibly eradicated or probably eradicated. Major progress has also been made in most other areas of the weed management strategy, although some tenacious weeds remain a challenge. Lessons learnt on Matiu during the last 20 years may be applicable to other sites, including larger ones; sites with multiple land uses, owners and management regimes; and sites with greater chances of weed invasion.

Managing *Vespula* wasp invasion in New Zealand

J.M. Schmack, M.C. Barron, D.F. Ward and J.R. Beggs

School of Biological Sciences, University of Auckland, Auckland, New Zealand. <j.schmack@auckland.ac.nz>

Introduced *Vespula* wasps cause severe problems to New Zealand ecosystems. Though vespulid wasps have successfully invaded most of New Zealand's offshore islands, little is known about their abundance and population development on those islands. Anecdotal observations suggest three offshore islands in the Hauraki Gulf and on the coast of the Coromandel (Little Barrier Island, Korapuki and Tiritiri Matangi) have become vespula wasp-free following successful mammal eradication. This study aims to investigate the drivers of successful wasp suppression and the prevention of reinvasion. Wasp monitoring will be conducted on different offshore islands along the northern east coast of New Zealand's North Island to measure the relative abundance of wasps and to collect a database on the island's environmental parameters. The combination of wasp trapping and a molecular analysis of paternity levels will allow us to estimate nest densities on offshore islands. The proposed study is novel because it will use a combination of methods (field based and molecular) to assess the density of vespula wasps in low-density areas (not beech forest). This database will also serve as a baseline for future investigations on pest dispersal and colonisation processes. It is crucial that we improve understanding of how different factors influence the development of wasp colonies to elaborate efficient pest control plans. The efficiency of five novel control methods will be forecasted using population modelling on colony and landscape scales.

Invasive rat colonisation history and movement dynamics in Haida Gwaii

B. Sjodin, R. Irvine, G. Howald and M. Russello

University of British Columbia, 1531 Appleridge Rd, Kelowna, British Columbia V1W3A5, Canada. <Bryson.Sjodin@ubc.ca>

The brown rat (*Rattus norvegicus*) and black rat (*R. rattus*) are among the most invasive species worldwide with distributions encompassing every inhabited continent. Through predation and competition, invasions from both species have caused range contractions, local extirpation, and extinctions, resulting in reduced biodiversity. On Haida Gwaii, invasive rats have been implicated in population declines of six seabird species. Eradications were conducted on several islands where important nesting sites for sea-birds exist. On the Bischof Islands, reappearance of rats post-eradication has been observed. The objectives of this research are to investigate population history and movement dynamics of invasive rats in Haida Gwaii. Presently, 551 brown and black rats have been sampled from eighteen islands, collected from 2008 to 2016. Pre- and post-eradication samples were collected from the Bischofs allowing for an explicit evaluation of re-emergence versus re-colonisation in these locations. Genomic DNA was extracted from ear samples and used to construct double digest restriction site associated DNA sequencing libraries and sequenced using the Illumina HiSeq2500 PE125 platform. Single nucleotide polymorphisms (SNPs) were identified, genotyped, and used to assign individuals to species using a Bayesian clustering approach. The two species were then separated, and SNPs were re-identified and genotyped for further analysis. Resulting SNP data will be analysed using a series of population genetic and spatially-explicit analyses to determine the source of re-established populations and quantify the extent and direction of gene flow throughout the system. Genotypic data are being collected such that they offer full connectibility to a global SNP database of brown rats to infer potential sources of the populations in Haida Gwaii. Results of these analyses will help facilitate future eradications and provide useful insights to prevent the spread of rats elsewhere within the system.

B. Skei

Garden cans and river rafts – equipped to approach invasive freshwater fish

B. Skei

Environmental and Biosecurity Measures, Norwegian Veterinary Institute, Nordengbakkan 47, Levanger, +47 7602 Norway. <bjorn.skei@gmail.com>

How can environmental and fishery managers benefit from a natural toxin when aiming to maintain healthy native aquatic ecosystems? Rotenone is the only substance on the EU Biocides Regulation 528/2012 product-type 17 (piscicides) list and considered one of the most environmentally benign toxicants available for eradication of invasive fish. The substance is distributed in the formulated product CFT Legumine (CFT-L). In the wake of a CFT-L treatment, rotenone persistence in natural waters differs from a few days to several weeks depending on the season. Unless all parts of a large water body or catchment can be treated more or less simultaneously, the breakdown of rotenone may allow fish migration back into previously treated areas, i.e. undermining a successful treatment operation. When aiming for treatment of invasive alien species against a complex hydrogeological backdrop, standard tools are often pushed towards customised equipment. This poster presents equipment and techniques used in CFT-L treatment of diverse habitats such as groundwater entries, ponds and lakes, streams and rivers, tarns and marshlands, opening a toolbox containing garden cans, peristaltic pumps, backpack pumps and river rafts.

What happens after the helicopters have gone – assessing post-eradication changes on Macquarie Island

K. Springer

K. Springer

16 Rinaldi Ave, The Pines Beach, North Canterbury 7630, New Zealand. <keith.springer@gmail.com>

In 2014 an eradication operation targeting house mice (*Mus musculus*), black rats (*Rattus rattus*) and European rabbits (*Oryctolagus cuniculus*) on sub-Antarctic Macquarie Island was successfully concluded. Monitoring of outcomes since that time has been sporadic and some is partly anecdotal, however the changes apparent on Macquarie Island in the absence of pest species are nonetheless considerable and are significant indicators of the progressive recovery of an island ecosystem. Vegetation changes following cessation of rabbit grazing are the most visually dramatic and widespread and are demonstrated partly by use of photo-points. Censuses of some seabird and invertebrate species have documented changing trends in island populations. Further changes can be expected for decades to come although some changes will be influenced by changing climatic conditions.

Predicting the distribution of island invader bird species under climate change

M. Thibault, F. Brescia and M. Barbet-Massin

M. Thibault, F. Brescia and M. Barbet-Massin

Institut Agronomique Néo-Calédonien (IAC), Equipe ARBOREAL (AgricultuRe BiOdiversité Et vAlorisation), BP 73, 98890 Païta, New Caledonia. <thibault@iac.nc>

The red-vented bulbul (*Pycnonotus cafer*), the common myna (*Acridotheres tristis*) and the red-whiskered bulbul (*P. jocosus*) are three passerine bird species native to the Indian subcontinent that were transported to islands from the early 1900s. Nowadays, the common myna is considered established in 20 island territories, the red-vented bulbul in 11 (32 islands) and the red-whiskered bulbul established in four island territories. Considering that perturbations associated with human activities will continue to increase during the 21st Century, leading to unprecedented species transportation rates, understanding potential climatic ranges of these species could be crucial. Moreover, predicting future range shifts under various climate change scenarios could be very useful in order to better inform management strategies. This is particularly true for birds as climate is often assumed to be one of the main drivers of the distribution of this taxon at large spatial scale. Here, we used eight species distribution models, five global circulation models and four representative concentration pathways using presence data from both the native and alien ranges of the three species. The objectives of this study were to i) assess the potential invasion risk of the red-vented bulbul, common myna and red-whiskered bulbul; ii) highlight priority locations for the management of these species and prevention of their introduction; and iii) explore the likely influence of climate change on the future climatic range of each. Our world climate suitability maps for each species predict a latitudinal expansion of climatic range. Then, our projections highlight three major potential climatic pathways for the establishment of the three species around the coasts of Northern Brazil, Guinea Gulf and North-West of the United States.

Biosecurity Plan for invasive ants in the Pacific

C. Vanderwoude, S. Boudjelas, P. Andreozzi, P. Cowan and J. Wainiqolo

Invasive Species Programme, Secretariat of the Pacific Regional Environment Programme, PO Box 240, Apia, Samoa. <cas@littlefireants.com>

Invasive ants are very adept hitchhikers and invaders of novel ecosystems. They have the ability to move through a wide range of international trade pathways. Once established, invasive ants are very difficult to eradicate or control. Their impacts are felt across many sectors including, agriculture, horticulture, trade, tourism, human health and the environment. Pacific islands are un-adapted to the presence of invasive ants and largely devoid of native ant species. Their impacts are often more far-reaching than at other locations, threatening not only delicate and complex island ecosystems, but the livelihoods and wellbeing of island communities. In the face of climate change, invasive ants will further reduce the climate resilience and food security of subsistence economies. A best practice integrated biosecurity system is needed to prevent the entry and establishment of these species as well as mitigate impacts caused by priority invasive ants currently present in the region. We recommend a regional approach to invasive ant biosecurity be established, which includes the essential elements of prevention, early detection, rapid response, ongoing management, capacity building, outreach and research. This system should operate at island, national and regional scales.

Rat control to protect the Turks and Caicos rock iguana: monitoring and responding to rat activity on a Caribbean island Nature Reserve

K. Varnham, E. Radford, S. Busuttil, C. Forbes, E. Gibbs-Williams and G. Gerber

Nature Recovery Unit, RSPB, The Lodge, Sandy, Beds, SG19 2DL. UK. <karen.varnham@rspb.org.uk>

A significant proportion of the global population of the Critically Endangered Turks & Caicos rock iguana (*Cyclura carinata*) is found on the small 43 ha island of Little Water Cay, which is managed as a nature reserve by the Turks & Caicos National Trust (TCNT). Black rats (*Rattus rattus*) and feral cats (*Felis catus*) are also found on the island, which is connected by sand bars to two larger islands and within black rat swimming distance of the large inhabited island of Providenciales. While rat eradication is not currently thought sustainable, a control programme began in 2015 aiming to control rats to zero/low density, reducing predation pressure on young iguanas. The baiting programme uses the first-generation anticoagulant rodenticide diphacinone set in bait boxes on a 50 m grid across the island. Following three weeks of baiting in November 2015 anecdotal changes were observed; increased sightings of young iguanas, nesting least terns (*Sternula antillarum*) on the sand bar and presence of a juvenile Antillean nighthawk (*Chordeiles gundlachii*). However, a second scheduled baiting round in November 2016 showed that rats were once more found across the entire island. We therefore devised a monitoring system to observe the speed and distribution of the influx of rats, predicted to walk across from the adjoining cays and/or swim from Providenciales. After the second baiting season non-toxic chocolate wax monitoring blocks were set in 20 bait stations across the island and checked weekly for signs of rat activity. These data will inform the timing and duration of future rat control undertaken on the island, allowing us to maximise the conservation benefits to iguanas while minimising the amount of rodenticide used, and thus non-target impacts. TCNT staff have been trained in rat control and monitoring techniques and now lead this project to reduce the impact of invasive rats on this important species.

An innovative programme to protect the UK's seabird islands

K. Varnham, S. Thomas, L. Bambini, S. Havery and L. Lock

Nature Recovery Unit, RSPB, The Lodge, Sandy, Beds, SG19 2DL, UK. <karen.varnham@rspb.org.uk>

The UK supports globally significant populations of seabirds, including 80% of the world's Manx shearwaters (*Puffinus puffinus*) and almost 60% of northern gannets (*Morus bassanus*), with breeding populations mostly restricted to offshore islands. However, many of these islands have one or more invasive non-native mammals present which negatively impact seabirds as well as many other native species. In 2013 the RSPB's innovative Seabird Island Restoration Project was established to protect these important islands using three key approaches. Firstly, we have developed a best practice toolkit for UK ground-based rat eradication projects, to be launched in 2017. This toolkit is based on international standards but tailored to the UK environmental, legal and social situation, consisting of technical advice documents on planning and carrying out eradication, biosecurity and incursion response work, as well as templates and series of worked examples. We have also collaborated on a prioritisation exercise to identify the UK islands where the greatest conservation gains can be made through eradication of invasive non-native mammals (eradication priorities) and where the greatest losses would be expected to occur were brown rats (*Rattus norvegicus*) to arrive on currently rat-free islands (biosecurity priorities). Finally, we are building UK capacity in island restoration through supporting UK-based conservation organisations, offering training in biosecurity, safe and effective rodenticide use, and incursion response planning, as well as writing, and supporting others to write, biosecurity plans, feasibility studies and operational plans. We have supported and trained two incursion response teams, one in south-west England and one in north Scotland, and plan to extend this network UK-wide. We believe this combination of working at the sites where the greatest conservation gains can be made, with well-trained people following tailored best practice guidelines offers the best chance to protect the UK's iconic seabird island heritage.

Prioritising islands for the eradication of invasive vertebrates in the Arctic

S.D. Veatch

American University, 4400 Massachusetts Avenue, N.W., Washington, D.C. 20016, USA. <sarah.d.veatch@gmail.com>

As human activity increases and climate warms, invasive alien species pose a serious, growing threat in the Arctic to native biodiversity, ecosystems, and inhabitants, particularly those of Arctic island ecosystems. Consequently, Arctic states have recognised the need to eradicate invasive alien species from Arctic island ecosystems. The Arctic Council – an intergovernmental forum comprised of eight countries and six Permanent Participants that represent Arctic indigenous peoples – has defined a collective priority for upcoming action in the Arctic Invasive Alien Species (ARIAS) Strategy and Action Plan: "actively facilitate the eradication of invasive alien species from island ecosystems throughout the Arctic, as well as the recovery of native island species and habitats that have been impacted by invasive alien species". Prioritising islands for eradication activity is both necessary and strategically important in order to achieve this goal with limited resources across multiple jurisdictional authorities. This paper will explore the application of a study published in Conservation Biology ("Prioritising islands for the eradication of invasive vertebrates in the United Kingdom overseas territories") to the development of a prioritisation schema for the eradication of terrestrial invasive vertebrates on Arctic islands. The paper will provide a summary of key findings, including the identification of relevant data gaps; a proposed Arctic island prioritisation schema for the eradication of terrestrial invasive vertebrates; and a summary of further needs for input from scientific and policy perspectives. These findings will be applied to the ARIAS Strategy and Action Plan Steering Committee's efforts to develop a plan for the eradication of invasive alien species from Arctic island ecosystems.

Changes in forest passerine numbers on Hauturu following rat eradication

C.R. Veitch

48 Manse Road, Papakura, New Zealand. <dveitch@kiwilink.net.nz>

Passerines were monitored on Hauturu (Little Barrier Island) over 15 years (1975–89) spanning the period (1976–80) when feral cats were eradicated from the island and again for the period 2013–2017. All birds seen and heard were recorded while walking three transects representing an altitudinal range from near sea level to approximately 550 m above sea level. Analysis of variance statistics were used to test for differences in bird numbers between transects and between years. Bird species were examined by transect to test for changes in numbers over time. Following cat eradication three species had increased on some transects, and two species had decreased on some transects, but it was difficult to attribute changes in bird numbers to the one cause which we were able to study: reduced cat numbers. Following rat (*Rattus exulans*) eradication in 2004 there have been significant increases and decreases of forest dwelling passerines. Field work for this study was completed in March 2017 and the data have yet to be analysed in detail.

Habitat features that influence predation of endangered Hawaiian common gallinule nests by invasive vertebrates in Hanalei and Huleia National Wildlife Refuges

B. Webber, K. Uyehara, T. Luxner and D. Dewey

Kauai National Wildlife Refuge Complex, U.S. Fish and Wildlife Service, PO Box 1128, Kilauea, Hawaii 96754, USA. <brynwebber@gmail.com>

Hanalei and Huleia National Wildlife Refuges (NWRs) on the island of Kauai in Hawaii are designated as core wetland areas essential to the recovery of five endangered Hawaiian waterbird species. These two sites support approximately 50% of the endangered Hawaiian common gallinule (Alae ula, *Gallinula galeata sandvicensis*) population state-wide. On Hanalei NWR, taro (*Colocasia esculenta*) farming provides dense emergent aquatic vegetation needed for breeding gallinules, but previous research suggests that dikes, water drawdowns, and harvested fields may increase access by introduced mammalian predators. Although these studies documented egg predation, researchers were unable to determine nest fates for 25% of the nests using observer-based methods. In this pilot study, we evaluated the use of remote motion detection cameras as a method to determine gallinule nest fates and elucidated factors related to predation events through the early brooding phase. We predicted that taro farming practices influence predation by invasive vertebrates (e.g. feral cats (*Felis catus*), rats (*Rattus* spp.)) and negatively affect gallinule nest success in taro fields, when compared to managed wetland units that have fewer dikes, suitable vegetative cover, and stable water levels. Higher gallinule nest success in wetland units, coupled with reliable data regarding drawdowns and predation of nests in taro fields, allows managers to implement more specific management and monitoring methods to control and reduce access of invasive vertebrates that prey on endangered gallinule nests in these critically-important wetland, riverine, and agricultural landscapes.

Using sUAS to direct trap placement in support of feral cat eradication on islands

D. Will, T. Hall, M. Khalsa and J. Bruch

Island Conservation, 2100 Delaware Ave, Suite 1, Santa Cruz, CA 95060, USA. <dwill@islandconservation.org>

Trap location is one the most important elements in a successful trapping programme and requires specialists that can analyse microhabitats across a landscape and identify areas of likely cat (*Felis catus*) presence and key travel routes. This is particularly true when determining the location of walkthrough trap sets. Existing remote sensing data can help specialists identify macrohabitats where cat activity is suspected but is not collected at a fine enough resolution to resolve microhabitats or topographical features where cat activity is likely. Using a case study on Kaho'olawe, Hawaii we evaluate how placing very high resolution sUAS-derived data in the hands of trapping specialists can be used to direct trap placement reducing the need for time intensive exploration of the landscape. On Kaho'olawe (11,550 ha), there is considerable need to direct trap placement because the presence of unexploded ordnance (only 10% of the island is cleared to a depth of four feet and 69% of the island surface-cleared) poses a significant risk to staff safety and greatly increases project risk and cost. In this case study, we use traditional remote sensing techniques to select three representative study areas that have limited UXO concerns and estimated high cat habitat suitability. Each study area is mapped at a resolution of less than 5 cm and resulting products are reviewed in 2D and 3D by trapping specialist to select suitable trap locations. Trapping specialists evaluate each study area on foot using their normal protocols to determine trap locations. Finally, we evaluate the efficacy of sUAS direct trap placement by comparing the sUAS derived trap locations with the ground-truthed locations. The workflows for collecting, processing and analysing sUAS data that we describe should enable managers to determine if integrating sUAS into trapping programmes is a cost-effective and efficient way to improve project success.

Removal of invasive, black rats increases activity levels and population density of Christmas Island's last remaining endemic reptile

M. Wynn and D. Driscoll

The Australian National University, Fenner School of Environment and Society, Canberra, Australian Capital Territory, Australia. <melissa.wynn@anu.edu.au>

Invasive black rats (*Rattus rattus*) have been implicated in the extinctions of native species across the globe, particularly where native fauna are predator-naïve and are within insular island systems. Through the process of introduced disease and predation, Christmas Island in the Indian Ocean has suffered catastrophic extinctions of four endemic mammals and four reptiles since the early 1900s. Up until now, the endangered Christmas Island giant gecko (*Cyrtodactylus sadleiri*) has resisted extinction, but the interactions of this rainforest-dwelling endemic species with invasive and abundant black rats are unclear. With the recent onset of feral cat eradication by the Australian Government's *Christmas Island National Park*, a greater understanding of the potential for rats to impact on threatened reptile species is critical. Here we will present novel findings from a large-scale manipulation experiment to determine the impacts of the removal (using poison bait) of black rats from primary rainforest areas on Christmas Island, and the consequential behavioural and population responses of giant geckos. Giant gecko activity levels were found to increase as rat activity dropped, and gecko population density doubled, from 27 to 62 geckos per hectare, when rats were no longer present in high densities in the rainforest, with the greatest effect occurring in the dry season, eight weeks after initial baiting. Interestingly, insect and forest bird activity was also observed to increase with the reduction of rat activity, suggesting the role of the black rat as a predator of other native forest species. This research will assist in predicting the consequences of increased rat predation on Christmas Island's last remaining endemic reptile, helping to guide future management of invasive black rats, and suggests the urgent need for further research on complex interactions between invasive species and native prey on Christmas Island, and a multi-species approach to any further predator eradication.

Effect of *Spartina alterniflora* invasion on benthic macro-invertebrate communities in Guangxi Zhuang Autonomous Region

C. Zhao, J. Li and X. Liu

Chinese Research Academy of Environmental Sciences, Beijing, China. <zhaocy@craes.org.cn>

In order to assess the ecological impacts of *Spartina alterniflora* invasion in Guangxi Zhuang Autonomous Region, we analysed communities of macro-invertebrates in different habitats and with different invasion times of *Spartina alterniflora*. Results showed that Shannon-Wiener index and Simpson diversity indices differed between the *S. alterniflora* wetlands and a mangrove wetland, and macro-invertebrate communities in *S. alterniflora* habitat mainly differed from those of mangrove habitats based on the non-metric multidimensional scaling used in this study. Perhaps due to the invasion of *S. alterniflora*, the bivalve *Glauconome chinensis* became the predominant species, leading to a greater macro-invertebrate biomass in *S. alterniflora* wetlands than in mangrove wetlands. Species composition, biomass and diversity of macro-invertebrates were assessed between the different invasive years of *Spartina alterniflora* including 20 years, five years and one year. Results showed that the community structures of macro-invertebrates were distinctly different between the 20-year *Spartina alterniflora* communities and the other two communities. The biomass of macro-invertebrates decreased with the length of time *Spartina alterniflora* communities were established. No significant differences of richness of macro-invertebrates were found among different invasive years ($p<0.05$). The results also showed all of these changes of macro-invertebrates at different communities or different invasion time were related to the density of *Spartina alterniflora* based on multiple linear regressions.
