Occasional Paper of the IUCN Species Survival Commission No. 62

The papers and abstracts published in this book are the outcome of the Island Invasives 2017 Conference co-hosted by the University of Dundee and the South Georgia Heritage Trust, held at the University of Dundee, Scotland, from 10 to 14 July 2017.

The guidelines for this conference were: "any topic relating to invasive alien species on islands, where the term 'island' is broadly interpreted and (rather ironically from a classical perspective) may include a submarine island – e.g. a coral reef. The invasive species involved may be flora or fauna. Particularly encouraged were papers that relate to the theme of the conference – scaling up to meet the challenge – or to either biosecurity/quarantine or post eradication impacts on native biota."

The editors thank Carola Warner for her assistance with editing of many papers.

All papers have been peer reviewed and we thank all reviewers. The content of the papers is the choice of the authors. The style of presentation has been modified in consultation with the editors. Nomenclature follows international published standards.

This publication has been made possible in part by funding from the South Georgia Heritage Trust.

The papers in this volume were, with a few exceptions, presented at the third Island Invasives conference, held in Dundee, Scotland in July 2017. The conference was attended by 254 people from 41 countries or territories, reflecting growing global recognition of the problems caused by invasive alien species (IAS) on islands and recent progress in solving those problems.

The prefaces of the Proceedings of the two earlier conferences in this series (Veitch & Clout, 2002, Veitch, et al., 2011) discussed many of the threats posed by IAS on islands, conditions for eradication feasibility, possible complications and successes to date. They remain as relevant today as when they were first published. So, what has changed in this field of conservation in the seven years since the last conference proceedings? In a nutshell, scale, diversity and experience.

The first two conferences in the series were influential in bringing together people from many parts of the globe to discuss and exchange ideas, to learn from the experience of others, to inform and inspire. The principal motive for the South Georgia Heritage Trust and University of Dundee to host the third conference in Dundee was a desire to give something back to the island invasives community in recognition of the enormous support and assistance provided by so many people to the South Georgia Habitat Restoration Project. The 2010 Auckland conference, and the contacts made there, were undoubtedly pivotal in guiding the South Georgia operation to success (Veitch, et al., 2011).

The sub-title of the Dundee conference was 'Scaling up to meet the challenge'. The papers in this volume and in the recent literature demonstrate up-scaling in several aspects of eradication operations – not least in ambition, land area, operational size, global reach and of course financial cost. In the space of a few decades, the size of islands treated for invasive species has increased by five orders of magnitude – from a few hectares to over 100,000 ha or 1,000 km^2. Meanwhile, the diversity of species being tackled has increased, as has the range of countries now actively carrying out island restoration work. Inspired by pioneers from New Zealand and Australia, principally, today the movement has spread to islands in all oceans and off all continents. This expansion has been informed by, and has in turn produced, growing experience in all aspects of this field, from non-target impacts to ecological responses to factors affecting eradication success. We now know much more about why some eradication attempts fail, and consequently how to prevent subsequent failures. We know how much operations will cost, and what level of budget contingency to allow – hugely important considerations for potential organisers, fund-raisers and sponsors. Crucially, and due in large measure to the internationally recognised work of the Island Eradication Advisory Group (IEAG – staff of the New Zealand Government's Department of Conservation), operation planners now have access to Best Practice guidelines, and these have underpinned much of the work reported upon in this volume. This field of conservation is remarkable in the degree of mutual support and encouragement between individuals, organisations, countries, and between Government and non-Government institutions.

The Dundee conference was opened by Her Royal Highness The Princess Royal, Patron of the South Georgia Heritage Trust. Lord Gardiner, Parliamentary Under Secretary of State for Rural Affairs and Biosecurity, spoke to the conference about the British Government's support of the South Georgia Habitat Restoration Project and its commitment to confront problems caused by Invasive Alien Species in the United Kingdom and its overseas territories more widely. Both addresses are published in these Proceedings, with kind consent.

Indicative of the level of ambition now influencing the field, several papers in this volume address topics related to the unveiling of *Predator Free 2050*, a campaign to rid New Zealand of its most damaging invasive mammalian predators by the year 2050. If this bold objective is to be achieved, novel tools will be needed to complement the existing arsenal of traps, bait, shooting etc. Among the concepts being considered is that of gene drives – a means of reducing an invasive population to zero by genetic engineering. The potential power of such developments generates both excitement and concern, was the subject of much discussion at the conference and illustrates how the field is adapting to the ever-increasing challenges posed by invasive species worldwide.

Learning from mistakes is a vital driver of progress, yet authors and journal editors alike are often reluctant to publish papers that discuss failure. The editors of this volume have consequently encouraged practitioners to write about what went wrong or could have been improved in their own projects. Such openness is a sign of confidence and of a desire to advance the field, with each operation being informed by the experiences of those that have gone before.

The editors of this volume have summarised what they consider to be key conclusions and lessons to be drawn from the many, diverse papers published within it. They are:

- The size of islands successfully cleared of invasive alien species that have been the target of eradications has increased by an order of magnitude since the previous Island Invasives conference.
- Successful and large-scale eradications of invasive mammals other than rodents from islands continue to occur, although some (e.g. mustelids) present significant challenges.
- There are still relatively few examples of successful eradications of invasive birds, but some have been achieved, despite management challenges and the threat of new incursions.
- The herpetofauna papers really highlight the need for effective border biosecurity to exclude pests as well as information to guide the importation of exotic organisms.
- For invertebrate eradications, principles are the same as for mammal eradications however revisions to criteria to guide terrestrial arthropod eradications are proposed. Adaptive management during eradication attempts is a consistent theme and methodologies to evaluate the response of invertebrate communities to mammal eradications and non-target impacts of vertebrate toxins on endemic molluscs are proposed.
- Plant eradications require persistence over the long term because many species have a seed bank (or similar cryptic life-stage) of high and often unknown longevity: regular surveillance is essential to detect and remove plants as they germinate from the seed bank and before they reproduce. In many situations, eradication is the optimal solution rather than ongoing control.
- Successful eradications of invasive aquatic species continue to be reported and can be achieved using tools and knowledge currently available.
- The presence of human populations can raise the cost and complexity of invasive eradication operations, but investment in community engagement and participation may remove barriers and should be factored in to all future operations on inhabited islands.
- Reviews of single or across multiple operations show the breadth of scope of invasive rat eradications and are important for knowledge sharing and understanding failure.
- Lessons from invasive rat eradications, particularly from those facing complex or novel challenges, are important to inform attempts on other islands.
- Effective biosecurity is essential to prevent new invasions and re-invasions and requires community involvement, proactive planning, monitoring and rapid response.
- Cooperation between indigenous (local) and national governments may allow projects to expand beyond biodiversity conservation to become culturally significant as well, i.e. restoring or aligning with existing traditional knowledge or resource use practices or refining and improving these and bringing them into the realm of the total, diverse human population locally, regionally or nationally.
- Successful eradications of invasive species often yield significant benefits to native species, natural ecosystems and local communities.
- The effect of climate change on invasive species impacts is poorly known, so further research is needed as well as application of the precautionary principle.
- Genetic techniques such as gene drives offer the potential to facilitate eradications on very large scales, but must be treated with caution until more research is conducted on impacts and feasibility.
- As ambition grows, so does the need for new techniques to facilitate eradications on geographical scales never previously considered.

Our field is as much practical as it is academic, and a major aim of publishing these Proceedings is to inform people who are, or will in the future be, planning new projects to free islands of invasive species. Regardless of its location or the target species involved, each successive operation builds on the experience of those who have gone before, and the papers in this volume represent an invaluable wealth of such experience.

OPENING ADDRESS

Her Royal Highness, the Princess Royal

Princess Anne

VICE-CHANCELLOR, LADIES AND GENTLEMEN,

it is a real pleasure to be able to join you for this, the third of the Island Invasive conferences. I can work out by the very fact of their subject matter being islands that these conferences are few and far between, but judging by the programme I have seen for the next five days you are really making up for the gap in between. There are a lot of good things to report and to talk about and to share.

I am delighted that one of those discussions will be about the South Georgia Heritage Trust and the rat eradication scheme that has been underway. It has been a real privilege to visit South Georgia, not once but twice, in order to see some of that work and understand the environment in which the Trust is functioning. I am hugely impressed by just how successful that work appears to have been, though we are not counting our chickens, or indeed any of the other birds that appear to be doing better as a result of the rat eradication so far, and we look forward to being able to prove the project's success in the future.

The progress that has been made in many of the eradication schemes must give enormous encouragement to others, to know now what is really possible and to believe that they can do the same. It perhaps underlines just how important it is to have your methodology, logistics and various other aspects in line before you can begin to have a successful project.

You have here an astonishing gathering of those who have been most involved at both the research and the practical delivery end of these eradication schemes, which covers a pretty wide range of talents. Looking at your conference book there is an enormous diversity of success stories to tell. You have seven of the world's foremost specialists in their respective fields who have agreed to give keynote presentations at this conference. They will talk on a wide range of topics, from island biosecurity to invasive plants and international policy.

Contemplating invasive plants, I have to say, makes eradicating rats look positively straightforward, but I'm sure we will come up with a process for tackling those too. Scotland of course has its own conservation challenges, as we will hear in the keynote speech, which will talk about the Shiant Islands, somewhere that I have also had the pleasure of visiting, not officially but as part of a sailing trip. If you time it right and the puffins are still there it is an extraordinary place, well worth a visit, but it faces similar challenges as South Georgia.

In other islands around Scotland there are other issues to face. An invasive species I can think of in Coll came all the way from New Zealand and is composed of some large and rather successful worms, which everybody hoped would eat themselves out of house and home but have failed to do so yet!

The challenges facing the organisations attempting to remove invasive species from islands are diverse. Progress can be made from the experience of earlier operations and oddly the operations that failed can teach us even more. The South Georgia Heritage Trust has hugely benefitted from the knowledge of the Island Invasives community in tackling South Georgia's eradication work. In deciding to help host this next Island Invasives conference in partnership with the University of Dundee, we really do believe that that will inspire the next generation of island conservationists. Dundee is a very good place to be able to do that, and to the Vice-Chancellor and everybody here from the University of Dundee, thank you for your hospitality.

On our last trip to the island we were in Possession Bay to celebrate Captain Cook's first arrival at South Georgia two hundred years before. When we looked at Possession Bay at that particular moment one could sympathise with Cook as he wondered what on earth he was doing there, but it would be very nice to be able to say that South Georgia had returned to the condition in which Captain Cook found it and claimed possession. We still believe that might be possible, so we look forward to the next couple of years and being able to revisit South Georgia to really prove that the eradication has been a success before we declare the island rodent free. We all understand that 99% success is not quite enough when it comes to removing rats and mice.

I am sure that this conference is something that you have all been looking forward to, but I hope that you enjoy it on a number of different levels, not least for the chance to make friends because however successful you are at communicating online, it is really nice and possibly more encouraging to meet the people who have been involved and can give you that very personal information about what really works, what didn't work and the little things that caused the big problems. And those valuable lessons from each other's experiences will be something that you can all take away, as well as happy memories of your time in Dundee.

KEYNOTE ADDRESS

Protecting the biodiversity of the UK Overseas Territories

Lord Gardiner of Kimble

LADIES AND GENTLEMEN,

It is a great privilege to be here at this Conference and I am delighted to learn more about how we can better protect the biodiversity of our island ecosystems from the threat of invasive alien species.

As you will hear, this week, much has been achieved by passionate and committed conservationists around the world since you last met in Auckland seven years ago. We have a great opportunity this week to celebrate successes and learn from these experiences.

The eradication work completed by the South Georgia Heritage Trust, which you will hear about later this evening from Professor Tony Martin is undoubtedly among the most remarkable of recent island conservation efforts.

As we approach 2020, it is also a good time to reflect on our progress towards the ambitious targets adopted by the global community on invasive alien species as part of the Aichi Targets and the Sustainable Development Goals.

UK successes

The past decade has seen a step-change in how the UK responds to invasive non-native species. We now have a co-ordinating secretariat, a risk analysis mechanism, a GB Strategy and are prioritising species and pathways for action.

My ministerial colleagues and I meet each month to consider emerging threats across the biosecurity spectrum – including animal diseases, plant pests and invasive non-native species. The UK Department for Environment, Food and Rural Affairs and the Scottish and Welsh Governments will soon be putting in place contingency plans to stop over 30 high-risk invasive species getting a foothold in the UK.

This approach was tested last autumn when one of our top threats – Asian hornet – was spotted in the south west of England. My Department had a team on the ground within 48 hours and had successfully eliminated this specific threat within 10 days.

The UK has also completed three further national rapid response eradications, targeting two fish and one amphibian species. Another six eradication campaigns are underway. The biggest of these, the eradication of the Ruddy duck, a world class effort covering the whole of the UK, is now almost complete after more than a decade of concerted effort.

Sadly, some non-native species are here to stay, yet we seek to mitigate their impact. To this end, we have invested over £1m in research on biocontrol agents for several invasive plants.

The Department has also invested in a public-private partnership to research novel methods of grey squirrel control. Scotland is fortunate to have the Red Squirrel still relatively widespread here.

We also recognise that effective awareness-raising is key – for example, the GB Non-Native Species Secretariat is leading an awareness-raising campaign called *Check Clean Dry*, aimed at encouraging anglers and boaters to reduce the risk of moving invasive species between waterways. We adapted this from an excellent New Zealand campaign of the same name.

I believe that it is vital to learn from the experiences and good practice of others. We within the UK are keen to share the lessons that we have learnt and the expertise that we have developed – and to put these at the disposal of the Overseas Territories and in collaboration more widely.

Focus on Overseas Territories

It is clear that much remains to be done to tackle the issue of invasive non-native species. This is why the International Union for Conservation of Nature launched the global Honolulu Challenge last year. In December, the UK Government pledged £2.75 million for priority activities to tackle invasive species in the UK Overseas Territories.

The UK is proud to be custodian of the precious and unique biodiversity of 14 Overseas Territories, which account for over 90% of UK biodiversity and contain two World Heritage sites.

Our pledge shows our commitment to working in partnership with the Territories to address what is probably the single greatest threat to these unique places.

Many of the Overseas Territories are small island environments that are highly vulnerable to environmental change. They contain rare species found nowhere else on the planet; species that have often evolved over thousands of years in isolation from predators, competitors and diseases, and are therefore highly susceptible to invasive threats.

Sadly, we have already seen the loss of some unique species, like the giant earwig of St Helena. Others, like the endangered Henderson petrel, and the Cayman blue iguana, remain under pressure from invasive species. Crucial work is underway to save the Monserrat mountain chicken, a unique frog which nearly disappeared from the island following the incursion of an aggressive fungal disease.

Territory Governments are increasingly alive to these issues and addressing them head on, putting in place biosecurity regimes to prevent new introductions and manage existing threats.

On the ground, the National Trusts of Monserrat and Saint Helena, for instance, have worked in partnership with the RSPB to protect critical habitats and manage the impact of invasives on two unique bird species: the Monserrat Oriole, the national bird of Monserrat, and the Saint Helena Plover, the island's last remaining unique bird. In no small part thanks to these efforts, as of last December, these unique birds are no longer listed as critically endangered.

I am delighted that the Governments of Ascension, the British Virgin Islands, the Falkland Islands, and Tristan da Cunha are here in Dundee this week to share their experiences so we can learn from them.

Honolulu Challenge projects

As part of the UK's contribution to the Honolulu Challenge, the UK Government has committed £1m to support Territories in improving their biosecurity. The GB Non-Native Species Secretariat has already identified the key gaps in practices and capacity. They will now take targeted action to address them, sharing UK expertise on pathway management, horizon scanning, pest identification, and the development of effective legislation.

The UK Government is also contributing £1.75m to support the work led by the Royal Society for the Protection of Birds to restore Gough Island. Seabird populations on the island – including the critically endangered Tristan albatross and Gough bunting – are threatened by invasive house mice that have evolved to become the largest in the world. Every year, an estimated 900,000 seabird chicks are killed. The aerial eradication operation planned for 2019 can turn things around for this precious World Heritage Site. The RSPB, working in partnership with the Tristan da Cunha Government, is making excellent progress in preparing for the operation and is working hard to attract further support for this vital project.

The teams delivering both of these projects are here in Dundee this week. I know that they have planned useful discussions and are eager to draw on your expertise to advance their work. I wish you all possible success.

Learning from experience: South Georgia

Over the past 20 to 30 years, the pace of island eradications has quickened and projects have become increasingly ambitious. But each project tends to build on what has gone before.

We in the UK have learnt a lot from the ground-breaking work that New Zealand, Australia and South Africa have carried out in this field. It is their systems that have been adapted for recent work in South Georgia and that will be applied on Gough Island in 2019.

We have also learnt from the failure of the eradication project on Henderson Island. I know that the island restoration community remains committed to solving such difficult issues.

Tonight, you will hear about what has undoubtedly been one of the most ambitious island eradications carried out to date.

Less than a decade ago, seabirds in South Georgia, including the unique South Georgia pipit, were in decline and increasingly confined to a small number of rodent-free areas.

Remarkably, by 2015, the South Georgia Heritage Trust had completed the final steps of what has been the largest island rodent baiting operation ever attempted.

Great credit is due to the Trust for completing this ambitious operation – and for raising the majority of the funds needed to support it.

When you see Tony's pictures, you will appreciate the harsh terrain and weather conditions faced by the Trust in delivering this project.

Initial reports suggest that the endangered South Georgia pipits are already returning to areas where populations had previously been decimated by rats. This is a great success for the Trust, South Georgia, and the protection of UK biodiversity.

The UK Department for Environment, Food and Rural Affairs is proud to have supported the Trust's work with £885k, including through our dedicated Overseas Territories Environment and Climate Change grant scheme, Darwin Plus.

The South Georgia Habitat Restoration Project sets an outstanding example for island eradications in the UK Overseas Territories and beyond. I hope future island restorations will be able to emulate the project's success.

The Trust's work also well and truly establishes the place of conservation charities – working in partnership with local governments – in the field of island eradications. I would like to pay tribute to the Trust and our other partners in the Overseas Territories, both Governments and charitable organisations, for their vital work.

I am delighted to now be able to hand over to Professor Tony Martin for a full account of the Trust's exceptional work in South Georgia.

I regret that I will not be able to stay for Tony's lecture and the fascinating discussions planned for the rest of this week, as I have to return to London to answer questions in Parliament tomorrow.

It has been a privilege to join your discussions today. I am sure that this will be an inspirational week, which will be the basis for vital progress in the years to come: 44 countries collaborating together is an inspirational force.

Invasive alien species management is an area where we can have a real and immediate positive impact and in many cases reverse the errors of our ancestors and leave the environment in a better state than we found it. It is our generation's responsibility to rise to this challenge and the expertise of all of you at this Conference give confidence and, importantly, hope.

PRESENTED PAPERS

Abstract Invasive rodents have significant negative impacts on island biodiversity. All but the smallest of rodent eradications currently rely on island-wide rodenticide applications. Although significant advances have been made in mitigating unintended impacts, rodent eradication on inhabited islands remains extremely challenging. Current tools restrict eradication efforts to fewer than 15% of islands with critically endangered or endangered species threatened by invasive rodents. The Genetic Biocontrol of Invasive Rodents partnership is an interdisciplinary collaboration to develop and evaluate gene drive technology for eradicating invasive rodent populations on islands. Technological approaches currently being investigated include the production of multiple strains of *Mus musculus* with a modified form of the native t-complex, or a CRISPR gene drive, carrying genes or mechanisms that determine sex. These systems have the potential to skew the sex ratio of offspring to approach 100% single-sex, which could result in population collapse. One goal proposed is to test the ability of constructs to spread and increase in frequency in *M. musculus* populations in biosecure, captive settings and undertake modelling to inform development and potential deployment of these systems. Structured ecologically-based risk assessments are proposed, along with social and cultural engagement to assess the acceptability of releasing a gene drive system. Work will be guided by an external ethics advisory board. Partners are from three countries with significant regulatory capacity (USA, Australia, New Zealand). Thus, we will seek data sharing agreements so that results from experiments may be used within all three countries and treat regulatory requirements as a minimum. Species-specific, scalable, and socially acceptable new eradication tools could produce substantial biodiversity benefits not possible with current technologies. Gene drive innovation may provide such a tool for invasive species management and be potentially transformative and worthy of exploring in an inclusive, responsible, and ethical manner.

Keywords: conservation, CRISPR, genetic biocontrol, invasive species, mice, *Mus musculus*, pest management, public engagement, risk assessment, transgenic

INTRODUCTION

Three *Rattus* species (*R. rattus, R. norvegicus, R. exulans*) and house mice (*Mus musculus*) are, outside of their native ranges, globally widespread invasive species (Capizzi, et al., 2014). These invasive rodents negatively impact stored foods, crops, and infrastructure and can carry pathogens that impact the health of people and their livestock (Stenseth, et al., 2003; Meerburg, et al., 2009; Banks & Hughes, 2012). Invasive rodents cause population declines and extinctions of island floras and faunas and interrupt ecosystem processes with negative cascading effects (Towns, et al., 2006; Jones, et al., 2008; Kurle, et al., 2008; Doherty, et al., 2016). To recover endangered populations and restore ecosystem processes, invasive rodents on islands are increasingly targeted for eradication, with at least 650 eradication attempts of introduced *Rattus* spp. populations to-date (Russell & Holmes, 2015). These and other island-based invasive mammal eradications have resulted in positive responses by native species with few exceptions (Jones, et al., 2016).

Anticoagulants are the most common control method for invasive rodents (Capizzi, et al., 2014). Rodent eradication on any island typically >5 ha has relied exclusively on the use of anticoagulant toxicants incorporated into cereal or wax baits (DIISE, 2016). Second generation anticoagulants are most commonly used and have had the highest success rate (Howald, et al., 2007; Parkes, et al., 2011). However, their broad-spectrum toxicity to vertebrates, duration of persistence, ability to biomagnify, mode of death and negative public perception limit their responsible use (Eason, et al., 2002; Fitzgerald, 2009; Broome, et al., 2015). These features can lead to negative impacts, including for conservation targets (e.g. Rueda, et al., 2016), although significant advances in strategies to mitigate these impacts have been made (e.g. Rueda, et al., 2019). Inhabited islands with children, livestock and pets present significant challenges because eradication is currently limited by a lack of species-specific methods, animal welfare issues, high fixed costs, and socio-political opposition (Campbell, et al., 2015). Hence, even with optimistic assessments for current methods (islands up to 30,000 ha and/or 1,000 people), eradications are possible on fewer than 15% of islands with critically endangered or endangered species threatened by invasive rodents (Campbell, et al., 2015). New species-specific, scalable tools are needed if we are to prevent extinctions.

Genetic biocontrol in the form of gene drives coupled with sex-determining genes to produce single-sex offspring, offers a potentially transformative new tool to add to the rodent eradication toolbox, by offering species-specificity not readily achievable in existing technology (Campbell, et

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 6–14. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

al., 2015). Gene drives cause a gene to spread throughout a population at a rate higher than would normally occur (Champer, et al., 2016). Gene drives occur naturally and are not recent phenomena (Lindholm, et al., 2016); for example, mice with the native *t*-complex gene drive were first described in 1927 (Schimenti, 2014). Attempts to harness naturally-occurring gene drive systems, primarily for invertebrate pests and disease vectors have had mixed results (Sinkins & Gould, 2006; Champer, et al., 2016). In 2012, the Genetic Biocontrol of Invasive Rodents (GBIRd) partnership was formed between North Carolina State University (NCSU), Island Conservation (IC) and later Texas A&M University (TAMU). GBIRd started exploring opportunities for harnessing the native *t*-complex gene drive in mice to eradicate invasive mouse populations on islands (Kanavy & Serr, 2017; Piaggio, et al., 2017). Other partners were identified through professional networks and during searches for specific skillsets. GBIRd currently includes seven partners in three countries: TAMU, NCSU, University of Adelaide (UA), USA Department of Agriculture's National Wildlife Research Center (NWRC), the Agriculture and Food Business Unit of the Commonwealth Scientific and Industrial Research Organisation (CSIRO), Landcare Research (LR), and IC.

Beginning in 2013, a harnessed bacterial immune response system called CRISPR/Cas9 revolutionised the field of genetic engineering. CRISPR/Cas9 can be used to delete, modify or insert new genes more precisely, effectively, time- and cost-efficiently than previous gene editing tools (NASEM, 2016). Multiple genes can also now be edited simultaneously. In 2014, a landmark paper (building upon earlier concepts of Burt, 2003), described how a cassette encoding the CRISPR/Cas9 machinery could be precisely inserted into an organism's DNA, creating a self-replicating gene drive with potential to modify wild populations by design (Esvelt, et al., 2014). Since then, CRISPR/Cas9 gene drives have been developed in yeast *Saccharomyces cerevisiae* (DiCarlo, et al., 2015), fruit fly *Drosophila melanogaster* (Gantz & Bier, 2015) and both *Anopheles stephensi* (Gantz, et al., 2015) and *A. gambiae* (Hammond, et al., 2016) mosquitoes as proof-of-concept demonstrations in biosecure laboratories. This field has become a significant focus of research, and USA and Australian Academies of Science have provided recommendations aimed at guiding its development (NASEM, 2016; AAS, 2017). GBIRd, with its partnership already established, adopted CRISPR as a gene editing and potential gene drive tool.

Gene drives are a technology platform. GBIRd partnership considers *Mus musculus* the logical starting point for developing, exploring, and providing proof-of-concept for a genetics-based invasive vertebrate eradication tool. They are the model vertebrate species for genetics, possess a short generation-time, are small, husbandry is straight-forward, and they are invasive around the world including on many islands (Guénet & Bonhomme, 2003; Phifer-Rixey & Nachman, 2015). Mice are also among the best studied species in terms of mammalian sex determination, reproductive biology, behaviour, genetic manipulation and genetic control of phenotypic traits (Guénet & Bonhomme, 2003; Eggers, et al., 2014; Phifer-Rixey & Nachman, 2015; Singh, et al., 2015). If proof-of-concept, safety, and efficacy are demonstrated in *Mus musculus*, it should be possible to apply this approach to *Rattus* species.

The GBIRd programme (<http://www.geneticbiocontrol.org/>) aims to develop multiple gene drive systems in mice for simultaneous evaluation of safety and efficacy, while carefully assessing the social, cultural and policy acceptability of such an approach. Our staged inclusive approach reflects USA and Australian Academies of Sciences' recommendations (NASEM, 2016; AAS, 2017) that we treat as our minimum standards. The GBIRd partnership aims to provide vital data for conducting risk assessments, determining efficacy, and engaging stakeholders and communities in order to inform and enhance progress, or identify limitations, of future research. A potential longer-term goal is submission of an application to a regulatory agency for release of gene drive constructed mice on a small, biosecure island to test eradication of the wild, invasive mouse population.

This paper provides an overview of the GBIRd programme as it has developed to-date, including the risks and opportunities as they are currently envisioned and understood. These will certainly evolve, and the programme must strategically evolve with them.

Genetic Biocontrol of Invasive Rodents programme

The programme's guiding principles provide context for decision making:

- Proceed cautiously, with deliberate step-wise methods and measurable outcomes;
- Engage early and often with the research community, regulators, communities and other stakeholders;
- Maintain an uncompromising commitment to biosafety, existing regulations, and protocols as minimum standards (e.g. NASEM, 2016; AAS, 2017);
- Use, and participate in developing best practices;
- Only operate in countries with appropriate regulatory capacity; and
- Be transparent with research, assessments, findings, and conclusions.

1. Governance and Coordination

GBIRd involves seven organisations from Australia, New Zealand and the USA; three universities (NCSU, TAMU, UA), three governmental research (CSIRO, LR, NWRC) and one non-governmental non-profit (IC). Each has specific roles and responsibilities (Fig. 1) as detailed in the memorandum of understanding that formalises the partnership. A steering committee comprised of one or two representatives from each organisation provides direction and decision making, and a programme coordinator facilitates activity. The consortium is inclusive and, indeed, strengthened by a transparent internal dialogue in both the scientific positioning (e.g. Gemmell & Tompkins, 2017) and societal/values realm (e.g. Webber, et al., 2015). GBIRd has 14 component areas and three cross-cutting themes (Fig. 1) being investigated, as follows.

2. Gene drives

Three gene drives are currently being investigated; a modified *t*-complex, a CRISPR/Cas9 and a CRISPR/Cpf1 gene drive. The *t*-complex on chromosome 17 in mice is a natural male-transmitted meiotic drive (Lyon, 2003; Schimenti, 2014). The *t*-complex impairs sperm not carrying the *t*-complex, leading to an increased frequency of *t*-complex carrying sperm fertilising ova. The frequency of the *t*-complex in natural populations of house mice is typically lower than predicted given the often very strong transmission ratio distortion displayed. This phenomenon is not completely understood (see Lindholm, et al., 2016), but may imply that a sex-biasing system based on the *t*-complex would require ongoing releases to be effective (Backus & Gross, 2016). The *t*-complex haplotype we are using is free of recessive lethals and has a high rate (>95%) of inheritance, also called transmission distortion (Kanavy

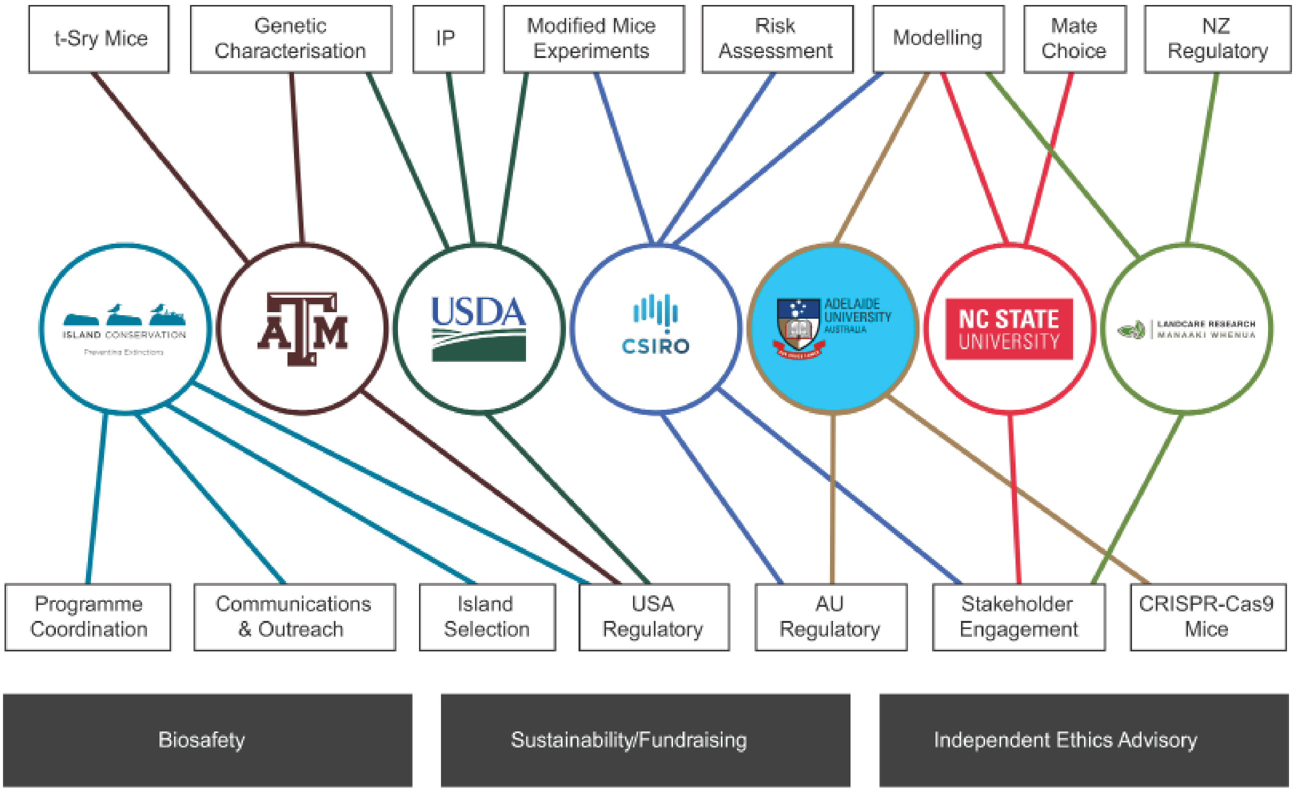

Fig. 1 Programme map, showing 14 component areas being investigated by partners of the Genetic Biocontrol of Invasive Rodents programme. The three components not linked to any organisation are cross-cutting themes.

& Serr, 2017; Piaggio, et al., 2017). The remaining offspring (<5%) would not carry the gene drive or exhibit the phenotypic traits of the genes being driven (Piaggio, et al., 2017).

CRISPR/Cas9 gene drives are capable of >94% inheritance (Gantz, et al., 2015; Hammond, et al., 2016). Once inserted within one individual's genome, a gene drive can work in one of two ways. A zygotic gene drive works when that individual's ova or sperm are fertilised. If the gene drive cassette is activated in the fertilised egg (zygote), the guide RNA (gRNA) directs Cas9 to produce a double-stranded break in the DNA at the target site in the chromosome lacking the gene drive. This triggers the cell's repair mechanism to repair the break using the gene drive-containing chromosome as a template resulting in self-replication of the gene drive. Alternatively, in a germline gene drive, germ cells can be targeted as the stage for self-replication of the gene drive.

3. Targeted genes

Genes can be targeted for deletion, modification or insertion of new genes in conjunction with a gene drive to increase inheritance of specific traits. Investigations currently focus on the appropriateness of two target genes (*Sry*, *Sox9*) to be inserted and one chromosome to be deleted (Y-'shredder'), each in coordination with a gene drive. The *Sry* gene is found on the Y chromosome and is considered the master sex-determining gene in most mammals (Kashimada & Koopman, 2010; Eggers, et al., 2014). Another key component of the testis pathway is the autosomal gene *Sox9*, which acts immediately downstream of *Sry* (Eggers, et al., 2014). Both genes drive the development of male testes in mammals and sex reversal has been demonstrated in transgenic female (XX) mice (Koopman, et al., 1991; Vidal, et al., 2001; Eggers, et al., 2014). A Y-shredder (Adikusuma, et al., 2017) promotes solely offspring with one (XO) or two X (XX) chromosomes, i.e. females. Initial developments focus on *t*-complex with *Sry* inserted (*t-Sry*), and CRISPR/Cas9 and CRISPR/Cpf1 gene drives with *Sox9* and Y-shredder.

As of June 2018, partners attempting to incorporate *Sry* into a *t*-complex drive have been challenged by the large construct size of *Sry*. If that technological hurdle can be overcome, these mice are expected to produce >95% phenotypically male offspring (Kanavy & Serr, 2017; Piaggio, et al., 2017). The mice currently under development in Australia are expected to test the functionality of a split CRISPR/Cas9 gene drive that uses phenotypic coat markers as genetic 'cargo'. A 'split gene drive system' has the gene drive in two separate 'cassettes' (DiCarlo, et al., 2015). This design is a safety feature for laboratory testing where the separation of the cassettes results in drive components being inherited separately even if a drive carrier were to escape, thus preventing drive function (since both are necessary for function). Development of CRISPR/Cpf1 gene drives and incorporating *Sox9* and the Y-shredder are underway.

4. Spatial control of gene drive

Spatially or temporally limiting drive function is one of the major research challenges for CRISPR gene drives, e.g. restricting a gene drive to affect only a single island's rodent population. Our programme is investigating genome-level targeting of population-specific locally-fixed alleles as a potential spatial control mechanism. It is likely that through the process of invasion, founder effects and population bottlenecks, certain alleles across the genome have become fixed in any island population (Britton-Davidian, et al., 2000; Hartl & Clark, 2006). This pattern of fixation is likely a unique genomic signature in every genetically isolated island population. Similar to the molecular confinement strategy being implemented in the laboratory (see *Biosafety*), population-specific locally-fixed alleles (and their sequence) could act as unique gRNA targets for a CRISPR gene drive that will not function outside the island population. Others are investigating alternative approaches to temporally and/or spatially contain gene drives and their relative effectiveness (e.g. Dhole, et al., 2018).

5. Biosafety

Multiple biocontainment strategies accompany all laboratory work and are part of our staged testing pathway (following the recommended approach by NASEM, 2016). Recommended containment standards for gene drives include at least two stringent confinement strategies wherever possible, in addition to containment (Akbari, et al., 2015; NASEM, 2016), and our programme exceeds these standards. For example, the CRISPR gene drive studies are using physical containment at the currently required level (PC2) (AAS, 2017) and three containment/confinement methods; a 'split gene drive system' as explained above (DiCarlo, et al., 2015); coat colour (white or black) to identify the zygotic homing in offspring – white mice (Cas9-positive) are less likely to survive in the wild (Vignieri, et al., 2010); and gRNA exclusively targeting a synthetic sequence not present in wild mice, providing molecular confinement to transgenic laboratory mouse populations. For scaled laboratory trials, CSIRO and NWRC state-of-the-art facilities provide the opportunity to safely conduct trials with colonies of mice that could originate from islands.

6. Safety and efficacy experiments

Experiments demonstrating that constructs work effectively and efficiently, are species-specific and safe to the environment are needed. Data needs for risk assessments and field trial applications have yet to be determined in conjunction with regulatory agencies, and this will dictate minimum requirements for experiments. Experiments will inform risk assessments to reduce uncertainty surrounding outcomes and probabilities. Phased testing and experiments are viewed as part of the development process, and occur at each tier (i.e. molecular level, individual mice, mouse population, ecological community). This phased development process incorporates feedback loops to developers, and evaluates efficiency, stability, specificity and safety to determine whether a specific construct proceeds to the next stage (e.g. molecular to insertion in a mouse or going from individual mice to a colony). Constructs that pass will go on to more rigorous testing, and those that don't will either be dropped or modified and then re-evaluated. No functional CRISPR drives have yet been reported for vertebrates. Attempting development of multiple combinations of gene drives and gene targets within our programme increases the likelihood of success, and, if successful, would provide opportunities for comparative analyses and risk assessments. High-quality data for modelling and risk analyses will be necessary.

7. Mate choice

Behavioural barriers to mating success and resulting gene flow must be considered, as to how (or if) a gene drive will successfully spread through a population, and if understood and used correctly may provide significant advantage. Key characteristics influencing male reproductive success in mice include aggressive dominance for securing territories, and a preference among females for unfamiliar males (Gray & Hurst, 1998; Cunningham, et al., 2013). Promiscuity of male mice and their ability to inseminate many females provides males the potential to disproportionately influence the genetic makeup of future generations. Experiments in the 1980s introducing Isle of Eday mice to the Isle of May (57 ha) demonstrate the power of selecting appropriate stock for facilitating introduced individuals 'invading' another population (Berry, et al., 1991; Jones, et al., 1995). A Y-chromosome (i.e. male) linked marker spread across the Isle of May site within six months and in 18 months only hybrids could be detected (Berry, et al., 1991; Jones, et al., 1995). The 42 Isle of Eday males introduced were estimated at <5% of May's resident mouse population, demonstrating differential success of introduced versus resident males (Berry, et al., 1991; Jones, et al., 1995). We aim to rank the 'invasability' of males from laboratory strains, selected islands and mainlands so that appropriate stock may be selected for backcrossing in gene drives and their cargo. Initial trials involve *t*-complex carrying laboratory mice (C57BL/6/129 strain), Southeast Farallon Island, and F1 hybrid Farallon-laboratory mice in small cages with single males and females, to determine if mating would occur (Serr & Godwin, 2019). (Note: Southeast Farallon Island is not considered a potential site for field trials at this time). Larger arenas were used to determine mate choice and male competition where males from different populations would have to compete for females and resources (Serr & Godwin, 2019).

Behavioural experiments to-date indicate that *t*-complex carrying lab mice can successfully mate with island mice in captivity (Serr & Godwin, 2019). Other mate competition results indicate that male F1 hybrid Farallon-laboratory mice may be able to outcompete male Farallon island mice.

8. Island selection

As part of our staged, stepwise approach, if biosecure laboratory studies support safety and efficacy in biasing sex ratios and supressing test populations, the next stage will involve studies in natural settings under conditions where dispersal or persistence of the organisms outside the evaluation area is restricted (NASEM, 2016). We have identified a suite of ecological criteria for initial selection of potentially appropriate islands for trials, including 1. the island is biosecure (i.e. closed to public or infrequent/controlled visitation; and remote enough (>1 km from other land masses) to avoid unassisted immigration or emigration), 2. no significant challenges exist to treatment using traditional toxicant-based methods to eradicate mice (e.g. no major non-target species, regulatory environment allows the use of brodifacoum bait products, single land manager), 3. *M. musculus* are the only rodent present *or* could be introduced, and 4. the island is reasonably economical and feasible to visit year-round (see Harvey-Samuel et al., 2019 for a more detailed account and rationale). By selecting islands where the use of traditional eradication methods could readily be used to eradicate all rodents (Howald, et al., 2007) a contingency (i.e. exit strategy) explicitly exists. However, these ecological criteria are just a first filter and additional steps would be required prior to any field trial, including engagement with stakeholders (e.g. land managers, local communities) and regulators to determine final approval (Harvey-Samuel et al., 2019).

9. Population genetic characterisation

Genetic characterisation of mouse populations from islands selected for potential trials will occur using next-generation sequencing technologies (e.g. Illumina Mi-Seq). Analyses of these data will inform the feasibility of using population-specific fixed allele sequences as gRNA targets to provide spatial control of any gene drive trialled. They will also provide baseline assessments of genetic characteristics of target island populations, and potentially inform future strategies.

10. Modelling

Modelling can be used to inform broad strategies, such as male or female biasing gene drives and, within those strategies, to identify heritable traits or environmental conditions that provide disproportionate advantages (Bax & Thresher, 2009; Backus & Gross, 2016). Modelling is contemplated at each development stage (i.e. molecular, individual mouse, mouse population, ecological community), incorporating data from experiments and trials, and providing feedback to developers and trial designs. It aims to predict outcomes, reduce the number of animals required in experiments and trials and provide insight on strategies. At the molecular level, for example, the efficiency and stability of homing and non-homologous end joining for Cas9 and Cpf1 zygotic and germline homing approaches can be modelled based on data from experiments informing on likelihood of failure (Prowse, et al., 2017). Models also consider individual mouse characteristics and the effects these may have at the population level. A population model would estimate the number of gene drive mice with certain characteristics required for release to a specific island, the optimal frequency, timing and location of releases, and time until eradication. The impacts of changes to specific mouse characteristics (or other variables) can then be estimated. As data sets accumulate, the accuracy and sophistication of models will increase. The opportunity exists to leverage a 30+ year dataset and existing mouse population models, which will facilitate sophisticated analyses and allow the development of advanced deployment strategies that optimise seasonal and climatic variation (Singleton, et al., 2005; CSIRO, unpub. data). The use of these and other models will be critical in the development of robust ecologically-based risk assessments.

11. Risk assessment

There is the possibility that releases of gene drive-modified organisms will lead to unpredicted and undesirable side effects. Ecologically-based risk assessments (EBRA) aim to reduce some types of uncertainty surrounding outcomes and probabilities (NASEM, 2016; AAS, 2017). They are used to estimate the probability of immediate and long-term environmental and public health harms. EBRAs allow alternative strategies to be compared (e.g. traditional use of toxicants), incorporate the concerns of relevant publics, and can be used to identify sources of uncertainty, making them well-suited to inform research directions and support public policy decisions about emerging gene drive technologies. EBRAs provide the ability to trace cause-and-effect pathways and the ability to quantify the probability of specific outcomes. We regularly consult with risk assessment experts leading other gene drive EBRAs and plan to apply specific tools to identify where, within our development process, additional studies are required to reduce uncertainties, complementing regulatory requirements. The large existing body of work on rodent eradications, including the potential ecological impacts from toxicant use (Broome, et al., 2015) and probability of success of traditional methods (DIISE, 2016), along with meta-data analyses on the ecological impacts of removing invasive rodents (Jones, et al., 2016) will facilitate rigorous EBRAs. Our staged experimental approach prior to any potential release would culminate in trials within biosecure simulated natural environments with colonies of mice imported from the target island(s) with the most efficacious gene drive mice. This allows simulations of various ecological scenarios and increases the power of predictive analyses, resulting in increased levels of certainty around potential outcomes and ecological impacts.

12. Social engagement

The emergence of gene drives and other genetic technologies will force not only technologists, but conservationists, other environmentalists and the public to "negotiate with unfamiliar interest groups and perhaps compromise on deeply held positions if they are going to succeed in a complex world of contradictory perspectives" (McShane, et al., 2011, p. 969). We hope to develop guiding principles to establish dialogue between these disparate groups to identify and eventually negotiate trade-offs, things that should not be traded off, and also to "render explicit the relevant justice dimensions and principles at play in particular contexts" (Martin, et al., 2015, p. 176). The programme aims to establish a transparent process that both encourages public participation and offers a trustworthy and responsible decision pathway for making decisions about releases of gene drive organisms.

Specifically, members of our team have developed a three-part plan for social engagement. First, we will conduct a stakeholder landscape analysis to understand the mix of interests, priorities, concerns, and hopes of diverse stakeholders that surround the programme. Second, we will convene a stakeholder workshop to create a forum for discussion, provide feedback to the technical project team, and strategise the design of community engagements. Third, we propose to organise community focus groups near potential island release sites to engage relevant publics sufficiently early to influence technological innovation and field trial research (see Chapter 7, NASEM, 2016). Importantly, the international nature of our partnership will foster the sharing of best practices – and challenges – of social engagement across different cultural contexts.

To-date, engagements have occurred with publics, scientists, conservationists, indigenous groups and other stakeholders (including those opposing gene drive research, Borel, 2017; Reese, 2017), but more work is required.

13. Communications and outreach

The investigation requires clear, concise, and transparent communications to ensure public perceptions by target audiences are based on facts, and not unduly influenced by scientifically-unsubstantiated fears and hyperbole. Communicating to stakeholders, researchers, communities, and decision-makers interested in this evaluation is the foundation of the programmatic principle of transparency. Coordinated external communications by the partnership's representatives through media, in peer-reviewed publications, presentations, and one-on-one outreach have and will continue to be core to our mission. Informing stakeholders and decision-makers in fora such as the IUCN's World Conservation Congress and the United Nations' Convention on Biological Diversity encourages public discourse about this innovation, engages thought leaders in making our investigations more robust, ensures that fact-based concerns can be addressed while unsubstantiated fears can be allayed, and helps guide decision-makers in developing policies and guidelines complementary to the precautionary, stepwise research guiding principle, even as the technology is being developed.

14. Ethics

There are considerable potential benefits of this technology and we are committed to exploring it in a responsible and inclusive manner. But the question remains, if the technology works, should it be used? This key ethical question is best answered once robust EBRAs have been completed and in the context of rigorous social and regulatory engagement. The USA and Australian

Academies of Science recommend that research continue and decisions to release gene drives continue to be made on a case-by-case basis following a comprehensive environmental risk assessment that includes ecological and evolutionary modelling (NASEM, 2016; AAS, 2017). We have volunteered our programme as a case study for discussion at various fora, including ethical deliberations amongst ethicists and peers (e.g. NCSU Genetic Engineering and Society Center, 2016; Leitschuh, et al., 2018), on national radio (Barclay, 2017) and for the USA National Academies of Sciences Engineering, and Medicine's report on gene drives (case study 4, NASEM, 2016). Emulating the Target Malaria partnership (<http://targetmalaria.org/>), an independent ethics advisory board has been established to provide advice on ethical matters and identify issues for the partnership's consideration.

15. Regulatory

Our regulatory engagement strategy is to ensure transparent and early engagement with the regulatory agencies responsible for the oversight and review of the program. Varying regulatory maturity exists around the world, with Australia and New Zealand having possibly the most developed and mature biotechnology regulatory review processes. The USA is revising regulatory guidelines through the Coordinated Framework for the Regulation of Biotechnology (Barbero, et al., 2017). Currently, in the USA it is likely the Food and Drug Administration will lead regulatory review of GBIRd.

Regulatory data-sharing agreements for registration of pesticides exist between Australia, New Zealand, and USA, and we anticipate that this will carry over to review of biotechnology. The design, execution, and data collection will be compliant with all three countries' regulatory agency requirements or under data sharing agreements.

The regulatory oversight and testing is intended to demonstrate efficacy and safety of the construct, i.e. does it work and what are the ecological consequences. Managing risks associated with its potential release, including capacity to "shut off" in vivo in case of unanticipated consequences is one hallmark of our programme. Testing will take place in a step-wise manner, laboratory development and characterisation, laboratory testing, pen trials and field trials. With the lack of clarity of regulatory pathways at this time, we are engaging regulators early, and have done so in Australia, New Zealand and USA to inform and ideally strengthen regulatory standards, while ensuring open dialogue and regulatory awareness of GBIRd exists.

16. Intellectual property

A patent for RNA-guided gene drives was filed in 2014 and two competing patents exist over CRISPR gene editing technology (Egelie, et al., 2016; AAS, 2017). However, there may be little scope for commercialisation for CRISPR/Cas9 gene drives for conservation and public health purposes (AAS, 2017). The intent of our partnership is to safely and effectively develop and assess this technology in a socially responsible manner that democratises the science involved with the innovation. Our partnership is composed of organisations that are dedicated to the public good potential of this technology. We intend for intellectual property to be secured in a manner that prevents unintended use but allows maximum benefit for communities and environments in need. The mechanisms with which to do this have not yet been identified.

17. Financial

Budget estimates until completion of experimental biocontained trials are uncertain until refinement of constructs to ensure appropriate characteristics is clear. Technical issues may arise, and data needs for risk assessments and field trial applications have yet to be determined in conjunction with regulatory agencies. The timeline for completion of experimental biocontained trials is also uncertain as not all funding has been secured, processes are of uncertain duration in some cases and requirements for experiments have not yet been determined in conjunction with regulators. Considering these caveats, we estimate US$16–22M will be needed over the next 4–5 years to complete experimental biocontained trials.

All programme areas are unfunded or partially funded at this time. We are actively pursuing opportunities for complementary funding.

DISCUSSION

Unlike incremental advancements in current technology or tools, the development of transformative applications cannot be undertaken within existing rodent eradication projects on islands or as part of rodent control on mainlands. Transformative innovations require deliberate intent and focussed programmes. GBIRd includes interdisciplinary scientists, varied experience, backgrounds and viewpoints. An analysis of the hazards associated with a hypothetical split gene drive is underway. If proof of concept of the gene drive can be established in laboratory populations, and suitable target populations can be identified, funding will be sought to perform a risk assessment building on the results of the hazard analysis. GBIRd is also engaging with independent external ethicists to develop best practice ethical conduct for gene drives. Indeed, as a programme we have attempted to maintain a balanced approach and wish to inform future decisions with the best science at that time. This does not preclude pursuing a pathway to broader deployment of this type of technology if, indeed, it proves to be safe, efficacious, and socially accepted.

In addition to impacting biodiversity on islands, invasive rodents also negatively impact the health of people and their livestock, and greatly reduce agricultural productivity, stored food stocks and damage infrastructure. In the future, these problems may also benefit from the application of gene drive systems in invasive rodents. However, the GBIRd programme is currently focussed on the development and evaluation of gene drives in invasive rodents on islands to prevent biodiversity loss. We are committed to a deliberate and step-wise approach following National Academies' recommendations (NASEM, 2016; AAS, 2017).

Eradication is a biological extreme involving all individuals in a population (Parkes & Panetta, 2009). Populations hold a diversity of genes that provide plasticity in behaviours and susceptibilities (e.g. Buckle & Prescott, 2012; Cunningham, et al., 2013). Eradication of a population requires that eradication method(s) overcome this variability (Parkes & Panetta, 2009). That we are looking to develop an eradication (i.e. complete and permanent removal of a population), and not a control (i.e. frequent removal of a portion of a population for perpetuity) tool, is intentional and strategic. Eradication provides permanent solutions and for invasive species is nearly always desirable when it can be achieved (Parkes & Panetta, 2009). Eradication methods may be used for control, but not necessarily vice-versa. Our methods must be robust enough to eradicate populations independent of their variability but specific enough, or controlled in some way, that the global population (especially native populations) are not at risk. The concept of eradication units is a useful way to think of this (Robertson & Gemmell, 2004). Are there alleles shared by all individuals (i.e. fixed) within invasive populations that are not found in the native population, or only a subset of individuals have? Gene drive could be contained under either of these scenarios. GBIRd is attempting to identify island-specific locally-fixed alleles that would provide molecular confinement of the gene drive to the target island population. If this is possible, potential exists for the approach to be scaled (e.g. where locally-fixed alleles can be identified for archipelagos, or for invasive but not native populations). Further, our programme is also researching differential mating success of males between populations to be able to select the most effective stock for transmitting a gene drive and associated genes to a target population.

CRISPR has transformed gene editing and CRISPR gene drives are providing similar transformational opportunities for genetic pest management (Webber, et al., 2015; Harvey-Samuel, et al., 2017). Our partnership was formed prior to these revolutionary tools, providing a ready foundation upon which we expanded our partnership and incorporated these tools, increasing the number of technical approaches and likelihood of success. CRISPR, as an editing tool, has also increased the efficacy of inserting large genetic sequences (e.g. 10kb *Sry*) and due to its precision, efficacy and high success rate has often reduced the number of animals required compared to previous approaches. We anticipate there will be other opportunities, technological or otherwise, that emerge throughout the life of our programme.

CRISPR has been shown to be able to edit DNA in a range of taxa (NASEM, 2016; AAS, 2017) and a CRISPR gene drive has advantages when developing a technology platform, when compared to the *t*-complex drive which may not be effective in species other than mice. However, the *t*-complex provides options and, being naturally occurring in mice, may increase social acceptability, or be technically more appropriate for certain situations. Having multiple gene drives and target genes or mechanisms allows for many potential combinations and simultaneous comparisons in efficacy, safety and acceptability. We are currently investigating various combinations of gene drive mechanisms (i.e. *t*-complex, CRISPR/Cas9, CRISPR/Cpf1) and target genes or deletion mechanisms (i.e. *Sry*, *Sox9*, Y-shredder), providing multiple potential combinations.

Spatial control and remediation of CRISPR/Cas9 gene editing and gene drives has been a major concern and is the focus of significant research. We are keeping abreast of advances in this field and will look to incorporate mechanisms developed where appropriate. Recent research identified CRISPR/Cas9 inhibitors that can block genome editing, providing a means to spatially, temporally, and conditionally control Cas9 activity (Pawluk, et al., 2016; Rauch, et al., 2017). As a nascent field, it is understandable that not all technological concerns have yet been addressed (NASEM, 2016; AAS, 2017), but a significant amount of research is underway to do so.

Few, if any, people are opposed to preventing extinctions but there is mixed opinion about the methods by which this is done. Rodent eradication on islands of any significant size can currently only be implemented with toxicants, the least publicly accepted of all control methods (Fitzgerald, 2009). Gene drives hold promise as putting an additional tool in the practitioner's toolbox that could increase the feasibility and scale of conservation efforts. In contrast to toxicant-based invasive rodent eradication campaigns characterised by a short duration of implementation and high fixed costs (Howald, et al., 2007; Holmes, et al., 2015), gene drive approaches could provide an alternative and flexible financial model. Alternative financial mechanisms such as endowments covering annual costs instead of single campaigns costing tens of millions of dollars may be feasible. If the anticipated species specificity holds true, risks from methods to non-target species (e.g. raptors, Rueda, et al., 2016) would be eliminated and the ability for non-specialists to implement projects would increase. Animal welfare concerns over the mode of death of rodents and non-target species from toxicants could be alleviated by gene drives that bias the sex of invasive populations as no animals would be killed (Dubois, et al., 2017). This approach could also facilitate potential future developments with other invasive mammals beyond rodents, including foxes (*Vulpes vulpes*) and rabbits (*Oryctolagus cuniculus*) in Australia (Kinnear, et al., 2016; AAS, 2017), brushtail possums (*Trichosurus vulpecula*), and stoats (*Mustela erminea*; Owens, 2017) in New Zealand. New Zealand has set a goal of eradicating invasive mammal predators from their country ('Predator Free New Zealand 2050' – New Zealand, 2016). One interim 2025 goal in this strategy is to develop a scientific breakthrough capable of removing at least one small mammalian predator from New Zealand entirely (New Zealand, 2016), and gene drive is one of a suite of potential innovations currently being considered. Globally, invasive rodents are linked to 30% of all extinctions (Doherty, et al., 2016), and currently threaten 88% of all insular critically endangered or endangered terrestrial vertebrates (TIB Partners, 2014). New, scalable, species-specific tools are needed to prevent further extinctions. The opportunity that gene drives as a transformative technology may bring to invasive species management is significant and worthy of exploring in a responsible and inclusive manner.

ACKNOWLEDGEMENTS

This programme's financial support has come from CSIRO, IC, LR, NCSU, NWRC, TAMU, UA, US National Science Foundation (to NCSU; NSF IGERT grant # 000166685), and The Seaver Institute (to IC). Thanks to N. Holmes, G. Baxter and two anonymous peer reviewers for suggestions that improved the manuscript.

Black rat eradication on Italian islands: planning forward by looking backward

D. Capizzi[1], P. Sposimo[2], G. Sozio[1], F. Petrassi[1], C. Gotti[3], E. Raganella Pelliccioni[3] and N. Baccetti[3]

[1]Regione Lazio, Direzione Capitale Naturale, parchi e Aree Protette, via del Pescaccio 96 - 00166 Rome, Italy. <dcapizzi@regione.lazio.it>. [2]NEMO s.r.l., Piazza D'Azeglio 11 – 50121 Florence, Italy. [3]Istituto Superiore per la Protezione e la Ricerca Ambientale, via Ca' Fornacetta 9 – 40064 Ozzano dell'Emilia (BO), Italy.

Abstract Since 1999, the black rat (*Rattus rattus*) has been eradicated from 14 Italian islands, and eradication is ongoing on a further five islands. Most projects were funded by the European Union (EU) Life Programme. Over the years, eradication techniques have been improved and adapted to different situations, including aerial bait distribution on islands with large inaccessible areas, which otherwise would have relied on a manual bait distribution. A priority list of eradications on islands, which was compiled ten years ago, has been met to a large extent, as rats have been successfully eradicated from many islands of great importance to breeding seabirds. Despite some cases of re-invasion occurring in early projects, advances in biosecurity measures have allowed for eradications on islands where this was previously considered unfeasible due to a high risk of re-invasion. This paper reports on black rat eradication work performed on Italian Mediterranean islands with small villages. We show biodiversity benefits of these programmes, but also qualitatively address socio-economic and health impacts on local communities. Eradication projects have faced new obstacles, due to recent changes in legislation which complicated the application of rodenticides and made it very difficult to get permission for aerial distribution of bait on some of the priority islands.

Keywords: biosecurity, cost-effectiveness, invasive alien species, *Rattus rattus*, reinvasion, shearwaters

INTRODUCTION

In recent years, a growing awareness about the importance of the threat posed by alien species on native ecosystems has driven an increasing number of interventions aimed at eliminating or mitigating their impacts. Much of the effort to restore native ecosystems has been directed towards islands, which represent ideal environments for implementing eradication actions, because the impact of alien species may be especially important (e.g. Manne, et al., 1999; Baillie, et al., 2004), and their natural isolation helps to maintain the benefits achieved.

On Italian islands, measures to eradicate rats have had great success. Since the late 1990s, rats have been eradicated, or locally controlled on many islands (Capizzi, et al., 2016), with the EU Life programme providing important financial support, making it possible to achieve significant conservation objectives.

Rat eradications were carried out over the years on islands with different characteristics, and experience built up in selecting context-sensitive materials, techniques and strategies. Indeed, activities were carried out on islands small and large, uninhabited or with small residential areas, flat or with very rough terrain and with significant differences in the presence of non-target species.

Although there have been successes over the years, some mistakes have also been made. In our opinion, a critical review encompassing the activities so far carried out, along with the results achieved, can help to effectively plan future eradications.

In this paper, we review the rat eradication actions carried out in past years as well as those currently implemented, highlighting the progress, problems and constraints experienced so far, and analyse the strengths and weaknesses of the solutions adopted. Our aim is to show that a review of past experiences can have a positive influence on planning for future eradication attempts.

Evolution of techniques and targets

Priority list

Since resources for conservation actions are limited, priority setting is considered a key aspect in defining conservation strategies (Hughey, et al., 2003; Joseph, et al., 2009), including those involving invasive alien species management (e.g. Gallardo & Aldridge, 2013). Capizzi, et al. (2010) established a priority list of islands for rat eradication on Italian islands, considering the optimal allocation of available resources. This prioritisation considered the number of shearwater pairs and the monetary costs of rat eradication on each island, as well as the risk of reinvasion. To date, all the islands in the top five (and seven in the top ten) were included in eradication projects performed or still ongoing (Table 1). Furthermore, recent advances in biosecurity measures have allowed the carrying out or planning of eradications on islands that were previously not included on the priority list because of a high risk of reinvasion, such as Linosa (eradication ongoing) and Ventotene (eradication ongoing).

Island size

Since our eradication projects began, the number of rat free islands has increased considerably. This was possible due to increased experience and confirmation that these interventions bring substantial benefits to birds (see below).

The first eradications in 1999–2000 were carried out on islands of a few hectares (Table 2), but since 2005 rats have been eradicated from islands with an area of over 100 hectares (Zannone, Giannutri, Molara). Since 2012, islands with over 1,000 hectares have also been attempted (success declared in 2014 for Montecristo, ongoing actions on Tavolara and Pianosa).

Field techniques

Bait delivery

In the first eradication programmes, rodenticide baits were placed inside bait stations, at a relatively high density (about 10 stations/ha). In subsequent eradications, involving islands larger than 100 ha (i.e. Giannutri and Zannone, between 2005 and 2006), bait station density was reduced to an average of 4/ha. On Zannone, given its relatively rough terrain, bait distribution, in some inaccessible areas, was carried out by hand-broadcasting from a helicopter, using rodenticide bait blocks, which were secured inside biodegradable dispensers (sections

Table 1 List of islands prioritised for rat eradication (from Capizzi, et al., 2010) and status of eradication interventions. Crosses indicate the presence of the two shearwater species on the various islands.

		Scopoli's shearwater (*Calonectris diomedea*)	Yelkouan shearwater (*Puffinus yelkouan*)	
1	Tavolara	X	X	Eradication planned in 2017
2	Palmarola	X	X	Eradication planned in 2018
3	Montecristo	X	X	Eradication in 2012
4	Pianosa Group (La Scola and Pianosa)	X		Eradication in La Scola (2000), and Pianosa (2017)
5	Giannutri	X	X	Eradication in 2005
6	Santa Maria Group (14 islands)	X	X	No action
7	Molara		X	Eradication in 2009
8	Zannone	X	X	Eradication in 2006
9	Spargi	X	X	No action
10	Soffi Group (four islands)	X		No action

of bamboo trunk). On larger, mainly inaccessible islands, aerial distribution was carried out on the whole island. Bait, in the form of pellets, was distributed using helicopters, with an automated distributor (bucket) purchased in 2008 and used by all projects since then.

Optimisation of active ingredients

In the first eradication projects (e.g. those in 1999–2000 on small islands), both bromadiolone and brodifacoum were used, regardless of the presence of non-target animals. In subsequent years, on larger (> 100 ha) islands (i.e. Giannutri, Zannone and Molara), we relied solely on brodifacoum, which was judged, on the basis of published data, to be the most effective and the most used active ingredient (e.g. Howald, et al., 2007; Buckle & Eason, 2015). However, when dealing with inhabited islands with pets (e.g. Linosa and Ventotene, where eradication is ongoing) and livestock (Pianosa, Tavolara), we chose to perform a two-stage bait distribution, with a different active ingredient. In the first phase (first two distributions), when rat populations were still at a high level, a bait containing an active ingredient less toxic for non-target species was used (e.g. bromadiolone or difenacoum, e.g. Capizzi & Santini, 2007; Buckle & Eason, 2015), thereby reducing the risks of secondary poisoning for animals that could eat dead or dying rats. The use of brodifacoum was limited to the last two applications (second phase), when the population of rats was expected to have been decimated by previous baiting campaigns, and therefore the risk of a poisoned rat (or mouse) being eaten by a non-target species was much lower.

Biosecurity issues

Rat reinvasion following an eradication programme is a real threat (Russell & Clout, 2005; Russell & Clout, 2007), wasting a great deal of time and monetary effort. In recent years, rats have reinvaded some of the islands where they had been previously eradicated (Table 3). Reinvasion occurred as rats swam from neighbouring islands or the mainland (maximum distance of reinvaded islands: 320 m, average distance: 218.6 ± 102.7 m). In the case of Molara, the hypothesis of an unsuccessful eradication was not supported by evidence, as genetic analyses have shown that the reinvading rats were different from the eradicated ones (Ragionieri, et al., 2013). The distance of Molara from other neighbouring islands and the mainland (1,400 m), plus the simultaneous appearance of rabbits, suggests that they have been transported by boat. However, recent progress in the understanding of biosecurity measures, i.e. a better understanding of rat swimming abilities as well as of effective quarantine measures (Russell, et al., 2008; Oppel, et al., 2011), allowed us to plan and complete eradication programmes on islands where there is a boat service and on islands with small villages. Therefore, in 2016, rat eradication was achieved on Linosa, which has a small village of about 500 people, and has just started (January 2018) on Ventotene, which has about 700 residents. If the Ventotene rat eradication is successful, it will be the largest inhabited island in the Mediterranean cleared of rats.

Ecological and socio-economic benefits

Benefits for shearwaters

The detrimental impact of rats on nesting shearwaters has been well documented on several islands, both oceanic and Mediterranean. In the Mediterranean, observed population declines of burrowing seabirds such as Scopoli's shearwater (*Calonectris diomedea*), yelkouan shearwater (*Puffinus yelkouan*), Balearic shearwater (*P. mauretanicus*) and storm petrel (*Hydrobates pelagicus*) was mainly attributed to alien predators, especially rats (e.g. Penloup, et al., 1997; Martin, et al., 2000; Igual, et al., 2006; Baccetti, et al., 2009). Detailed surveys on Italian islands (for survey methods see Baccetti, et al., 2009) corroborated the evidence, showing a large difference in terms of breeding success between islands with or without rats; the latter included both islands where rats had never been present and where they had been eradicated (Capizzi, et al., 2016, Fig. 1). Pooled data from both Scopoli's shearwater and yelkouan shearwater indicated that breeding pairs on islands without rats had much higher breeding success (0.78±0.17, n=15) than those breeding on islands with rats (0.14±0.25, n=11). Rat removal also affected the size of shearwater colonies. At La Scola, ten years after rat eradication, the colony of Scopoli's shearwater increased from 60–100 pairs in 2001 to 150–250 pairs in 2010. At Zannone, after rat eradication (2007) there was an increase in the Scopoli's shearwater colony from 27 pairs in 2007 to 80 pairs in 2016.

The completed rat eradications have rendered over 1,500 ha rat-free, and ongoing or planned projects will likely increase this surface area to 4,500 ha (Fig. 2). Currently,

Table 2 Summary table showing the Italian islands where rat eradication was completed in the period 1999–2017, and those where the intervention is scheduled in coming months, with details on the islands, the interventions and project details. Success (i.e. successful eradication) was established two years after the last sign of rats.

Year	Island	Region	Area (ha)	Distance (m)	Active ingredient	Bait method	Responsible (funding)	Outcome
1999	Isolotto di Porto Ercole	Tuscany	6.5	320	Bromadiolone, brodifacoum	bait station	National Park	successful, reinvaded
1999	Isola dei Topi	Tuscany	1.3	300	Bromadiolone, brodifacoum	bait station	National Park	successful, reinvaded
1999	Peraiola	Tuscany	1	30	Bromadiolone, brodifacoum	bait station	National Park	successful
1999	Palmaiola	Tuscany	7.2	2,950	Bromadiolone, brodifacoum	bait station	National Park	successful
1999	Gemini Alta	Tuscany	1.9	48	Bromadiolone, brodifacoum	bait station	National Park	successful, reinvaded
1999	Gemini Bassa	Tuscany	1.6	120	Bromadiolone, brodifacoum	bait station	National Park	successful, reinvaded
2001	La Scola	Tuscany	1.6	242	Bromadiolone, brodifacoum	bait station	National Park	successful, new incursions (3) promptly eradicated
2006	Giannutri	Tuscany	239.4	11,471	Brodifacoum	bait station	National Park	successful
2007	Zannone	Latium	104.7	5,700	Brodifacoum	bait station	Circeo National Park	successful
2008	Molara	Sardinia	347.9	1,400	Brodifacoum	aerial	MPA	successful, reinvaded in 2010
2008	Proratora	Sardinia	4.5	200	Brodifacoum	bait station	MPA	successful, immediately reinvaded, eradicated 2010, reinvaded in 2010
2010	Isola Piana	Sardinia	13.6	551	Brodifacoum	bait station	MPA	successful
2010	Isola dei Cavalli	Sardinia	2.2	300	Brodifacoum	bait station	MPA	successful, new incursions (2) promptly eradicated
2012	Montecristo	Tuscany	1071	29,410	Brodifacoum	aerial	National Park	successful
2016–2017	Linosa	Sicily	545.1	43,000	Difenacoum & brodifacoum	bait station	Sicily Region (LIFE)	to be confirmed
2017	Pianosa	Tuscany	1026	13,300	Bromadiolone & brodifacoum	bait station	National Park	to be confirmed
2017	Tavolara	Sardinia	602.0	1,150	Brodifacoum	aerial	Municipality of Olbia (LIFE)	started in autumn 2017
2018	Palmarola	Latium	125.1	7,300	Brodifacoum	bait station	Latium Region (LIFE)	started in January 2018
2018	Ventotene	Latium	143.6	43,000	Bromadiolone & brodifacoum	bait station	Latium Region (LIFE)	started in January 2018

Distance = from mainland or other islands in metres. National Park = National Park of Tuscan Archipelago (LIFE). MPA = Marine Protected Area of Tavolara – Punta Coda Cavallo

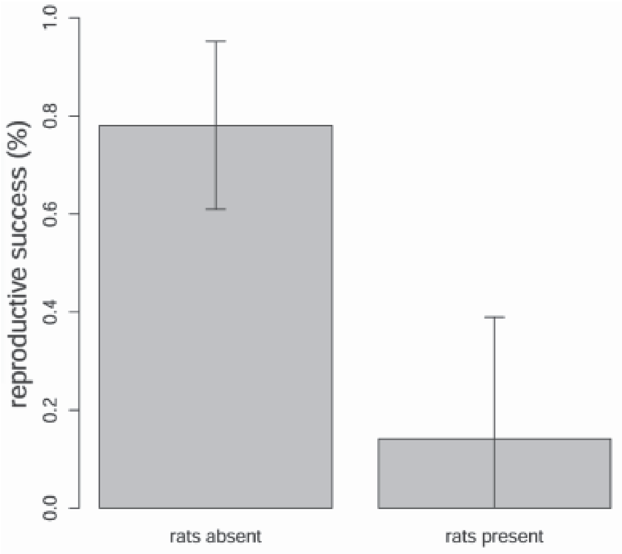

Fig. 1 Boxplot showing mean and standard deviation of breeding success (in terms of percent chick survival) of both shearwater species on Italian islands with (n=11) and without (n=15) rats.

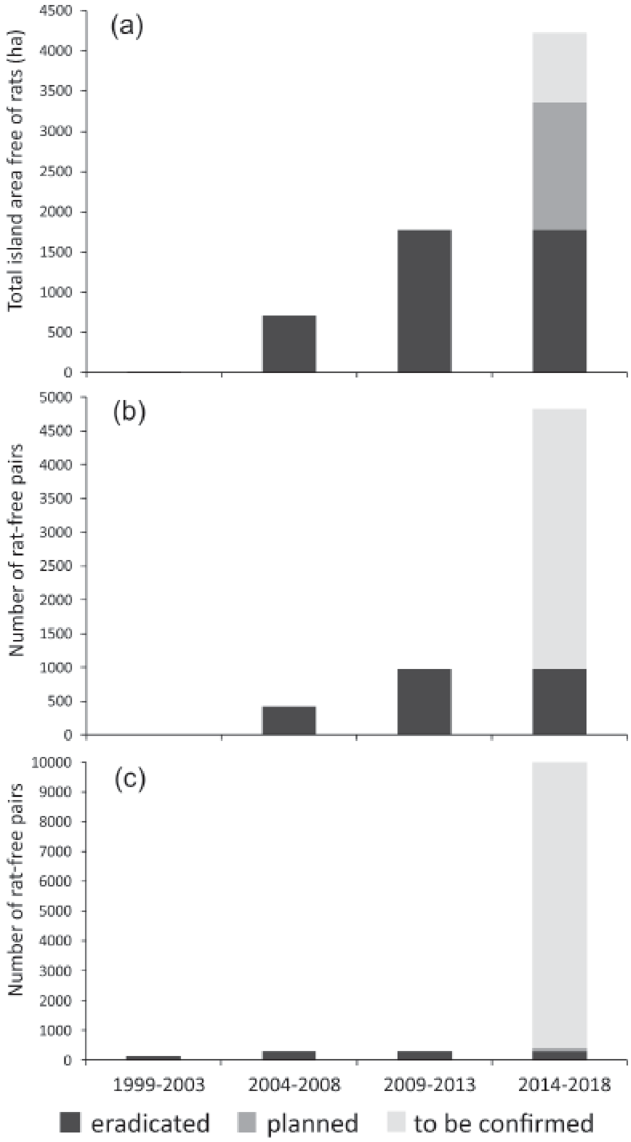

Fig. 2 Results of rat eradications on Italian islands in terms of pest free area and native species recovery since 1999 in five-year intervals a) total island surface area (ha) freed of rats, b) number of pairs of yelkouan shearwater (*Puffinus yelkouan*) and of c) Scopoli's shearwater (*Calonectris diomedea*) released from rat predation. The graphs also include eradications where the outcome is still to be confirmed, as well as those planned in the coming months.

15% of the Italian population of shearwater pairs (both *Calonectris diomedea* and *Puffinus yelkouan* computed as the geometric mean of minimum and maximum estimates, data from Baccetti, et al., 2009, updated when necessary) have been released from rat predation (Fig. 3). Increased benefits to the Italian population will occur with ongoing and planned eradications (i.e. Linosa for Scopoli's shearwater and Tavolara for yelkouan shearwater).

Socioeconomic and public health issues

Islands where rats have been eradicated are uninhabited or host just a few houses. Recently, the possibility of conducting rat eradication programmes on islands with small villages (Linosa, 500 residents, and Ventotene, 700) also provides significant socio-economic and health benefits for residents and tourists (see below). As an example, in Ventotene (120 ha, 700 inhabitants, rat eradication funded within Life PonDerat project), we ran a preliminary survey (performed through interviews to residents, which is still ongoing) to estimate the economic benefits when removing rats. First, in terms of prevented management costs, we estimated the current yearly quantity of rodenticides used to protect crops from rat damage at about 100 kg, corresponding to a yearly overall cost of about €5000. Also, the municipality runs its own pest control activities in public areas, hiring the service of a pest control company at an annual cost of about €3000. Second, rat eradication brings biodiversity benefits. As bait is generally used improperly, by using the most toxic active ingredients (usually brodifacoum) and by distributing baits indiscriminately, the risk to non-target species is apparent. Eradication would reduce these non-target effects. Third, direct damage costs are prevented because a certain amount of crop damage still occurs despite the current use of rodenticides which would also be prevented if rats were eradicated.

Lastly, rat eradication brings health benefits. For example, we recorded a 15.5% prevalence of *Leishmania infantum* in *Rattus rattus* from Montecristo, an island far from the mainland without carnivores (except the sporadic presence of dogs), leading us to identify rats as possible reservoirs and vectors of this protozoan (Zanet, et al., 2014). On inhabited islands (e.g. Ventotene and Linosa), it is likely that rat removal will bring health benefits by reducing the impact of rodent borne diseases, although social costs associated with rodent-borne diseases are difficult to quantify (e.g. World Bank, 2010). On Ventotene, the challenge is to obtain an overall estimate of the benefits of eradication, both ecological and socio-economic (García-Llorente, et al., 2008).

Therefore, the associated economic benefits should also be considered when evaluating the cost-effectiveness of these conservation efforts, as they may confer an added value that can help with public acceptance of this type of project.

Impact on non-target species

Conservationists, researchers and land managers can look pragmatically at the possible loss of individual non-target species, by comparing them with the increased benefits to native species and ecosystems (e.g. Ogden & Gilbert, 2009; Capizzi, et al., 2010; Gillespie & Bennett,

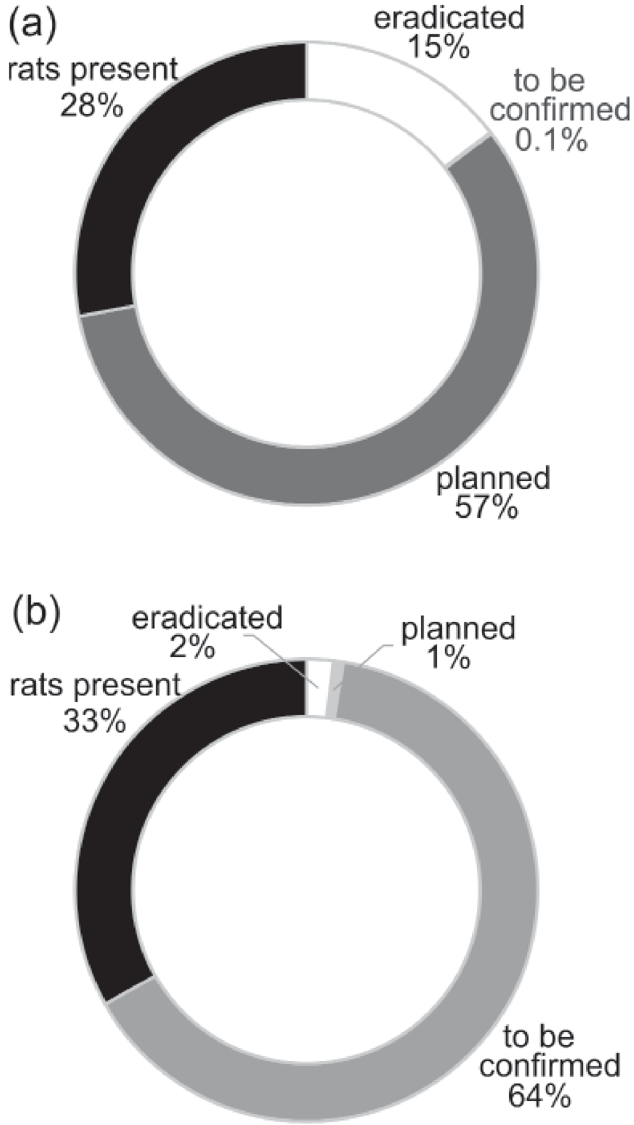

Fig. 3 Percentage of the Italian population of yelkouan shearwater (a) and Scopoli's shearwater (b) nesting pairs released from rat predation.

2017). However, minimal impacts on non-target species are often crucial to the acceptance of the project by the general public and are a significant factor in obtaining authorisation from public authorities. Indeed, much of the concerns of the public and public authorities were around the impact on non-target species, which has been demonstrated to be almost negligible (Capizzi, et al., 2016). In a few cases, the actual non-target impact involved species that, following rat removal, would have become extinct anyway, i.e. a few pairs of nocturnal raptors (barn owl, *Tyto alba*). We did not observe any impact on other rat predators, such as snakes (green whip snake, *Hierophis viridiflavus* and the asp viper, *Vipera aspis*), or birds of prey (kestrel, *Falco tinnunculus* and peregrine falcon, *Falco peregrinus*).

In most cases, populations of lizards (both *Podarcis sicula* and *P. muralis*) and native geckos have increased since rat eradication. The populations of wild or feral ungulates (mouflons and goats, in most cases alien species themselves) did not experience significant impacts, despite some losses of goats on Montecristo. Finally, no impact on pets (dogs and cats), poultry or livestock has been recorded so far.

Unsolved problems and lessons learnt

Authorisation and legal aspects

Limitations resulting from the application of EU Biocide Regulation 528/2012 represent a major obstacle to running eradication programmes, even though this Regulation explicitly accommodates a derogation on the use of rodenticides (Article 43), including aspects relating to the protection of the environment. Italian authorities interpreted the European regulation on biocides to mean that they should only be distributed inside bait stations, thus implicitly forbidding aerial distribution. This has led to legal disputes during the eradication on Montecristo, which were resolved but will cause problems for many eradications to come. For instance, the derogation for aerial distribution on Tavolara (which hosts the largest colony of *Puffinus yelkouan* in the world) was only obtained more than one year after the original request, thereby risking the loss of funding and compromising the outcome of the project.

Dealing with stakeholders

It is well known that communication and information aspects are very important in projects involving the suppression or removal of invasive species to favour native species or ecosystems (e.g. Larson, et al., 2011; Adriaens, et al., 2015). In the case of island communities, the main issue is that, if not properly communicated, actions may be perceived as an intrusion by outsiders. On-site meetings with island inhabitants do not always receive good feedback. In our experience, ensuring a constant presence in the area and establishing positive relationships with locals are paramount to raising public awareness on relevant conservation topics, as well as gaining project acceptance. Public approval is indeed a key factor for rat eradication success on islands (Epanchin-Niell, et al., 2010).

It is also vital to establish a constructive dialogue with port authorities and ship owners, to allow boats and harbours to be monitored, so that rats cannot be transported with the possibility of them being distributed across the island. This is especially important on islands served by regular ship visits, such as those hosting small villages (e.g. projects ongoing on Linosa and Ventotene).

Learning from failures

As mentioned above, the analysis of recolonisations following eradications has allowed us to conclude that islands closely neighbouring other rat-inhabited islands present a high risk of re-invasion after a successful eradication operation. The case of La Scola Island is representative, with three reinvasions in about fifteen years. The eradication of rats from the nearby (320 m) island of Pianosa will solve the problem permanently. Rat eradication on Molara represents a different case of reinvasion. The island was reinvaded a few months after an apparently successful rat eradication, but invading rats were genetically different from the eradicated rats (Ragionieri, et al., 2013). We strongly suspect that this recolonisation event represents a case of sabotage, possibly caused by the hostility of some people towards the project: the simultaneous appearance of rabbits on the island corroborated this hypothesis. This confirms the importance of properly addressing community opinions (Genovesi & Bertolino, 2001) and trying to highlight critical issues that may otherwise compromise the outcome of the project. To avoid the voluntary release of rats on rat-free islands, it is crucial to implement long term biosecurity and provide the necessary human resources for continuous awareness-raising.

Abstract Sand Island, Midway Atoll National Wildlife Refuge (MANWR), is home to 21% of all nesting black-footed albatross (*Phoebastria nigripes*) and 47% of all nesting Laysan albatross (*P. immutabilis*) worldwide. During the 2015–2016 nesting season predation and disturbance by non-native house mice (*Mus musculus*), here documented for the first time, resulted in 70 abandoned nests, 42 adult birds killed and 480 wounded. In the following nesting season the affected area increased, resulting in 242 dead adults, 1,218 injured birds and 994 abandoned nests. Mouse predation activities triggered a mouse control response to reduce mouse densities in the affected areas using multi-catch live traps, kill traps, and limited use of anticoagulant rodenticides in bait stations. In 2016–2017 we applied a pelleted cholecalciferol rodenticide, $AGRID_3$ (Bell Laboratories, Madison, WI), at a rate of 20 kg/ha in all affected areas. The purpose of this study was to evaluate the efficacy of using $AGRID_3$ to reduce mouse density and rate of mouse attacks on nesting albatrosses on Sand Island. Mouse attacks decreased and mouse abundance was reduced following rodenticide applications in the plots treated in December but changes in attack rates in the plots treated in January were not detectable and mouse abundance increased subsequent to treatment. The plots in the December treatments were much larger than those used in January and rainfall rate increased after December. A minimum size of treatment area may be necessary to achieve a reduction in injury rates in albatrosses. No deleterious effects were observed in non-target organisms. The casualties resulting from mouse predation (mostly Laysan albatross) represent a small proportion of the 360,000 pairs nesting on Sand Island. However, the risk to adult breeding albatrosses representing such a large fraction of the global population prompted the United States Fish & Wildlife Service to prioritise mouse control efforts.

INTRODUCTION

Midway Atoll National Wildlife Refuge (MANWR) is home to over three million birds representing 29 species including species of conservation concern and the largest albatross breeding colony in the world. MANWR supports 36% of the earth's black-footed albatross (*Phoebastria nigripes*) and 73% of all Laysan albatross (*P. immutabilis*). Of the three islands that make up the refuge, Sand Island is the largest and provides habitat to approximately 360,000 breeding pairs of Laysan albatross, making it a globally significant colony. House mice (*Mus musculus*) were introduced to Sand Island more than 75 years ago and persisted after black rats (*Rattus rattus*) were eradicated in 1996. Until recently, these non-native mammals appeared to co-exist with the refuge's large seabird populations without harm.

This changed in December 2015 when, shortly after the initiation of the albatross breeding season, severe wounds were discovered on the dorsa of several incubating albatrosses on Sand Island and images from motion-sensing cameras revealed that the source of the wounds were mice (Fig. 1). This was the first time house mice had been observed attacking adult albatrosses and the first documentation of mice preying on albatross in the Northern hemisphere. House mice had not been considered a threat to seabird populations until 2001 when they were found preying on albatross chicks as well as other seabird species at two sites in the Southern hemisphere (Cuthbert & Hilton, 2004; Angel, et al., 2009; Jones & Ryan, 2009).

The discovery of attacks by mice on Sand Island caused immediate concern for wildlife managers at the refuge. Adult mortality has the strongest effect on population growth rates in species such as albatrosses with low fecundity, longevity, high age at first breeding, and prolonged parental care. The loss of the breeding adult is compounded by the loss of its egg or chick, and also reduces the fecundity of its surviving mate, as it often takes more than a year for a widowed bird to find a new mate. In response to the attacks first discovered in December 2015, emergency control efforts were immediately initiated at a 5 m grid resolution over attack areas using a combination of available methods; live traps, kill traps, and difethialone rodenticide applied in bait stations near structures.

When albatrosses returned to Sand Island in the autumn of 2016, surveys were initiated to look for signs of mouse attack and it quickly became clear that mice were attacking the albatross again. Moreover, the rate at which birds were being killed or injured suggested that the 2016–2017 outbreak might be much greater than during the previous year. This time, however, United States Fish & Wildlife Service (USFWS) staff had a plan and were prepared to address the situation. Research had suggested that $AGRID_3$

Fig. 1 Introduced house mouse attacking adult Laysan albatross as it incubates. As captured by a Reconyx trail camera.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 21–25. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

(Bell Laboratories, Madison, WI), a cholecalciferol rodenticide, might provide an effective tool for reducing the number of mice in areas where they were attacking albatross, thereby reducing the impacts to the nesting birds. A plan was developed for applying the rodenticide in affected areas and also for measuring the effects of the treatments on both mice and nesting albatross.

In this paper we describe the mouse predation on albatross that occurred on Sand Island during the 2016–2017 breeding season and the actions taken to abate the threat they imposed on the albatross population there: specifically, a broadcast application of AGRID$_3$ in the areas in which we observed mouse predation on albatrosses. We also describe the monitoring that was undertaken to measure both the direct effects of the rodenticide on the mouse population and the indirect effects that this treatment had on reducing albatross death, injury, and nest abandonment.

MATERIALS AND METHODS

Study area

MANWR is located at the north-west end of the Hawaiian Islands archipelago, 1,930 km from Honolulu, Hawaii at 28.208° N; -177.379° W. One of the oldest atoll formations in the world, MANWR consists of three islands within an 8 km diameter fringing reef. MANWR is classified as a tropical wet/dry savannah with an average annual rainfall of 1,104 mm (43.5 in). MANWR has had a relatively continuous human presence since 1904 when a station was built to support the construction of a trans-Pacific telegraph cable. From 1941 until 1997, Midway Atoll was used by the United States Military during which time both black rats and house mice were introduced. As a consequence, the atoll's ecosystems are highly altered. In 2015 there were 190 species of plants observed, 24 (13%) native and 166 (87%) non-native (Starr & Starr, 2015). The largest, and only, mouse infested island is Sand at 460 ha. MANWR currently supports a resident human community of 50 people along with an operational runway, Henderson Airfield. In 1988 the natural habitats of Midway Atoll began to be managed as part of the National Wildlife Refuge system. Its conservation importance is reflected in its designation as a UNESCO World Heritage Site and its inclusion within the Papahānaumokuākea Marine National Monument.

Baiting methods

During 2016–2017, AGRID$_3$ (Bell Laboratories, Madison, WI), a cholecalciferol rodenticide, was hand-broadcast in all affected areas to reduce mouse populations more effectively and with less disturbance to other wildlife species compared to trapping. AGRID$_3$ pellets contain 0.075% cholecalciferol (non-anticoagulant), which acts by disrupting calcium (Ca) homeostasis through increasing Ca absorption from the small intestine, mobilisation of Ca from the bones into the blood stream, and decreasing Ca excretion by the kidneys (Marshall, 1984). Cholecalciferol has been proven to be toxic and effective at controlling rodents, yet relatively safe to non-target species when used according to label specifications. Due to cholecalciferol's unique mode of action, target specificity, no taste aversion, and delayed toxic effect, it has been successfully used in commensal and agriculture field rodent control situations (Hix, et al., 2012). These attributes make it ideal for use as an interim control measure in the event that eradication is subsequently preferred and approved. The registered use of AGRID$_3$ in the United States has only been for agriculture purposes in the past. The USFWS collaborated with Bell Laboratories, Inc. to develop a supplemental label to be attached to AGRID$_3$ Pelleted Bait (EPA REG. NO. 12455-117-3240). This supplemental label specifically for use by USFWS to control house mice on MANWR was approved by the Environmental Protection Agency for use in a wildland setting.

We hand-broadcast AGRID$_3$ pelleted bait along a 5 m grid (one application within each 25 m^2 square grid cell) over every mouse attack area on Sand Island, as well as a 10 m buffer zone on the periphery of the area, on December 17–18, 2016. Previous experimental bait uptake trials using the protocol described in Pott, et al., (2015), in which we applied placebo bait at 40 kg/ha, marked pellets, and measured pellets taken over a four-day period, led to the selection of 20 kg/ha as an effective application rate under average conditions and 35 kg/ha when mouse density was very high. Following bait application, we surveyed treatment areas to document any sick or injured non-target species or instances of non-target species foraging on bait pellets. We repeated the application at the same rate of 20 kg/ha on 20 January 2017. Over the course of the season from 17 December 2016 to 20 January 2017 we applied 721 kg of AGRID$_3$ to the treatment areas. Areas receiving only a single application included the control plot and impact areas identified after the December application such as Plots 4 and 5. Each application took approximately 440 person-hours to complete.

Non-targets

In order to reduce house mouse predation on incubating albatrosses while minimising the effects (mortality and disturbance) to non-target species, including Laysan ducks and migratory shorebirds, managers treated albatross attack areas where dead adults or abandoned nests were found on Sand Island, MANWR, with AGRID$_3$. AGRID$_3$ was chosen specifically because of its minimal potential effects on non-target species, specifically endangered Laysan ducks (*Anas laysanensis*; listed under the United States Endangered Species Act of 1973) and shorebirds which are protected under the Migratory Bird Treaty Act, particularly bristle-thighed curlews (*Numenius tahitiensis*), Pacific golden plovers (*Pluvialis fulva*), and ruddy turnstones (*Arenaria interpres*). These species were present in large numbers on Sand Island, MANWR, during the mouse attacks and are known to have ingested rodenticide pellets or insects that have consumed bait at other sites where rodent eradication has been implemented. Eason, et al. (2000) documented that mallard ducks fed cholecalciferol at a rate of 2,000 milligrams/kilogram were not affected and concluded that ducks would have to consume 2,000 g (4.4 lbs) of bait with this concentration to receive a lethal dose. Smaller Laysan ducks may consume some bait; however, it is unlikely the ducks would consume enough to cause injury and would need to ingest more than twice their body weight in pellets to experience lethal effects.

Study design and monitoring methods

Starting in December 2016, when most albatrosses had laid their eggs, observers trained to detect mouse-injured albatrosses again searched for, documented, and mapped birds showing signs of mouse attack as well as areas that had an unusually high occurrence of abandoned eggs in nest cups across Sand Island. To avoid double counting, they marked dead adult albatrosses. Nests belonging to injured birds (typically bite wounds, sometimes resulting in severe infection) and abandoned eggs were also marked every three days in the intensive monitoring area (Plot 1). Once the majority of mouse attack areas had been identified, three baiting plots (Plots 1 [16,493 m^2], 2 [15,119 m^2], and 3 [11,740 m^2]) and a control [6,031 m^2] that was not treated with rodenticide were established and monitored for changes in mouse abundance in all plots prior to rodenticide applications on 17 December 2016 and for two weeks afterwards. Two additional baiting plots (Plots 4 [1,900 m^2] and 5 [4,725 m^2]) were added later and monitored for dead adults and abandoned eggs one day before and once at six days and once at 10 days after a second bait application that began on 18 January 2017. The plots were all of different sizes because we chose entire discrete areas in which dead albatrosses and abandoned nests were found to label as attack areas. The control area was smaller than the treatment plots because our priority was to implement a management action as quickly as possible in as much of the colony as possible. General surveillance for signs of mouse attacks continued after hatching in early February and throughout the rest of the chick rearing period.

All nests in Plot 1 were monitored to determine reproductive success, defined as number of nests with an incubating adult present at the beginning of February divided by the total number of nests with eggs present at the start of the study. The reproductive success in Plot 1 was compared to data from plots unaffected by mouse predation that were part of a long-term albatross demography project being conducted at MANWR for the same time interval.

We measured mouse relative abundance in all five plots and the control area two days before rodenticide treatment, one day a week later and one day two weeks after application. We used six multi-catch mouse traps (Trapper 24/7 Bell Laboratories) per treatment area, baited with peanut butter, and summed the number of mice captured over one night for each plot. The traps were centred within the plot ca.10 m from each other. To detect any change in number of mice at each plot, we conducted a one-tailed, paired t-test comparing the mean number of captures prior to bait application with the number of captures two weeks post-treatment ($\alpha = 0.05$). In addition, for Plots 1, 2, 3 and the control area we walked a 150 m transect and counted all mice seen within 2.5 m of the path on either side between 7:30 and 10:00 p.m. the night immediately before the bait application and then one night one week after broadcast and one night two weeks after the broadcast.

We used weather data measured daily at Henderson Airfield weather station located on Sand Island and available from the U.S. National Climate Data Center, <(https://www7.ncdc.noaa.gov/CDO/cdopoemain.cmd?datasetabbv=DS3505&countryabbv=&georegionabbv=&resolution=40>) to evaluate fluctuations in mouse relative abundance over time in the context of rainfall and aid in our interpretation of results.

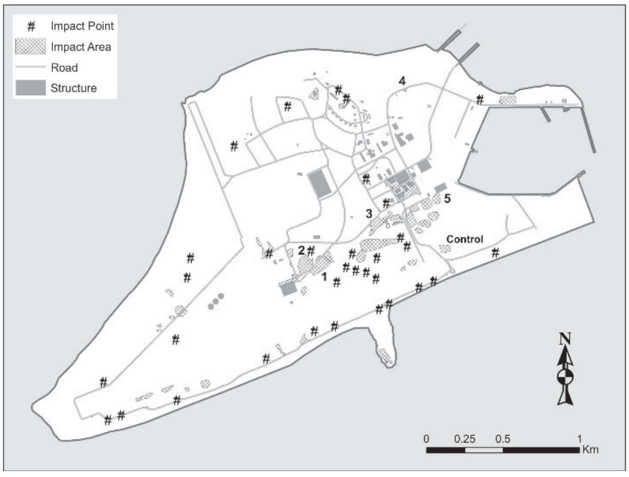

Fig. 2 Areas in which mouse attacks (dead adults, wounded adults, abandoned eggs) were detected in the 2016–2017 albatross breeding season.

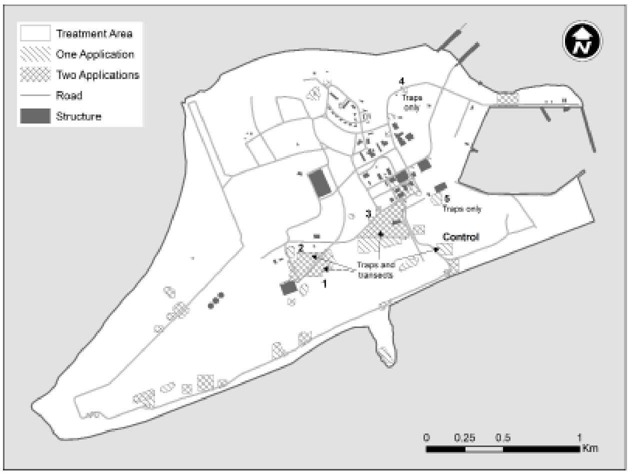

Fig. 3 Areas treated with AGRID$_3$ at a rate of 20 kg/ha December 2016 through January 2017.

RESULTS

Over the course of the 2015–2016 breeding season, mice killed at least 42 adult albatross, wounded an additional 480 birds, and resulted in 70 abandoned nests in three distinct areas, totalling 1.65 ha of Sand Island. During the breeding season of 2016–17 mouse predation was first observed on 4 December, 2016. Numbers of injured and dead adult albatross and abandoned nests increased dramatically in comparison with the previous breeding season. The number of affected areas in the colony increased from three to 50 and the total affected area increased from 1.65 ha to 11 ha (Fig. 2). Albatrosses nest on all of the 460 ha of Sand Island except where they are excluded by active runway paving or structures, so the area affected is still a relatively small proportion of all the albatrosses at Midway. All areas where albatross mortality was detected in 2015–2016 also had mouse predation in 2016–2017. By mid-February there were 242 dead adults, 1218 injured birds, and 994 abandoned nests. This represented a 7-fold increase in mortality, more than double the rate of injury and a more than 10-fold rate of nest abandonment compared to the previous year. The majority of birds found injured and dead were Laysan albatrosses; few black-footed albatrosses were affected. Six carcasses recovered fresh from the area were sent to the USGS Wildlife Health Laboratory in Honolulu in January 2016. Analysis of the specimens revealed that the birds were in excellent body condition with no cause of death evident other than the large wounds on their necks, backs or flanks. Study of the wound sites confirmed the rodent bites occurred before death.

There were no confirmed instances of mouse predation after February 6, 2017, about the time that most eggs started hatching. Most identified mouse attack areas were baited twice before predation stopped in February (Fig. 3). There were no observations of any non-target organism such as shorebirds or Laysan ducks interacting with bait pellets in the field or being found sick or dead in the baited areas.

The number of newly deceased adults and abandoned nests diminished after both bait applications in Plot 1 (Fig. 4) where we were able to conduct more intensive mortality and nest abandonment monitoring every three days. In contrast, during December, the number of abandoned eggs more than doubled in the control area from 10 to 23 but no dead adults were recorded in that area. In January, Plot 4 showed a decrease in the number of abandoned nests after the AGRID$_3$ application but Plot 5 continued to have relatively steady counts of newly dead adults and abandoned nests (Fig. 5). Reproductive success (number of eggs in early February / number of eggs in mid-December)

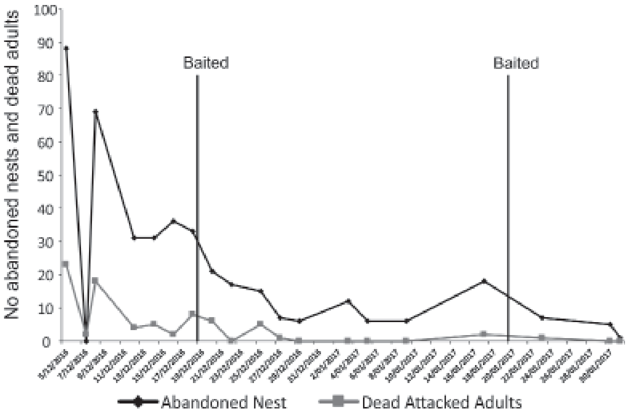

Fig. 4 Absolute counts of new detections of abandoned eggs and dead adults surveyed approximately every three days in Plot 1 throughout the incubation period of breeding Laysan albatrosses at Midway.

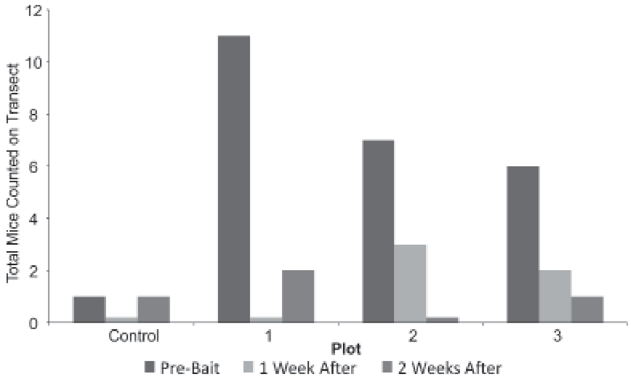

Fig. 7 Total mice counted at night on a 150 m transect (2.5 m to each side) prior to and one and two weeks after application of cholecalciferol bait in Plots 1–3 and a control site on Sand Island during December 2016.

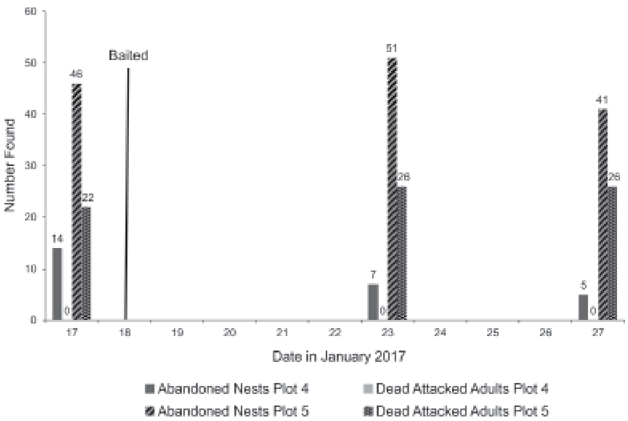

Fig. 5 Count of new detections of abandoned eggs and dead adults in Plots 4 and 5 immediately before and one week and two weeks after baiting.

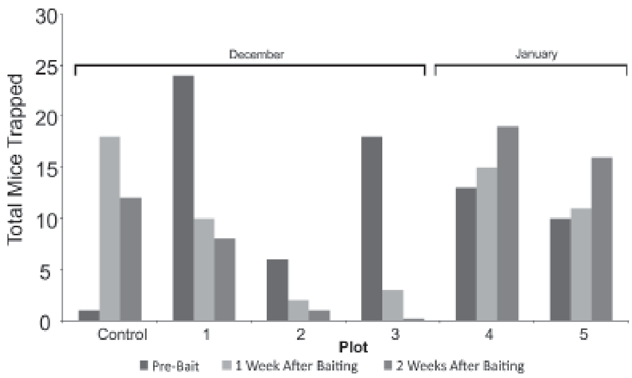

Fig. 6 Number of mice trapped in 6 multi-catch traps per plot, one day before and one and two weeks subsequent to applications of cholecalciferol rodent bait in Plots 1–5, and a control site at Sand Island during December 2016 and January 2017. Only 1 application was done in areas 4 and 5.

in Plot 1 was six percent lower than in the unaffected long-term demography plots.

After the December rodenticide application, the number of mice trapped in Plots 1, 2, and 3 dropped (Fig. 6) (Plot 1 $t(5) = 2.46$ $P = 0.03$; Plot 2 $t(5) = 0.8$ $P = 0.23$; Plot 3 $t(5) = 2.18$ $P = 0.04$). Over the same time period the control site showed an increase in mice trapped ($t(5) = -2.63$ $P = 0.02$). Trapping in Plots 4 and 5, done a month later in January, showed a different pattern with mouse numbers increasing after treatment (Plot 4 $t(5) = -0.99$ $P = 0.18$; Plot 5 $t(5) = -1.66$ $P = 0.08$). Mouse detections on the 150 m transect in Plots 1, 2, and 3 showed a decline after the application of $AGRID_3$ while detections remained much the same in the control plot (Fig. 7).

DISCUSSION

The exposure of a non-negligible proportion of the world's Laysan and black-footed albatrosses to a threat of adult mortality stimulated the management team at MANWR to seek short-term and long-term solutions. The application of a pelleted cholecalciferol rodenticide, $AGRID_3$, in a wildland setting at MANWR, where many non-target species are present, shows promise as a management tool to limit house mouse predation on breeding seabirds without causing harm to the non-target shorebird and duck species that inhabit Sand Island. $AGRID_3$ measurably reduced mouse predation on nesting albatross in the areas where injured and dead albatrosses and abandoned nests were being detected.

While this study was limited in scope and sample size due to the prioritisation of rodent management for the purposes of protecting nesting albatrosses, the larger plots studied during the December application of rodenticide showed decreases in the attacks by mice on albatross as well as some reduction in mouse abundance. The results from the January trial were less promising, showing an increase in mouse density and ambiguous effects on albatross mortality and nest abandonment counts.

There were two differences between the December and January trials that might explain the contrasting outcomes. First, the plots baited in December were much larger in area than the plots baited in January. In a food-limited environment, mice may have been attracted by the bait into the smaller plots elevating the mouse density thus offsetting mortality and mouse population reduction. In an experimental application of cholecalciferol over a much larger area of 100 ha in New Zealand Hix, et al. (2012) observed a 100% reduction of mouse numbers. Second, rainfall increased dramatically over the two months of the study. The increase in rain between December and January might have increased the amount of natural rodent foods within the study area while also leading to higher rates of pellet degradation due to the moister conditions, thus reducing bait availability. There was no control plot established in the January trials so changes in mouse behaviour or abundance cannot be evaluated but Plot 1 continued to show a decrease in mouse attacks throughout the January trial period leading to the possible conclusion that the results in Plots 4 and 5 were due to the smaller plot size. During future efforts to control rodent populations in targeted areas using a broadcast of rodenticide, control areas of at least 1.2 ha should be considered to ensure sufficient coverage to compensate for edge effects.

The decision to apply $AGRID_3$ prior to the albatross breeding season in any particular year may be informed by the likelihood that conditions will trigger mouse predation. Hypotheses about the conditions on Sand Island that may have triggered the emergence of house mouse attacks include population fluctuations of mice and a shift in mouse behaviour due to habitat changes and food availability. Golden crownbeard, *Verbesina encelioides,* an introduced sunflower-relative, was once dominant across the island with coverage now reduced to less than one percent due to control measures ongoing since 2011. We have no evidence that *Verbesina* is consumed by mice, and it is considered a poisonous plant to ungulates (Keeler, et al., 1992) and is allelopathic, thus inhibiting all other vegetation (Inderjit, et al., 2000). *Verbesina* distribution and density was much reduced several years before mice were documented killing albatrosses at Midway. Changes in seasonality of rainfall patterns observed during the 2015–16 and 2016–17 El Niño event may have shifted the timing of normal population fluctuations in the mouse population of Sand Island, in which drying conditions reduce forage and subsequently cause mass-starvation. In 2015–16 and 2016–17 this crash occurred just as albatrosses began the vulnerable incubation period when the adult birds are reluctant to leave their eggs. Rodent populations are well known to fluctuate with rainfall (Jaksic, et al., 1997) and climate change may increase the frequency of El Niño–Southern Oscillation events (Timmermann, et al., 1999), exacerbating the risk to albatrosses in the future. The question of whether there was cultural transmission of albatross predation behaviour in the mice at Sand Island remains open. During 2016–17 the behaviour arose almost simultaneously over much of the island so it seems unlikely.

Preparations for a proposed mouse eradication attempt at Sand Island, MANWR, are underway and the proposed toxicant is brodifacoum. $AGRID_3$, being a cholecalciferol-based rodenticide may be advantageous for control operations prior to a possible eradication to reduce the chance of mice developing aversion or resistance to the type of bait products and toxicants that might be used in an actual eradication operation.

ACKNOWLEDGEMENTS

We are grateful to the managers, staff, and volunteers of Papahānaumokuākea Marine National Monument and Midway Atoll National Wildlife Refuge including Matt Brown, Robert Peyton, Dan Clark, Carmen Antaky, Nasser Hasan, Taylor Smith, Mike Marxen, Katrina Scheiner, Stephanie Kolar, Ann Humphrey, David Dow, Kristina McOmber, Wieteke Holthuijzen, Preecha Songserm, Surat, Surasak Fakkaew, Chatpong Upara, Ek Anan in Uthen, Keely Hassett, Kiah Walker, Aisha Rickli-Rahman, Eric Baker, Beth Wolff, Michelle Smith, Naira DeGarcia, and Victoria Taylor for providing support and assistance at every step. Thanks to Craig Riekena and Amy Breunig at Bell Labs for generous donation of supplies and equipment to allow us to respond on very short notice, USDA-APHIS Wildlife Services for excellent advice, The National Fish and Wildlife Foundation (NFWF) for generous support, US Environmental Protection Agency for rigorous and helpful counsel and Thierry Work of the USGS National Wildlife Health Laboratory for quick diagnoses. The careful reading and fine suggestions from two anonymous reviewers were much appreciated.

Eradicating black rats from the Chagos – working towards the whole archipelago

G.A. Harper[1], P. Carr[2] and H. Pitman[2]

[1]*Biodiversity Restoration Specialists, P.O. Box 65, Murchison 7053, New Zealand. <biodivrestoration@gmail.com>.*
[2]*Chagos Conservation Trust, 23 The Avenue, Sandy, Bedfordshire, UK SG19 1ER.*

Abstract The Chagos Archipelago comprises some 58 islands covering 5,000 ha in the centre of the Indian Ocean. Black rats (*Rattus rattus*) were introduced about 230 years ago and have likely had a severe impact on the native terrestrial fauna, which is dominated by seabirds and land crabs. Most of the archipelago's terrestrial land mass is vegetated with old coconut plantations, with over 75% of the native forest cleared for coconut from 26 of the largest islands. Likely as a result of this colonisation and clearance, at least 30 islands have rats present (95.3% of the Chagos landmass) along with feral cats (*Felis catus*) on 62%, which suppresses the recovery of native fauna and flora. Efforts at rat eradication include the failed attempt on Eagle Island (252 ha) in the northern Chagos Archipelago in 2006 and the recent success of a ground-based eradication on Île Vache Marine in 2014, where two applications of brodifacoum poison were hand-spread at a rate of 18 kg/ha. Two islets on the nearby Salomon atoll were also cleared of black rats during the same operation with single bait applications. The 2014 operation was successful on what are regarded as difficult islands for rat eradication, being 'wet' tropical islands with land crabs and coconut plantations present, and has engendered confidence to proceed with additional rat eradications on other northern Chagos islands.

Keywords: atoll, *Birgus*, Chagos, eradication, hand-broadcast, *Rattus*, seabirds, tropical

INTRODUCTION

Invasive species have caused 75% of terrestrial vertebrate extinctions on islands (McCreless, et al., 2016) and of these species' rats are probably the most pervasive, having been introduced to more than 85% of oceanic islands and archipelagos (Harper & Bunbury, 2015). Rats have been responsible for some 40–60% of all bird and reptile extinctions (Howald, et al., 2007). Rats prey upon and compete with animals and can consume all parts of plants, which disrupts ecosystem function and can cause direct or indirect cascades of collapse, through interruption of pollination and nutrient pathways, seed predation, and in some cases leading to forest collapse (Towns, et al., 2006; Athens, 2009; Towns, 2009; Hilton & Cuthbert, 2010).

Black rats (*Rattus rattus*) have been present on the Chagos Archipelago, in the mid-Indian Ocean, since the late 1700s when the archipelago was settled (Wenban-Smith & Carter, 2016). Diego Garcia is in the southern Chagos Archipelago and is the largest (~2,900 ha) and only inhabited island, with a transient population associated with a military base. It has rats and cats (*Felis catus*) present and there are no current plans for rat eradication. In the northern Chagos Archipelago (~2,100 ha total combined area), 26 of the 55 islands are known or suspected to have black rats present (Carr & Harper, 2015). These rat-infested islands comprise some 1,700 ha in combined total land area or some 47% of the islands in the group. Only 4.7% of the entire Chagos terrestrial space is regarded as mammalian predator free and seabird population density is approximately 20 times higher on rat-free islands (Hilton & Cuthbert, 2010). (Fig. 1).

Low-lying, remote and geologically young (49 mMYA, Duncan & Hargraves, 1990), the Chagos Archipelago has not had the speciation that has developed on similarly isolated elevated archipelagos such as Hawaii and the Mascarene Islands. The atolls of the Chagos Archipelago are largely formed from marine sand deposits with some raised rock formations. Many islands had their native forest removed during settlement and replaced with a dense monoculture of coconut palms (*Cocos nucifera*). As several seabird species preferentially nest in native trees, this destruction of nesting habitat was probably the first major impact on the previously large seabird colonies that existed there (Carr, 2013). This was followed by direct persecution by man and other introduced predators; principally this was rats, cats, dogs and pigs. By the start of the 1900s, the vast seabird colonies now indicated by guano deposits had disappeared (Carr, 2011).

Fig. 1 Map of the Chagos Archipelago showing location of islands mentioned in the text.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 26–30. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

On less anthropogenic-impacted islands the architecture of the native oceanic rain forest allows arboreal nesting by lesser noddy (*Anous tenuirostris*) and red-footed booby (*Sula sula*), whereas the open areas are used by species such as brown booby (*Sula leucogaster*), brown noddy (*Anous stolidus*), sooty tern (*Onychoprion fuscatus*) and the tropical shearwater (*Puffinus bailloni*). Two introduced birds, the domestic chicken (*Gallus gallus*), and Madagascan fody (*Foudia madagascariensis*) are the only land birds resident in the northern Chagos, the former found on only a few islands. Fodies are found on most of the vegetated islands. Land crabs are the dominant invertebrates, with the coconut crab (*Birgus latro*) being the most obvious. Smaller hermit crab species, the burrowing land crab (*Cardisoma carniflex*) and other land crab species are present (Stoddart, 1971a; PC pers. obs.). There is a reviving population of green turtles (*Chelonia mydas*) and hawksbill turtles (*Eretmochelys imbricata*) that nest on some islands (Mortimer & Day, 2009). No native mammals, including bats, exist on the islands.

Rat eradication planning

The Chagos Conservation Trust is championing the eradication of rats from the archipelago, to provide an environment for populations of existing native species to recover and to restore the ecosystem to a state prior to rat invasion (<https://chagos-trust.org/about/vision-and-mission>). This endeavour is in concert with The British Indian Ocean Territory Interim Conservation Management Framework of 2014 (<https://biot.gov.io/biot-interim-conservation-management-framework-september-2014.pdf>), which has an overarching vision: "To maintain and, where possible, enhance the biodiversity and ecological integrity of the British Indian Ocean Territory (BIOT)".

All eradication attempts require comprehensive planning before implementation and this was particularly true for a rat eradication programme on a highly isolated tropical island, which presented a novel suite of problems. Invasive mammal eradication work in the Chagos Archipelago faces both logistical and ecological challenges due to the archipelago's remoteness and inaccessibility, along with the wet climate and the vegetation composition with the significant component of coconut 'chaos'. Île Vache Marine was selected for the initial rat eradication because it was: deemed a realistic and manageable size for a start-up operation; the risk of reinvasion was considered negligible due to its distance from other islands; there were no susceptible non-target species; it nestled in amongst five confirmed or proposed IUCN classified Important Bird Areas (Carr, 2011); there was some anecdotal evidence that shearwaters had once bred on the island and, if successful, the probability of re-colonisation by marine avifauna was likely.

Île Vache Marine (12.4 ha, 2 m elevation) is situated on the southern rim of the Peros Banhos atoll (05°25› S, 71°49› E, Fig. 1). It is a typical tropical low-lying oceanic coralline island and the vegetation comprises a shoreline perimeter of *Scaevola taccada* on the exposed southern coast with introduced coconut and the occasional *Guettarda speciosa* and *Morinda citrifolia* on the coast facing the atoll. The mean annual rainfall for the Peros Banhos atoll (data from 1950–1966) is approximately 4,000 mm, distributed bi-modally, with a slightly drier period through the austral winter (Stoddart, 1971b). Île Vache Marine was never inhabited, but was visited until 1974 for coconut harvesting. The plantation workers would have come from Île du Coin (126 ha), some 6 km distant, the former plantation headquarters and likely source of rats. In 2014 there were very limited numbers of seabirds present.

Previous rat eradication attempts in the Chagos

There was an attempt to eradicate black rats from Eagle Island (252 ha) in 2006. A team of 11 established 2,864 bait stations on a 30 m × 30 m grid of cut tracks starting in early February. The bait stations were loaded with Talon™ wax blocks (0.05 g/kg brodifacoum with bitrex) that was maintained in the stations until the team departed in late April (Meier, 2006). Later checks revealed that the operation had failed.

The Île Vache Marine eradication served two purposes. Firstly, it was an opportunity to undertake a rat eradication operation, albeit small, as proof that the method could be successful in the northern Chagos islands and engender confidence in the technique as a management tool for biodiversity gains in the region. Secondly, it added Île Vache Marine to a string of rat-free islands in eastern Peros Banhos, which were situated amongst Important Bird Areas and within an area designated as a Strict Nature Reserve under BIOT Law.

Rat eradications on tropical islands have a higher failure rate than temperate islands for a variety of reasons, including the presence of coconuts, land crabs as bait competitors, and on 'wet' tropical islands, in particular (Russell & Holmes, 2015; Holmes, et al., 2015). Ground-based operations also have had a higher failure rate than aerial bait applications but are usually cheaper to undertake on small islands, with less logistical and technical input required. Hence, for the rat eradications on the northern Chagos a ground-based eradication was planned for cost and logistical reasons but needed to be very cognisant of the risk factors associated with the islands. A successful outcome for the eradication operation in the face of these impediments would promote confidence in the technique for tropical islands with similar characteristics.

As an adjunct to the planned eradications, an additional bait trial was carried out on Diego Garcia in order to measure bait-take by rats at a measured rat population density and refine bait application rates for future rat eradications on Chagos atolls (Harper & Carr, 2015).

METHODS

Île Vache Marine rat eradication, Peros Banhos atoll

Parallel lines were cut at 25 m intervals across the island in June 2014. This was undertaken by volunteers from the British Forces stationed on Diego Garcia. The timing was important, in that it needed to be done long enough before the operation so that any disturbance did not affect rat behaviour but not too early as re-growth was rapid, particularly in *S. taccada* thickets.

August was chosen as the month for bait application as it was one of the driest months of the year (Stoddart, 1971b) and when a vessel was available. The eradication operation staff assembled the equipment and supplies in Diego Garcia on 31 July 2014 prior to departure on 1 August. The team, GH, PC and members of the British Forces on Diego Garcia, landed on Île Vache Marine early on 2 August to allow passage over the coral reef at high tide. The cut lines were checked and, where required, were either re-cut or additional lines slotted in between existing lines. Sites for bait throwing were marked at 25 m along the cut lines and black plastic bait stations (Protecta LP, Bell Labs, USA) laid at these sites for post-broadcast bait deployment. The bait stations were raised 40 mm off the ground with wooden blocks to reduce interference by hermit crabs. By the end of the first day there was a 25 m × 25 m grid of 154 sites across the entire island. The island size was also reconfirmed at 12 ha by walking the coast of the island with a GPS unit (Garmin 62S).

Bait application trials and eradications on other Indian Ocean islands showed that bait could be spread at a rate of >15 kg/ha and be available to all rats for four nights (Merton, et al., 2002, Harper & van Dinther, 2014). Bait was spread on Île Vache Marine on 3–4 August. Pollard pellet bait (Bell Labs 25W) was hand spread at a rate of 18 kg/ha by GH and PC. This involved hand-throwing bait at each of the grid sites. Bait (280 g) was thrown in four directions at right angles to each other, such that it reached about 10–12 m, along with 280 g spread at the throwing point. Bait spreading by the two operators began at each end of the island and lines were traversed such that the operators were converging on each other. Bait coverage was almost completed on the first day, except for a strip of about 2 ha in the centre of the island. This was covered the next morning and a little additional bait was spread above the high tide mark around the coast of the island where hermit crabs were abundant. All the equipment and empty poison bait containers were removed by the end of the morning. The team departed for Diego Garcia shortly thereafter.

A second bait application was undertaken 11 days later. This was to ensure all rats had access to bait, particularly if breeding was occurring and suckling mothers or young animals may have been missed in the first bait application. The island was revisited on 14–15 August and poison bait pellets (Pestoff 20R) were hand laid at a rate of 18 kg/ha. Differing bait types were used for the two applications as ship rats have been observed with distinct preferences for one or other bait, thus circumventing possible bait avoidance (Harper & van Dinther, 2014). Several recently dead rats were located during the second bait application, suggesting rats had readily consumed the poison bait laid in the first application. The bait stations were also then loaded with wax-based poison baits (Ditrac™ 0.005% w/w brodifacoum, Bell Labs) at a rate of three bait blocks (150 g) secured inside each station. This was to ensure that if heavy rain degraded the bait post-departure, or any rats missed the hand-laid bait, then poison bait was still available for several weeks after the operation. The team departed Île Vache Marine on 15 August at midday. It did not rain during either of the bait deployments.

Bird counts on Île Vache Marine had been undertaken by PC since 2009. Counts in 2014 revealed fewer than five pairs of brown noddy and white tern (*Gygis alba*) and ten pairs of great crested terns (*Thalasseus bergii*), were breeding on the island. About 15 pairs of the one introduced passerine, the Madagascar fody (*Foudia madagascariensis*) were present.

In April 2015, the bait stations were removed by PC and a Connect Chagos graduate (a Zoological Society/CCT project with funding from the UK FCO) during a different expedition.

The eradication phase of Îles du Sel and Jacobin, Salomon Islands atoll

Additional poison bait intended as a contingency for the Île Vache Marine operation was deployed on two islets, Îles du Sel (2.2 ha) and Île Jacobin (1.6 ha), in the Salomon atoll, some 25 km east of the Peros Banhos. These two islands were selected for their small size and their relative isolation from other islands. This meant there was a lower probability of re-invasion by rats than other islands in the area and a single application of the remaining bait was deemed practical. On arrival, a quick survey was carried out immediately before each operation to assess the likelihood of success. Both islands were dominated by coconut, with varying amounts of native forest present, with few other factors that would limit the probability of success, as identified by Holmes, et al. (2015). Of note was the lack of large seeds or seedlings of native trees.

Bait was deployed on Île du Sel and Île Jacobin on 16 August 2014. The islands were circumnavigated and waypoints marked at 25 m intervals on each side of the islands using a GPS unit (Garmin 62S). The operators (GH & PC) then walked from the first waypoint on one side to the corresponding waypoint on the opposite side of each island without cutting the vegetation. Pellet bait (Pestoff 20R) was broadcast at 25 m intervals, using the same method as on Île Vache Marine. Bait was spread at a higher rate of 20 kg/ha on Île du Sel and 25 kg/ha on Île Jacobin as it was a single application. The difference in application rate was due to slightly more bait remaining after the first island was treated.

There were opportunities for post-eradication monitoring on Île Vache Marine by PC as part of other expeditions. The first check was made seven months later in April 2015 with a Connect Chagos graduate during daylight, and during an overnight stay, and no sign of rats was seen. A second daytime check was made by PC in February 2016 and again no rat sign was recorded but signs of vegetative recovery were noted (Table 1). An opportunity for both GH and PC to undertake a more comprehensive survey of the island became available over 9–10 April 2017, when 45 rat snap-traps and wax tags were deployed over a 24-hour period. In addition, coconuts were cut open and placed on the ground near the campsite and searches were made for gnawed seeds/coconuts, rat tracks/caches etc. Additional searches were conducted at night by torchlight to detect rats.

During the same expedition, surveys were made at Île du Sel and Île Jacobin on 15 April and 15 rat detection devices (snap traps, wax tags, secured portions of coconut flesh) were deployed overnight on each island. Searches

Table 1 Initial checks of Île Vache Marine for rat sign.

Date	Event	Results	Responsible
24–25/03/2015	Rodent survey including: a. 50 × snap-traps deployed overnight b. Check for rat gnawing on fallen fruit and flowers c. Check for rat excrement d. Daytime visual inspection of island e. Nocturnal inspection of island (overnight stay)	No sign of rat presence	P Carr C Narina J Schlayer
09/02/2016	Rodent survey including: a. Check for rat gnawing on fallen fruit and flowers b. Check for rat excrement c. Daytime visual inspection of island	No sign of rat presence. Obvious signs of native tree seed germination especially *Guittarda speciosa and* extensive flowering of *Scaevola taccada*	P Carr

were made for signs of rats similar to the operation on Île Vache Marine. The islands were revisited the following morning and detection devices recovered and further searches made.

Diego Garcia bait trial

Two 1 ha plots were set out 200 m apart in disused coconut plantation forest some 2 km west of the small township on western Diego Garcia. The plots were divided into a 5 × 5 grid at 25 m intervals. Within the plots an internal trapping grid of 15 Victor snap-traps was established on an interval of 25 m × 12.5 m. The internal grid was centrally located so that there was a 25 m buffer from the plot perimeter.

Poison bait (Pestoff 25R pellets, Animal Control Products, NZ) was hand-spread on both 1 ha plots at a rate of 15 kg/ha on 7 August 2014. The bait had been dyed with Rhodamine-B, which fluoresces under UV light. After one night to allow rats to access the bait the snap-traps were baited with coconut and peanut butter and set. Trapped rats were collected morning and evening for the next three days. The rats were dissected and their gut cavities examined under UV light for evidence that the dyed bait had been consumed.

To give a simple estimate of rat population density, the number of rats caught was divided by the effective trapping area (ETA). To estimate ETA for rats, a boundary strip was added to the edge of the trapping grids (Dice, 1938). The width of the boundary strip was set by adding the average radius (15 m) of a home range of ship rats from mangrove forest on Aldabra Atoll and forest on Juan de Nova and Europa (Harper, et al., 2015, Ringler, et al., 2014).

RESULTS

Rat eradications in northern Chagos Islands

None of the various indicators used to detect rats during the overnight stay on Île Vache Marine on 9–10 April 2017 showed that rats remained on the island. Prior to the eradication rats had been seen on every previous inspection and were easily trapped both diurnally and nocturnally. Moreover, there had been an increase in breeding pairs of seabird species for pre- and post-eradication counts, including a significant increase in numbers of white tern ($T_1 = -2.32$, d.f. = 6, $p = 0.03$), which are vulnerable to rats, and great crested terns ($T_1 = -4.73$, d.f. = 3, $p = 0.009$).

Similarly, none of the indicators for detecting rats on Îles du Sel and Jacobin showed sign of any rats. Many seeds of the large native tree *Intsia bijuga* had germinated and there was a carpet of 300 mm high seedlings on the forest floor of both islands, along with many untouched seeds. These large seeds appear to be a favoured food of rats, as the seeds and seedlings are rarely found on rat-infested islands.

Diego Garcia bait trial

Sixty rats were removed from traps over the three days; 30 from each plot. There was significant interference with, and removal of, trapped rats by land crabs so this is highly likely to be a minimum number of rats trapped. Of the 60 rats, 59 (98.3%) had eaten dyed bait. The one rat that had not consumed bait was an adult female that was trapped in the first morning after the bait application, so bait had been available for a little over 36 hours. Some bait was still present on the last day of trapping.

Of the trapped rats, only two were juveniles (both female) and there was a slight sex bias towards males (32:28). Several adult male rats were in poor condition, whilst some rats were in good condition with substantial amounts of mesenteric fat. Of the 26 adult female rats trapped, two were pregnant.

The trapping grids within the bait grids were 25 m in diameter and adding a 15 m boundary strip gave a total radius of the ETA of 40 m, for an area of 0.5 ha. At least 30 rats were caught on each trapping grid, which translates to a minimum population density of 60 rats/ha.

DISCUSSION

Rats were eradicated on three small ‘wet tropical’ islands in the northern Chagos with two hand-spread application rates of 18 kg/ha each on the larger Île Vache Marine and single applications of 20 and 25 kg/ha respectively, on the smaller islets Îles du Sel and Jacobin.

Of particular interest was the success of the rat eradications on the very small islets, considering that only one bait application, albeit at a higher initial rate but cumulatively less than on Île Vache Marine, was made on each. Best practice suggests two applications, although it is generally acknowledged that the second application acts as an insurance policy against unforeseen confounding factors, such as heavy rain ruining bait (Keitt, et al., 2015), and because rats can breed year-round in the wet tropics (Russell & Holmes, 2015). In this case the small size of the islands, selection of the driest period of year and well planned rapid bait deployment by a small team is likely to have assisted with operational success as the factors associated with eradication failure on tropical islands were reduced (Holmes, et al., 2015).

Of crucial importance were the parallel and well-cut lines cut in the thick vegetation on Île Vache Marine, such that there were no gaps in bait coverage due to converging tracks. The bait application took 1.5 days, at a rate of about 5 ha/person/day. The bait applications began at both ends of the island simultaneously and a gap in bait coverage was left for one night in both cases, which did not affect the operational success. It is not known whether the bait was degraded by any heavy rain in the days immediately after bait deployment as the team left the area shortly after both applications. Although there were several land crab species, including hermit crabs, present on the island, coconut crabs that can outcompete rats for bait were absent.

It can be concluded that rats can be eradicated from small Chagos Archipelago islands with a minimum toxic bait application of 20 kg/ha, and the trials on Diego Garcia indicate that a 15 kg/ha application rate is too low. This suggests that on similar small islands at least, single applications of poison can successfully remove rats and should be considered in appropriate circumstances. A single bait application has advantages in reduced logistics, cost and possible impact on the environment. Where possible, further bait trials will be undertaken on islands in the northern Chagos Archipelago, to gain more confidence with the amount of bait and bait presentation required. These trials are of particular importance on islands largely dominated by coconut crabs, and with burrowing crab species present (Holmes, et al., 2015; GH & PC, pers. obs.) and where mangrove or *Pemphis acidula* is present at periodically flooded sites (Harper, et al., 2015).

This operation has provided evidence that rats can be eradicated from small wet tropical islands that contain large populations of land crabs and coconut forest that has previously been deemed difficult to achieve (Holmes, et al., 2015). We demonstrate that careful assessment and planning prior to the operation can result in a successful outcome (Keitt, et al., 2015). Given the success of ground-based rat eradication operations on the three small islands in the Chagos Archipelago, an eradication is being planned for larger islands in the near future, such as Île Yéyé (61 ha), which is the only remaining rat-infested island in the eastern Peros Banhos Strict Nature Reserve. If this is successful a larger operation to eradicate rats from all of the northern Chagos Archipelago is likely to be pursued.

ACKNOWLEDGEMENTS

The Chagos Conservation Trust and Dr Grant Harper would like to sincerely thank the UK Government who generously funded this project through the Darwin Initiative. This project would not have been possible without the help and support of several organisations and persons including the British Indian Ocean Territory Administration, London, UK; the BIOT Commissioner's Representative and British Forces, Diego Garcia; the Base Operating Service Contractor (BOSC) on Diego Garcia; the Captains and crews of BIOT Patrol Vessels - *Pacific Marlin* and *Grampian Frontier*; Royal Botanical Gardens Kew and Royal Society for the Protection of Birds. ACP (NZ) generously donated non-toxic bait and rodenticide and Bell Labs (USA) generously donated rodenticide. Two anonymous reviewers provided valuable comments which improved the paper.

Abstract The world is facing a biodiversity crisis. Nowhere is that more apparent than on oceanic islands where invasive species are a major threat for island biodiversity. Rats are one of the most detrimental of these and have been the target of numerous eradication programmes; a well-established conservation tool for island systems. For at-risk native species inhabiting large, populated islands, where rat eradication is not an option, control of rat populations has been conducted but this requires continuous management and therefore its long-term viability (and that of the at-risk native species which the project aims to protect) can be uncertain. Large-scale rat management areas or 'mainland islands' have been successfully developed in New Zealand. However, large-scale management is a long-term investment with huge financial implications and committing to such an investment can be met with reluctance. This reluctance, and its subsequent hindrance to decision-making, can be caused by uncertainty relating to species conservation outcomes, and the multiple objectives of stakeholders. We address the issue of uncertainty and the importance of communication between all stakeholder parties in relation to the Mauritius olive white-eye (*Zosterops chloronothos*), a critically endangered passerine endemic to Mauritius and highly threatened by invasive rats. Specifically, we illustrate how the combination of scientific research and communication, knowledge exchange, and stakeholder workshops, can address some of the barriers of decision-making, helping to bridge the research-management gap, and enable the timely expansion of existing rat management for the benefit of this highly threatened bird.

Keywords: mainland islands, Mauritius, rat control, uncertainty, *Zosterops chloronothos*

INTRODUCTION

The world is facing a biodiversity crisis and nowhere is that more apparent than on oceanic islands where invasive species are a major threat (Jones & Merton, 2012; Rodrigues, et al., 2014). Recent research has identified islands as conservation priority areas for evolutionary distinct and globally endangered (EDGE) species, increasing the importance of conservation for island endemics from areas such as Hawaii, New Zealand, the Mascarenes and the West Indies where there are high extinction rates (Diamond, 1989; Jetz, et al., 2014). A major cause of extinction for island birds has been invasive species and rats are the most detrimental; having reached around 90% of all islands they have been identified as a massive threat to ecosystems (Atkinson, 1985; Towns, et al., 2006; Blackburn, et al., 2014).

The eradication of invasive rats from islands is a well-established conservation tool with 474 successful eradications of *Rattus rattus* and *R.norvegicus* (black rat and brown rat) between 1951 and 2014 (Towns & Broome, 2003; DIISE, 2015). However, for species inhabiting large, populated islands, where eradication is not an option, localised rat control has to be conducted. However, this is not a long-term solution for many species of conservation interest as the areas of control can be too small to create viable populations and rat reinvasion rates can be too high. An alternative are large-scale rat management areas or 'mainland islands' which have been successfully developed in New Zealand (Saunders & Norton, 2001; Butler, et al., 2014). However, large-scale management is a long-term investment with huge financial implications and in a world of limited resources and accountability, committing to such an investment can be met with reluctance (Cullen, et al., 2001; Burns, et al., 2012; McCarthy, 2014; Smith, et al., 2015). This reluctance, caused by uncertainty, could hinder decision-making and result in projects maintaining inadequate small-scale management which does not ensure species survival.

Here we address this issue of outcome uncertainty and the importance of communication between scientists, project managers and stakeholders concerning the Mauritius olive white-eye (*Zosterops chloronothos*), a critically endangered passerine endemic to Mauritius and highly threatened by invasive rats (Maggs, et al., 2015; Birdlife International, 2016). The olive white-eye is part of an ancient Indian Ocean white-eye lineage and is in the top 10% of the EDGE bird species list based on their high level of endemism and evolutionary distinctiveness (Warren, et al., 2006; Jetz, et al., 2014). Research has identified rats (black and brown) as a major limiting factor for olive white-eye, preying on nests and causing an estimated annual population decline of 14%; however, rat management can mitigate this threat and ensure population persistence (Maggs, et al., 2015). Based on these findings, small-scale management has been implemented over remnant olive white-eye breeding territories around the Combo region of the Black River Gorges National Park (BRGNP), Mauritius (Fig. 1; Ferrière, et al., 2016). However, small-scale rat management is not adequate enough to enable olive white-eye population viability in the long-term, highlighting the need for large-scale management in the form of a mainland island (Maggs, 2017).

Here we illustrate how a collaborative approach to conservation management can aid decision-making through communication between scientists, managers, and project stakeholders which can facilitate scaling up small-scale rat control to the implementation of a mainland island. For highly threatened species, such as the olive white-eye, this approach ensures the timely implementation of evidence-based decisions and bridges the gap between research and management.

METHODS

To combat uncertainty, two tools were used; knowledge exchange and stakeholder workshops, in combination with scientific research, to break down some of the barriers to decision-making.

Knowledge exchange

When scaling-up invasive species management there are many logistical and financial considerations. For conservation programmes which have never established such large-scale management, accounting for these considerations and identifying limitations is difficult. Methods and costings of mainland islands have been published (Clapperton & Day, 2001; Gillies, 2002; Gillies, et al., 2006; Scofield, et al., 2011; Burns, et al., 2012; Norbury, et al., 2014; Carter, et al., 2016), but detailed information regularly remains in undocumented individual staff experiences or when data is gathered it remains in inaccessible forms and grey literature. This compounds information inaccessibility resulting in personnel within programmes making decisions based on limited experience rather than evidence (Sutherland, et al., 2004; Pullin & Knight, 2005; Kapos, et al., 2008). Gaining first-hand experience can enable a nuanced understanding of both short and long-term management, which for robust and realistic costing is vital.

To identify the considerations which should be made and gain first-hand information a knowledge exchange was conducted with rat control/eradication experts and conservation managers in the field across New Zealand during April–May 2015. These individuals were identified either through the Hihi Recovery Group, which works closely with numerous mainland island managers, or identifying people through published literature. Using a ‘boundary organisation’ approach (Cook, et al., 2013; Cvitanovic, et al., 2015) scientific researchers facilitated knowledge exchange between experts across New Zealand and project managers in Mauritius. Grey literature and expert knowledge were gathered, identifying potential management techniques and the demands and practicalities involved which aided scientific research.

The sites visited across New Zealand varied in management type and size but all targeted invasive rat species (black and brown). Meetings with the experts and managers were standardised by discussing the same topics, these included:

- Management history. Have other management techniques been previously used, if so, what was the scale of the management and why did it change?
- Identifying mainland island area. What process was used to identify locations, what were the constraints and benefits considered, how were topography and river courses tackled and what was the conservation objective of the mainland island?
- Management technique. What rat management technique is currently used, over what area, and how long has it been in place, is there a buffer zone, how many staff and volunteers work on the site, have additional techniques been trialled and if so what were the outcomes?
- Maintenance. How often are the traps/stations/fence checked or re-baited, how long does this take and how many staff members does this require, what maintenance demands are there, how often does equipment need replacing and how do weather conditions impact the management and work load?
- Management efficiency. Is rat abundance or presence monitored in the management site, if so, what is the rate of rat incursions or rat abundance and is there a response protocol and if so how quickly is this implemented?

Stakeholder workshops

Improving knowledge exchange between decision–makers and scientists is fundamental to support sustainable evidence-based management. However, despite evidence being available, in some cases decisions can still remain hindered due to multiple objectives from a mix of stakeholders with differing priorities, values or conflicting interests (Conroy, et al., 2002). Science can help overcome these obstacles by providing tools to inform decisions and aid stakeholders to make informed trade-offs if required.

An approach termed ‘interdependency’ recognises that all participants in knowledge exchange can contribute, emphasising the need for a two-way exchange between scientists and decision-makers (Contandriopoulos, et al., 2010; Cvitanovic, et al., 2015). This can increase understanding and stakeholder communication through access to the best scientific information, enabling science-based decision-making (Meek, et al., 2015). This process supports collaboration and bridges the research-implementation gap (Knight, et al., 2008), but requires the roles of participants to be outlined from the start to ensure clarity throughout the workshop process; identifying expert advisors, decision-makers or workshop facilitators to mediate between stakeholders.

To ensure collaboration between scientific researchers and decision-makers and avoid conflicting interests, a stakeholder workshop was held in the case of the olive white-eye. During this workshop there were three main objectives to be considered by decision-makers when tackling development from small-scale localised management to a large-scale mainland island: should a mainland island be established, what size it should be to enable population viability and management cost-effectiveness. The workshop was facilitated by scientific researchers, from the Zoological Society of London (ZSL) and University College London (UCL), who provided expert advice on these three objectives; this was accompanied by field staff providing first-hand information on the status of the species and the current management in place from the Mauritian Wildlife Foundation (MWF) (Ferrière, et al., 2016).

Scientific research on the olive white-eye has successfully developed decision-making tools identifying the mainland island area required to ensure population persistence and management cost-effectiveness (Maggs, 2017). These decision-making tools outline scenarios and assist in identifying informed, evidence-based management for the remnant olive white-eye population, ensuring population persistence and clear financial and logistical requirements over 50 years (see Maggs, 2017 for details). Using these tools, discussions were held between the expert advisors (scientific researchers and field staff) and the key decision-makers (project managers, organisation directors, project funders and government officials) where the scientific evidence was discussed, expert opinion shared and questions raised through open dialogue and in a transparent environment.

RESULTS

Knowledge exchange

In total, over four weeks, 30 individuals participated in the knowledge exchange including managers and volunteers from eight mainland island sites and experts from additional conservation companies, central government (Department of Conservation) and specialist groups across New Zealand (Fig. 2). The rat management techniques identified across these sites and discussed included trapping, ground-based poisoning, self-resetting traps and predator-proof fencing. The information gathered through the knowledge exchange was vital for the detailed long-term budgeting of a mainland island in Mauritius

Fig. 2 The distribution of the mainland islands visited during a knowledge exchange in April and May 2015 and the organisations who participated: Hihi Recovery Group, Biodiversity Restoration Specialists, (1) Shakespear Open Sanctuary (Auckland Council), (2) Tawharanui Open Sanctuary (Auckland Council), (3) Sanctuary Mountain Maungatautari, (4) Boundary Stream Mainland Island (Department of Conservation), (5) Rotokare Scenic Reserve Trust, (6) Bushy Park Sanctuary, (7) Zealandia, (8) Rotoiti Nature Recovery Project (Department of Conservation).

under each of the four management techniques, providing detail into the equipment and materials required and labour demands. This first-hand information was combined with existing literature and fed directly into scientific research conducting cost-effectiveness analysis for the four rat management techniques, accounting for the costs over 50 years. By accurately budgeting each management technique over 50 years the long-term cost-effectiveness of the four rat management techniques against olive white-eye population quasi-extinction risk were robustly illustrated; which acts as the effectiveness score of the rat management techniques (Table 1; see Maggs, 2017 for full details).

Stakeholder workshop

Eighteen delegates from six organisations participated in the stakeholder workshop; these included project management (MWF), organisation directors (MWF and Durrell Wildlife Conservation Trust), scientific researchers (ZSL and UCL), project funders (Chester Zoo) and government officials (National Parks and Conservation Service).

The olive white-eye is a priority species for conservation in Mauritius and it was decided, based on the scientific findings presented, that a mainland island should be established, aiming for the minimum area identified by Maggs (2017) of 275 ha; required at a low population density to ensure a 99% chance of population persistence over 50 years. Using the cost-effectiveness analysis conducted by Maggs (2017), and presented at the workshop, the rat management technique decided upon was Goodnature®A24 self-resetting traps based on their cost-effectiveness, specifically, their low labour requirements and competitive financial costs (Maggs, 2017). Although a relatively new technique, their long-term costs, maintenance and replacements, were accounted for based on manufacturer recommendations; the same long-term costs were accounted for all of the techniques discussed.

Trapping was considered too labour intensive even though it was highly cost-effective when considering equipment costs alone. Poison was ruled out based on the potential environmental impacts and the overall high cost of poison and associated labour. Predator-proof fencing was not considered as an option based on the huge initial setup cost and the long-term financial commitment, also the habitat loss associated with installing a predator-proof fence (at least 8m of forest would need to be cleared both sides of the fence to prevent mammals jumping over (Day, 2004); with highly threatened flora species within the BRGNP this cannot be justified at this time). Fencing is the most cost-effective technique when creating a mainland island over vast areas and could maintain zero rat densities, which the other techniques cannot achieve, but complete rat removal is not required for olive white-eye viability, merely reduced rat densities. The techniques combined were not discussed but could be in an additional option to consider in the future.

As well as the rat management technique it was also identified that the mainland island would have to take a 'multi-species/multi-threat' approach, targeting a number of invasive species until the impact of individual species is known in order to avoid the 'surprise factor' of secondary unexpected and undesired results (Alterio, et al., 1999; Saunders & Norton, 2001; Caut, et al., 2009; Carter, et al., 2016). This would involve targeting small Indian mongoose (*Urva auropunctata*), feral cats (*Felis domesticus*) and potentially crab eating macaques (*Macaca fascicularis*) as well as rats. This level of predator control would also benefit other highly threatened endemic species such as the Mauritius cuckoo-shrike (*Coracina typica*), echo parakeet

Table 1 The minimum area required for a mainland island to ensure a 99% chance of population persistence for the Mauritius olive white-eye over 50 years, the total cost of establishing and running a mainland island over 50 years, the establishment costs alone and the average annual costs; comparing trapping, ground based poisoning, self-resetting traps and predator-proof fencing (Maggs, 2017).

	Area (ha)	Total Cost (£ millions)	Establishment Costs (£)	Annual costs (£)
Trapping	275	2.9	186,700	37,908
Poisoning	300	7.9	40,925	157,913
Self-resetting traps	275	3.8	130,315	37,505
Predator-proof fencing	275	5.7	1,766,472	80,196

(*Psittacula eques*) and Mauritius pink pigeon (*Nesoenas mayeri*), which are found within the same regions.

Finally, it was suggested that, if possible, the site of a mainland island should be combined with existing conservation management areas (CMAs), which have been established on mainland Mauritius in the BRGNP to protect native vegetation communities by removing exotic flora (Cheke & Hume, 2008). The control of rats would encourage habitat regeneration and resources could be combined for both invasive fauna and flora control.

DISCUSSION

This case study aimed to illustrate how a collaborative approach to conservation management, through knowledge exchange and stakeholder workshops, can aid communication and decision-making. In this case, it was used to guide the timely expansion of rat management from existing small-scale control (32 ha) to a mainland island (275 ha), relatively quickly and effectively, which is vital for highly threatened and declining species, such as the olive white-eye.

A mainland island has never been established in Mauritius. The rat management techniques used for the olive white-eye have been limited to localised snap-trapping and ground-based poisoning (Maggs, et al., 2015). In the past, feasibility studies have been conducted for various techniques, including predator-proof fencing, but taking the step from localised to landscape scale management was not taken due to resource limitations and long-term financial and logistical uncertainty (Day, 2004).

Here we have tackled the barriers of logistical and financial uncertainty and decision-making through a 'co-production' approach with full cooperation between scientific researchers and decision-makers (Cvitanovic, et al., 2015; van Kerkhoff & Lebel, 2015). Conducting knowledge exchange allowed project managers to gain first-hand information and fill knowledge gaps from leading experts in the field of invasive species management. Incorporating this into a robust analysis of the financial and logistical requirements of a mainland island helped to minimise uncertainty, justify expenditure and identify the long-term financial support required from funders (Maggs, 2017). A stakeholder workshop then allowed scientific research to be fed directly back to all involved, successfully highlighting project priorities and enabling all participants to come to a unified decision on future management goals for the olive white-eye; guiding science-based conservation while maintaining transparency among stakeholders.

Through this collaborative approach, in just three years, long-term management goals have been identified to establish the first mainland island in Mauritius to protect the olive white-eye and ensure long-term population viability. Implementation of a mainland island within the national park has started in the Brise Fer CMA with the introduction of olive white-eye planned for 2021 if rat management can maintain adequately low rat densities over a prolonged period. The area of the mainland island will be increased with growth in capacity, aiming to reach the full mainland island size (275 ha) within 5–10 years. Without these processes, project decisions could have taken years longer to reach the same point if field trials were required (to test all potential rat management techniques), accurate long-term financial requirements were not known, open discussion was not had or scientific research was not fed back to decision-makers; delays which would have detrimental impacts on highly threatened and declining species like the olive white-eye.

The methods discussed here address ways to approach existing challenges, reduce uncertainty and enable evidence-based decision-making. The approaches taken, although case-specific, provide methods for researchers and managers to adopt and apply to different scenarios depending on the decision-making barriers and uncertainty being faced; bridging both the knowledge-action boundary and the research-management divide (Roux, et al., 2006; Cook, et al., 2013), which is rarely achieved in conservation.

ACKNOWLEDGEMENTS

The Mauritius olive white-eye recovery project is conducted by the Mauritian Wildlife Foundation in conjunction with the National Parks and Conservation Service (Government of Mauritius). We would like to thank all those who participated in the knowledge exchange – The Hihi Recovery Group: John Ewen, Lynn Adams, Troy Makan, Doug Armstrong, Allan Anderson, Kevin Parker, Julie Panfylova, John Perrott, Neil Anderson, Ian Fraser, John Stewart, Vix Franks, Anna Santure, Kate Richardson, Morag Fordham, Gen Spargo and Nick Fisentzidis; Peter Abbott, Jenny Long, Graeme Elliott, Jason Malham and Ruth Malham from the Department of Conservation; Matt Maitland from Auckland Council; Ron Millar and Matt Cook from Sanctuary Mountain Maungatautari; Allan Anderson from Bushy Park Sanctuary; Simon Collins from Rotokare Scenic Reserve Trust; Raewyn Empson and Russ Drewry from Zealandia; and Grant Harper from Biodiversity Restoration Specialists. We would like to thank the Mauritius olive white-eye project partner organisations for participating in the stakeholder workshop – Mauritian Wildlife Foundation, Zoological Society of London, University College London, Chester Zoo, Durrell Wildlife Conservation Trust and National Parks and Conservation Service. We would finally like to thank the anonymous reviewers for their comments and contributions to earlier drafts. Gwen Maggs was funded by Chester Zoo (UK) and Zoological Society of London.

Timing aerial baiting for rodent eradications on cool temperate islands: mice on Marion Island

J.P. Parkes

Kurahaupo Consulting, 2 Ashdale Lane, Christchurch, New Zealand. <john.parkes1080@gmail.com>.

Abstract Aerial baiting from helicopters with a bait-sowing bucket and GPS to ensure coverage with anticoagulant toxins in cereal-based baits can reliably eradicate rodents on islands. Current best practice for temperate islands is to bait in winter when the rodents are not breeding, rodent numbers are lowest so competition for toxic baits is lowest, natural food is likely to be scarce, and many non-target species are absent from the island. However, short winter day lengths at high latitudes restrict the time helicopters can fly and poor weather in winter may increase risks of failure. This paper notes precedents from cool temperate islands where baiting was not conducted in winter and then uses the extensive data on mice on Marion Island to explore whether current recommendations for winter baiting based on breeding and natural food availability are important risk factors in determining time of year to bait. Marion Island mice do not breed between early May and late September, mouse densities reach a maximum in May and minimum in November, but the biomass of main natural food (invertebrates) does not fluctuate greatly over the year. This means the per capita food availability is least in autumn and increases through winter to most in spring and summer. The weight of the stomach contents of mice is also highest in winter. Based on this per capita food parameter, mice are likely to be most hungry between about March and May suggesting baiting would be more effective in this period (perhaps towards the end of it when breeding stops) than in the more traditional winter season.

Keywords: food availability, rodent abundance, seasonality

INTRODUCTION

Successful attempts to eradicate one or more (up to four) species of rodent by sowing toxic baits from an aircraft have been made on at least 166 islands in 13 countries (DIISE, 2018; J. Parkes, unpubl. data) since the first use of this method in 1985 against Norway rats (*Rattus norvegicus*) on Whale Island (143 ha) in New Zealand (Imber, et al., 2000). Most of these islands are at latitudes with temperate climates (n = 96) biased by the large sample from New Zealand, or in tropical latitudes (n = 64) biased by those in the Montebello Group of islands in Western Australia. Few islands are at latitudes with cold climates similar to Marion Island (n = 6). Aerial baiting is currently the only practical option to eradicate rodents on large or topographically difficult islands and has a high success rate when modern best practice is followed (Parkes, et al., 2011; Parkes, 2016). The cost of operational failure is high, especially for large, remote islands, both in the money invested (Holmes, et al., 2016) and if failures discourage risk-averse funders from attempting further projects. Therefore, careful planning and application of best practice based on precedence and analysis of the particular constraints and risks for each project is essential.

Pest eradications achieved by reduction of the target population to zero by a sequence of removal events (e.g. by shooting, trapping or by deployment and re-baiting of bait stations) provide information (e.g. catch per unit effort, kill locations, trends in rates of bait-take across seasons and years) as the population is reduced (e.g. Thomas & Taylor, 2002). Under this strategy, the 'start rules' are not critical as managers can (and should) adapt actions as information accrues during the project, e.g. to allow a change in tactics to account for animals that might avoid one control method (Parkes, et al., 2010). In these projects knowing when to stop and declare success is the more critical issue – at least in terms of efficiency and risk management (Ramsey, et al., 2011).

In contrast, the use of aerial baiting provides little information on likely success or failure from the control itself, other than bait coverage if GPS technology is used. Under this strategy everything has to 'go right on the day' and 'start rules' with meticulous planning are critical (Cromarty, et al., 2002; Springer, 2016). One key 'start rule' is to identify the optimal time of year (or at least avoid sub-optimal times) to conduct the baiting. Broome, et al. (2014) suggest that winter to early spring is the preferred time of year to aerially bait rodents on New Zealand's temperate islands because it is supposed that (a) rodents are often not breeding and so young individuals that might not be exposed to bait because of possible lack of dependence or subordinate behaviours are at lowest levels of abundance, (b) rodent densities are likely to be lowest and so competition for baits least, (c) natural foods are likely to be least abundant, the rodents most hungry and so 100% are likely to eat the baits, and (d) some potential non-target animals such as seabirds are not present in this season. Most rodent eradication projects have followed this advice by baiting in winter for temperate islands. However, these factors are not always mutually independent (least food and fewest rodents), and other factors (weather or logistics) may constrain decisions. The parameter around food availability we are really seeking is the time of year when there is least per capita food, which may or may not be when there is least food or fewest rodents and may or may not be what drives any breeding season. Managers are probably wise to stick with precedence and bait in winter or early spring (or during dry seasons in the tropics) in the absence of any data on the seasonality of food, rodent dynamics or breeding seasonality.

However, for a variety of reasons a few rodent eradications on cool temperate islands using aerial baiting have been conducted in the summer. Mice (*Mus musculus*) were eradicated on Enderby Island (710 ha at 50ºS) in January 1993 because that was when the primary target species, the rabbits (*Oryctolagus cuniculus*), were not breeding (Torr, 2002). Norway rats and house mice were eradicated on the subantarctic island of South Georgia (103,000 ha and 4,900 ha, respectively, at 54ºS) between late February and late May (mostly in March–April) in phases between 2011, 2013 and 2015 because weather conditions and persistent snow cover made a winter operation impossible (Anon., 2016; Martin & Richardson, 2017). Timing and other operational details of aerial baiting on several islands in the French Southern Territories appear to have been determined by the timing of the supply ship, the *Marion Dufrense*. Rabbits and ship rats (*Rattus rattus*), but not mice were eradicated from Saint Paul Island (900 ha at 38ºS) in January–February (Micol & Jouventin, 2002). Attempts to eradicate rodents from some of the islands in the Golfe du Morbihan in the Kerguelen group (49ºS) have

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 36–39. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

been made during summer months when the supply ship visits the region. Ship rats and mice were eradicated from Île Château (220 ha) (Anon., 2006) and ship rats but not mice from Île Australia (2337 ha). Attempts to eradicate mice on Île Stoll (60 ha) and ship rats and mice on Île Moules (500 ha) failed (Anon., 2006; DIISE, 2018).

So, maybe we are unnecessarily constraining ourselves to times of year with the worst weather and shortest days on islands at high latitudes by baiting in winter. This paper explores this seasonality question by describing the process used to inform decision-makers of a proposed eradication of mice on Marion Island, a place where the long history of research by South African scientists has provided most of the information to answer the question.

RESULTS AND DISCUSSION

Marion Island

Marion Island (29,000 ha) and the adjacent Prince Edward Island are South Africa's only offshore islands. They lie on the sub-Antarctic convergence at 46º54′S in the south Indian Ocean. Apart from a meteorological station on Marion Island, the islands are uninhabited. Marion is an active volcano rising to 1,230 m a.s.l. (Fig. 1). The climate is cool, wet and temperate with only a few degrees seasonal variation between coldest and warmest months (mean annual temperature is 6.4ºC and mean annual precipitation is about 200 cm). The physical and biotic characters of Marion Island are described in detail in Chown & Froneman (2008) and the impacts and history of the introduced flora and fauna by Angel & Cooper (2011) and Greve, et al. (2017).

Mice were introduced accidentally some 200 years ago, probably with sealers, and are having a significant impact on the native biota (Angel & Cooper, 2011; Dilley, et al., 2016) such that the South African government is considering whether they might be eradicated (Parkes, 2016). Cats (*Felis catus*) were introduced in 1948 in an attempt to control mice at the meteorological station but soon spread as feral animals over the island, killing mice as primary prey and an estimated 450,000 seabirds per year (Dilley, et al., 2017). The cats were eradicated between 1977 and 1991 (Bester, et al., 2002).

Breeding season

Mice can breed all year if high quality food is available, e.g. during beech (*Nothofagus* spp.) mast events in New Zealand winters (Ruscoe, et al., 2005). However, mice

Fig. 1 Vegetated lava (foreground) and swamp habitat (middle background), Marion Island (Photo by John Parkes, April 2016).

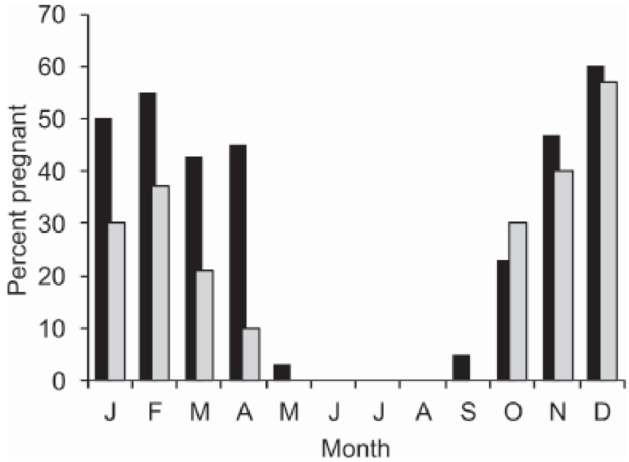

Fig. 2 Monthly pregnancy rates of adult mice, Marion Island in 1991/92 (after Matthewson, et al. (1994) black bars) and 1992/93 (after Avenant & Smith (2004) grey bars).

have a distinct breeding season on Marion Island with no pregnant animals present between early May and late September (Fig. 2). However, this is not a universal rule on all cool temperate islands as 16% of mice sampled during August/September 2012 on Steeple Jason Island (51ºS in the Falkland Islands) were pregnant (Rexer-Huber, et al., 2013).

Density of mice and competition for bait

This breeding season is reflected in the monthly abundance of mice on Marion Island with increasing numbers from the start of breeding in late spring and declining numbers once breeding ends in late autumn (Fig. 3), resulting in lowest densities (at the favoured habitats) at the start of the breeding season (43/ha) in spring and highest (242/ha) in early winter before the decline (Avenant & Smith, 2004).

Baiting during low rodent densities is recommended by Broome, et al. (2014) in part to ensure there are plenty of baits such that all mice, irrespective of their social status, have access to baits. Bait sowing rates in high-density rodent populations of 8 kg/ha in an initial sowing followed by a second sowing of 6 kg/ha about eight days later would result in 7,000 baits/ha – or even in the highest density mouse habitats of Marion Island of 23 baits per mouse. This seems more than adequate to overcome any potential between-mouse competition given each bait contains a lethal dose.

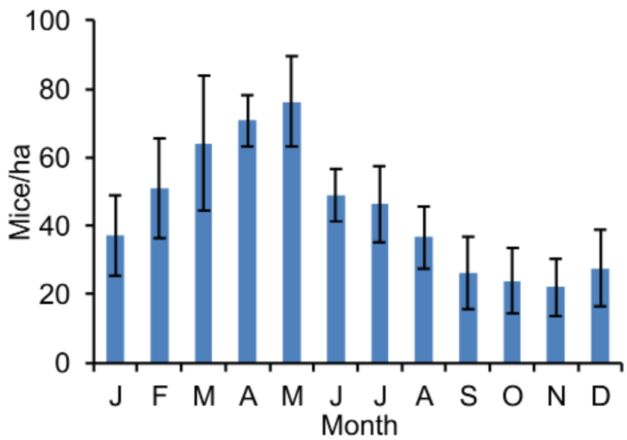

Fig. 3 Seasonal abundance of mice (minimum number known to be alive/ha) averaged across three main habitat types, Marion Island (after Ferreira, et al., 2006).

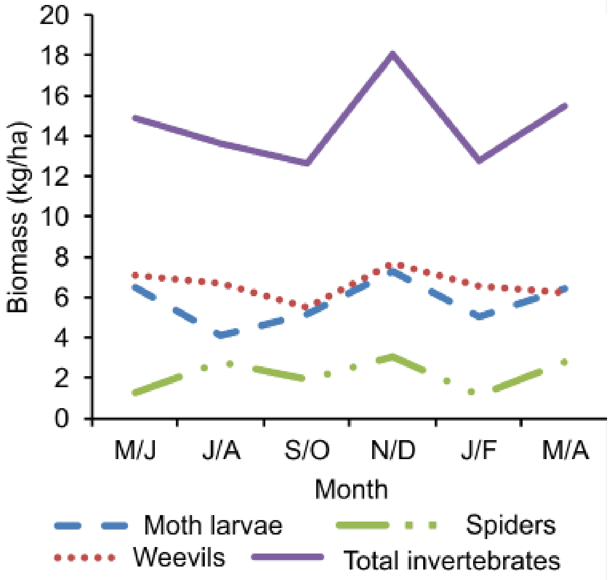

Fig. 4 Seasonal biomass of main invertebrate prey of mice (after Gleeson & van Rensburg (1982)). Total invertebrate biomass (top solid line), weevils (dotted line), moth larvae (dashed line), spiders (lower broken line).

Seasonal variation in per capita natural food

The decades of detailed research conducted on Marion Island (Chown & Froneman (2008) have included studies on the seasonal diet of mice and on the seasonal biomass of their prey. Invertebrates form the bulk of mice diet (depending on habitat) with the larvae and adults of the flightless keystone moth (*Pringleophaga marioni*) (between 13 and 64% by volume) and weevils (*Ectemnorhinus* spp.) (between 11 and 32% by volume) being the most important, followed by earthworms (*Microscolex kerguelarum*) (between 1 and 9% by volume). Plant material, mostly grass and sedge seeds was important, between 16 and 48% by volume (Smith, et al., 2002).

There appears to be only small seasonal variation in the abundance of the main invertebrate fauna favoured by mice (Fig. 4) and Avenant & Smith (2004) found no significant summer–winter differences in invertebrate biomass in the habitat most favoured by mice – apart from spiders which were actually more abundant in winter. The preferred prey for mice, larvae, pupae and adults of *Pringleophaga marioni*, has a long-life cycle of between two and five years (Haupt, et al., 2014) so the absence of seasonal fluctuations is not unexpected given also the small seasonal differences in climate on Marion Island (le Roux & McGeoch, 2008).

The absence of strong seasonal changes in invertebrate prey abundance mean that there is least food per mouse when mouse density is at a maximum, i.e. between March and May, and most food per mouse over winter and spring. For example, the per capita food availability is an order of magnitude lower in early winter when mice are at maximum densities than in early summer when they are at lowest densities. The weight of stomach contents of mice also increases during winter to reflect this (Fig. 5), and mice begin to scavenge or prey upon other mice in autumn and winter (Smith, et al., 2002).

Seasonal absence of non-target species

Most cool temperate islands have a mix of permanent resident bird and seasonally present nesting or moulting seabirds. Unacceptable risks to the former from toxic baiting and secondary poisoning have to be mitigated, e.g. by holding individuals in safe captivity (Rexer-Huber & Parker, 2011), but risks to the latter have to be accepted (e.g. as on Macquarie Island; Parkes, 2016; Springer, 2016) or avoided by baiting when the birds are least common on the island. Marion Island has only two terrestrial birds at risk – the kelp gull (*Larus dominicanus*) and lesser sheathbill (*Chionis minor*) while among the 26 nesting seabird species only three (sub-Antarctic skua (*Catharacta antarctica*), southern giant petrel (*Macronectes giganteus*) and northern giant petrel (*M. hallii*) are at low to modest risk if the baiting was conducted in mid-winter (Parkes, 2016; Springer, 2016).

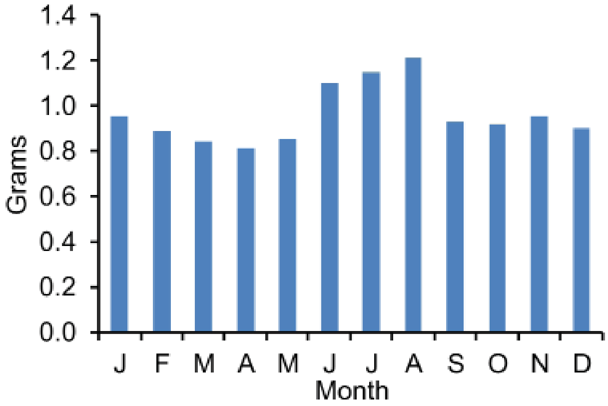

Fig. 5 Monthly changes in the weight of stomach contents adjusted for body weights of Marion Island mice (after Matthewson, et al. (1994) reported in Smith, et al. (2002)).

CONCLUSIONS

Optimal timing of aerial baiting on Marion Island depends on whether the non-breeding season is more or less important than the period with minimum per capita food availability for the mice. Neither hypothesis has been tested. If the latter is most important then a March–May baiting is indicated, but if the former then a May–September baiting is indicated – May at least being a month of overlap. Of course, an earlier timing in late summer is better than a later one in winter, when short days, snow and gales limit flying time.

It is not clear whether the lack of large changes in seasonal abundance and biomass of invertebrates seen on Marion Island is normal for all cool temperate islands. Most studies on other islands lack the year-round data on changes in invertebrate biomass available for Marion Island. However, mice on other cool temperate islands also show a lack of strong seasonality in the occurrence of invertebrates (the bulk of their diet) in their diet, e.g. on Macquarie Island (Copson, 1986) and Île Guillou (Le Roux et al., 2002). This suggests the multi-year life cycles of the invertebrate species on Marion Island may also apply on similar islands and the per capita food supply depends on seasonal changes in mouse density rather than on food abundance. Therefore, mice are likely to be hungriest when they are at maximum densities and not during the winter when they are likely to be least hungry and perhaps less likely to eat artificial food such as baits. An aerial baiting project between March and May is indicated on this condition. Of course, the other considerations mooted by Broome, et al. (2014) might constrain such a choice, as might weather, day length, logistics of ship and helicopter availability as with other projects noted in the introduction.

However, there are several caveats. First, the comparisons between mouse and food abundance are derived across several studies over several decades. This may not be a problem except that the whole ecosystem around mice on Marion Island is highly dynamic. Second, the biomass of invertebrates has collapsed by about 90% since the mid-1970s (Table 1 in Parkes, 2016 and references therein), despite which mouse densities have increased (between 1990 and 2002; Ferreira, et al. (2006) and well after cats were eradicated; the climate is warming (le Roux & McGeoch, 2008); and mice are switching their primary prey from moths to weevils and earthworms (Chown & Smith, 1993) and learning to eat albatross chicks (Dilley, et al., 2016).

Finally, if natural food availability is a problem limiting bait acceptance by rodents (i.e. the proportion of a population that eat the bait) as suspected for some recent failures on tropical islands (Parkes, et al., 2011; Keitt, et al., 2014), and such food competition cannot be predicted or avoided, then one solution is to increase the palatability of the bait relative to natural foods by adding lures or attractants.

ACKNOWLEDGEMENTS

I thank the South African Department of Environmental Affairs, the South African National Antarctic Programme and Birdlife South Africa for support during my visit to Marion Island. I also thank Ross Wanless and John Cooper and the many researchers, mostly ornithologists, for discussions on the problem when I was on the island and the many previous researchers on whose work I have relied to collate the argument for this paper.

Abstract House mice (*Mus musculus*) were introduced to South Africa's sub-Antarctic Marion Island, the larger of the two Prince Edward Islands, by sealers in the early 19th century. Over the last two centuries they have greatly reduced the abundance of native invertebrates. Domestic cats (*Felis catus*) taken to the island in 1948 to control mice at the South African weather station soon turned feral, killing large numbers of breeding seabirds. An eradication programme finally removed cats from the island by 1991, in what is still the largest island area cleared of cats at 290 km^2. Removal of the cats, coupled with the warmer and drier climate on the island over the last half century, has seen increasing densities of mice accumulating each summer. As resources run out in late summer, the mice seek alternative food sources. Marion is home to globally important seabird populations and since the early 2000s mice have resorted to attacking seabird chicks. Since 2015 c. 5% of summer-breeding albatross fledglings have been killed each year, as well as some winter-breeding petrel and albatross chicks. As a Special Nature Reserve, the Prince Edward Islands are afforded the highest degree of protection under South African environmental legislation. A recent feasibility plan suggests that mice can be eradicated using aerial baiting. The South African Department of Environmental Affairs is planning to mount an eradication attempt in the winter of 2021, following a partnership with the Royal Society for the Protection of Birds to eradicate mice on Gough Island in the winter of 2020. The eradication programme on Marion Island will be spearheaded by the South African Working for Water programme – Africa's biggest conservation programme focusing on the control of invasive species –which is already driving eradication projects against nine other invasive species on Marion Island.

INTRODUCTION

In the late 18th and early 19th century humans travelled far and wide in the southern oceans to exploit marine wildlife (Trathan & Reid, 2009). An unfortunate consequence of this travel was the deliberate or incidental introduction of alien animal and plant species to distant environments, causing extensive changes in biological communities (Mooney & Cleland, 2001). The effects of invasive species on biodiversity have been described as "immense, insidious and usually irreversible" (IUCN, 2000). Island ecosystems are highly susceptible to change and introduced species are the main cause of species extinctions on islands (Manne, et al., 1999; Chapin, et al., 2000).

Many seabirds nest on isolated islands that lack land mammals and consequently one of the major threats to oceanic seabird species is the introduction of mammalian predators such as rats (*Rattus* spp.), domestic cats (*Felis catus*) and house mice (*Mus musculus*) onto their breeding islands (Croxall, et al., 2012). The devastating impact of rats on seabird populations breeding on oceanic islands has been well documented (Atkinson, 1985; Jones, et al., 2008). However, mice have been introduced to even more oceanic islands than have rats and, although their impacts on sub-Antarctic island biota are legion (Angel, et al., 2009), until recently they were considered to have little impact on seabird populations (Wanless, et al., 2007; Jones, et al., 2008).

Sub-Antarctic Marion Island (290 km^2, 46°54´S, 37°45´E) is the larger of the two South African Prince Edward Islands which lie c.2,300 km south-east of Cape Town in the south-western Indian Ocean (Fig. 1). As a Special Nature Reserve, established in 1995, the Prince Edward Islands are afforded the highest degree of protection under South African environmental legislation (de Villiers & Cooper, 2008). They also have been a Wetland of International Importance in terms of the Ramsar Convention since 2007 (de Villiers, et al., 2011) and are surrounded by a large (180,000 km^2) Marine Protected Area, declared in 2013, that reaches in places to the edges of South Africa's Exclusive Economic Zone (Lombard, et al., 2007; Nel & Omardien, 2008).A revised management plan adopted in 2014 guides and controls activities at the island group, including biosecurity protocols to avoid alien introductions (DST-NRF Centre of Excellence for Invasion Biology, 2014).

The Prince Edward Islands currently support breeding populations of 29 species of birds, all but two of which probably breed on Marion Island (Ryan & Bester, 2008; Peter Ryan, FitzPatrick Institute unpubl. data; Table 1). Eight bird species of the order Procellariiformes that breed on Marion are listed by the International Agreement on the Conservation of Albatrosses and Petrels, to which South Africa is a founding signatory (Cooper, et al., 2006).These four albatross and four petrel (*Macronectes* and *Procellaria*)

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 40–46. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

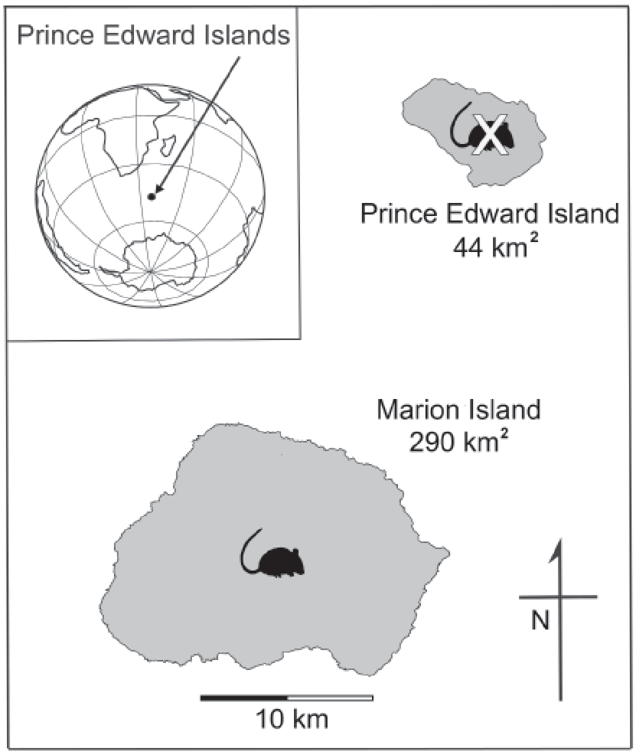

Fig. 1 South Africa's Prince Edward Islands (46°54´S, 37°45´E) lie 2,300 km south-east of Cape Town in the south-western Indian Ocean. Marion Island has introduced house mice, but Prince Edward Island, 22 km to the north-east, remains free of introduced mammals.

species are at risk at sea to bycatch by commercial fisheries, especially longlining, and are considered threatened or near threatened at regional (Taylor, et al., 2015) and global (BirdLife International, 2017) levels. Marion Island supports about 25% of the world's breeding population of wandering albatrosses *Diomedea exulans* (globally and regionally Vulnerable), 12% of sooty (*Phoebetria fusca*) and 7% of grey-headed (*Thalassarche chrysostoma*) albatrosses (both globally and regionally Endangered) and smaller percentages of light-mantled albatrosses (*P. palpebrata*) (globally and regionally Near Threatened) and grey petrels (*Procellaria cinerea*) (globally Near Threatened and regionally Vulnerable).

We show that these five ACAP-listed species, along with the regionally Near Threatened great-winged petrel (*Pterodroma macroptera*), are at serious risk to predation from introduced mice on Marion Island. Mice were accidentally introduced to Marion Island during the sealing era sometime before 1818 and were the sole introduced mammal until 1948 when five domestic cats were introduced to control mice at the newly-established weather station (Watkins & Cooper, 1986). However, even in the 1950s, little was known about the potential harmful effects of invasive species on islands. Rand (1954) was the biologist on the Eighth South African Expedition to Marion Island over 1951/52 and noted how "a few domestic cats have gone feral and prey on the smaller petrels or mice that are widespread over the coastal plain" (p. 178) and "mice often burrow into the [albatross] nest cone but do no appreciable damage" (p. 189). Unfortunately, the cats preferred to eat the island's native birds, especially the burrow-nesting petrels, and by the 1970s more than 2,000 cats were killing some 450,000 birds each year (van Aarde, 1980). As a result, at least one species, the common diving petrel (*Pelecanoides urinatrix*), disappeared from the island and all the other burrowing petrels became far less common than at nearby predator-free Prince Edward Island. A sustained eradication programme that commenced in the mid-1970s had finally eradicated cats from the island by 1991 (Bester, et al., 2002), in what until recently was the largest island area cleared of cats.

We give an overview of the adverse impacts of mice on Marion Island's biota and ecosystem and discuss the mouse eradication attempt planned for the austral winter of 2020.

A syndrome of adverse factors

House mice have been present on Marion Island for nearly 200 years (Berry, et al., 1978), significantly disrupting terrestrial ecosystem functioning (Chown & Smith, 1993). The mice may be seen as part of a syndrome of interacting factors (Parkes, 2016) having adverse impacts on native invertebrates, plants and seabirds (e.g. Phiri, et al., 2009; Angel & Cooper, 2011). The mice have changed the state of Marion Island's ecosystems compared with the near-pristine condition of neighbouring Prince Edward Island (45 km^2, see Fig. 1).

For more than 30 years the burrowing petrel populations on Marion Island were impacted by cats (top predators) and mice (mesopredators). Whereas mice target eggs and chicks (Fugler, et al., 1987; Dilley, et al., 2015; Dilley, et al., 2018), reducing reproductive success, cat predation was far more detrimental because they killed chicks and adults, affecting both reproduction and adult survival (Le Corre, 2008). Removal of the top predator on Marion Island has benefited adult survival but may have triggered a 'mesopredator release' effect (Zavaleta, et al., 2001; Le Corre, 2008), whereby mouse numbers expanded, increasing their impact on petrel populations (Rayner, et al., 2007). The dramatic decrease in burrowing petrel populations at Marion Island caused by the cats is again presumed to have adversely affected key ecological processes driven by burrowing petrels such as soil turn-over and marine nutrient imports (Caut, et al., 2012).

Mouse numbers cycle seasonally on Marion Island, linked partly to changes in the abundance of invertebrates and seeds. Mouse densities are highest in autumn, when breeding ceases, and are lowest in early summer, before breeding resumes. Invertebrate biomass also changes seasonally, but not to the same extent, so that the *per capita* food supply (from macro invertebrates as the primary food of the mice) was estimated to be 3.4 kg/ha and 3.6 kg/ha in early summer but only 0.4 kg/ha and 0.2 kg/ha in early winter in the Biotic and Mire habitats favoured by mice, respectively (Avenant & Smith, 2003).

Peak mouse densities occur in April–May, and have increased between 1990 and 2008, driven in part by a warmer, drier climate (Ferreira, et al., 2006; le Roux & McGeoch, 2008; McClelland, et al., 2018). By comparison, invertebrate biomass has decreased >80% since the late 1970s (McClelland, et al., 2018). Since 2015, there has been a marked increase in the frequency of mice attacking surface-breeding seabird chicks (Dilley, et al., 2016a) and if invertebrate biomass continues to decline, the impact of mouse predation on Marion's seabird chicks is likely to become even more serious.

Overview of mice attacking seabirds at Marion Island

The first signs of mouse attacks on seabirds at Marion Island were recorded in 2003, when wandering albatross chicks were observed with rump wounds typical of those inflicted by mice on Tristan albatross (*D. dabbenena*) chicks on Gough Island (Jones & Ryan, 2010; Table 2). The first attacks on summer-breeding albatross chicks were

Table 1 Estimated risk of local extirpation of bird species currently known or thought to breed on Marion Island if the mice are not eradicated.

Species	Estimated numbers of breeding pairs	Known or considered vulnerable to predation	Estimated years to local extirpation
Grey-backed storm petrel *Garrodia nereis**	? [1]	yes	possibly locally extirpated
Black-bellied storm petrel *Fregetta tropica**	? [1]	yes	possibly locally extirpated
Grey petrel *Procellaria cinerea*	800[2]	yes	30
Cape petrel *Daption capense*	<5[2]	yes	30
Kerguelen petrel *Lugensa brevirostris*	5,000[2]	yes	50
South Georgian diving petrel *Pelecanoides georgicus*	1,000[1]	yes	50
Common diving petrel *Pelecanoides urinatrix*	50–100[2]	yes	50
Great-winged petrel *Pterodroma macroptera*	14,000[2]	yes	50–100
Light-mantled albatross *Phoebetria palpebrata*	300[3]	yes	50–100
Sooty albatross *Phoebetria fusca*	1,465[3]	yes	50–100
Grey-headed albatross *Thalassarche chrysostoma*	7,900[1]	yes	50–100
Wandering albatross *Diomedea exulans*	1,800[1]	yes	50–100
Fairy prion *Pachyptila turtur*	1,000[1]	yes	50–100
Salvin's prion *Pachyptila salvini*	150,000[2]	yes	50–100
Blue petrel *Halobaena caerulea*	145,000[4]	yes	50–100
Soft-plumaged petrel *Pterodroma mollis*	5,000[1]	yes	50–100
White-chinned petrel *Procellaria aequinoctialis*	24,000[5]	yes	50–100
Antarctic tern *Sterna vittata*	25[1]	yes	50–100
Kerguelen tern *Sterna virgata*	50[1]	yes	50–100
Southern giant petrel *Macronectes giganteus*	1,750[1]	uncertain	
Northern giant petrel *Macronectes halli*	400[1]	uncertain	
Crozet shag *Leucocarbo melanogenis*	270[1]	uncertain	
Brown skua *Catharacta antarctica*	300[6]	uncertain	
Kelp gull *Larus dominicanus*	100[1]	uncertain	
Lesser sheathbill *Chionis minor*	700[1]	uncertain	
King penguin *Aptenodytes patagonicus*	220,000[1]	no	
Gentoo penguin *Pygoscelis papua*	900[1]	no	
Macaroni penguin *Eudyptes chrysolophus*	370,000[1]	no	
Southern rockhopper penguin *Eudyptes chrysocome*	67,000[1]	no	

*Current breeding not proven but suspected
Data sources: [1]Ryan & Bester (2008); [2]FitzPatrick unpubl. data; [3]Schoombie et al., (2016); [4]Dilley et al., (2017); [5]Ryan et al., (2012); [6]Ryan et al., (2009)

recorded in April 2009 when sooty albatross fledglings at two colonies were found 'scalped' with raw, bleeding crowns and necks (Jones & Ryan, 2010; Fig. 2). Mice were suspected of being responsible for these wounds (Jones & Ryan, 2010), even though summer-breeding albatross chicks are seldom attacked by mice on Gough Island (Cuthbert, et al., 2013). Another sooty albatross fledgling was attacked in 2010 at one of the colonies where scalpings occurred in 2009 (Ben Dilley, FitzPatrick Institute unpubl. data), but no further attacks were recorded until 2015, when mice attacked large chicks of all three albatross species that fledge in autumn: grey-headed (Fig. 3), sooty and light-mantled albatrosses (Dilley, et al., 2016a, Table 2). Filming at night confirmed that mice were responsible for these wounds, with most affected chicks dying within a few days of being attacked (Dilley, et al., 2016a). Attacks started independently in small pockets all around the island's 70 km coastline, separated by distances hundreds of times greater than mouse home ranges (Wanless, et al., 2008; Dilley, et al., 2016a; Fig. 2). In 2015, three of the six mouse-injured wandering albatross chicks had head wounds ('scalpings', see Fig. 4). In 2016, 2017 and 2018 mouse attacks continued on summer-breeding albatross fledglings, indicating that the sudden increase in 2015 was not a one-off event.

With cats having been eradicated from Marion Island by 1991, we expected burrowing petrel populations to

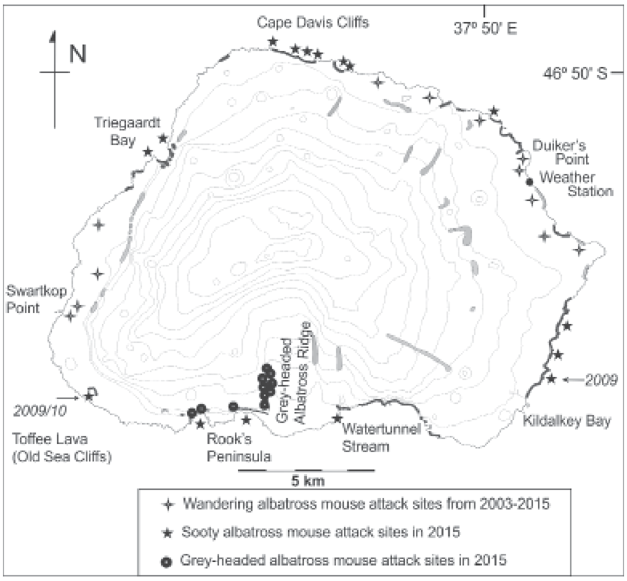

Fig. 2 Marion Island showing the locations of albatross breeding colonies (sooty albatross = dark grey shade; light-mantled albatross = light grey shade; all grey-headed albatross colonies are along Grey-headed Albatross Ridge and Rook's Peninsula) and mouse-attack sites from 2009–2015 (adapted from Dilley, et al., 2016a). Contour lines indicate 100 m.

Fig. 3 Grey-headed albatross chicks showing distinctive 'scalping' wounds inflicted by mice on Marion Island in 2015 (photo Ben Dilley).

have recovered by two decades later. Initial indications were positive; following the removal of cats there were marked increases in the breeding success of burrowing petrels, especially great-winged petrels that breed in winter when cat predation pressure was most severe (Cooper & Fourie, 1991; Cooper, et al., 1995). However, the post-cat recovery of burrowing petrel numbers on Marion has been much slower than anticipated, especially for smaller species (Dilley, et al., 2016b). Of the nine species of burrowing petrels breeding on Marion Island, the two smallest species (black-bellied (*Fregetta tropica*) and grey-backed storm petrels (*Garrodia nereis*)) are now very uncommon and are likely locally extirpated on the island due to mice (Dilley, et al., 2016b). Recent evidence from a repeat survey of burrow densities (Dilley, et al., 2016b) and from analyses of brown skua *Catharacta antarctica* prey remains (Cerfonteyn & Ryan, 2016) both suggest there has been little or no recovery of burrowing petrel populations at Marion since cats were eradicated.

Predation by mice is the most likely explanation for the limited recovery of Marion's petrel populations (Dilley, et al., 2016b). Recent evidence from breeding success studies shows that mice are suppressing the recovery of burrowing petrel populations, especially those that breed in winter, through predation on eggs and chicks (Dilley, et al., 2018). Winter breeders had lower breeding success than did summer breeders, with most fatalities being of small chicks <14 days old. Mice were filmed attacking and killing chicks of two winter-breeding species: grey petrel (three of 18 nests filmed; <https://youtu.be/Og1d6a2cmXQ>) and great-winged petrel (one of 19; <https://youtu.be/D9vPoFsjvgs>, Dilley, et al., 2018). Grey petrel chicks, which had the highest mortality rate, hatch in early winter when mouse densities are still fairly high, but food availability is low, resulting in the lowest seasonal *per capita* food availability for mice (Dilley, et al., 2018). Most grey petrel mortalities occurred when chicks were <7 days old, and were likely due to mouse predation (Dilley, et al.,2018).

We conclude that mice are currently suppressing the recovery of burrowing petrel populations on Marion Island, especially those that breed in winter, through predation on eggs and chicks. The widespread increase in mouse predation on albatross chicks at Marion in 2015 is also a cause for concern. Left uncontrolled, it is feared that 18 of the 28 species breeding on Marion Island may be vulnerable to local extirpation (see Table 1), should the mice not be eradicated.

PLAN OF ACTION

The Prince Edward Islands are recognised as a Special Nature Reserve, which affords the highest degree of protection under South African environmental legislation, and the islands' management plan aims to eradicate alien plants and animals as far as possible (DST-NRF Centre of Excellence for Invasion Biology, 2014). As summarised above, the structure of Marion Island's terrestrial ecosystem has been radically transformed by introduced mice, which are now threatening the island's globally important seabird

Table 2 Summary of mouse attacks on surface-nesting seabirds breeding on Marion Island (from Dilley, et al., 2016a and FitzPatrick Institute unpubl. data).

Species	Year of first attack	Maximum number attacked	% of annual production
Wandering albatross	2003	6	0.8%
Sooty albatross	2009	45	4.3%
Light-mantled albatross	2015	1	4.0%
Grey-headed albatross	2015	102	4.6%

Fig. 4 A Wandering albatross chick being scalped by a mouse on Marion Island in the winter of 2015 (photo Stefan Schoombie).

populations. Given the island's importance as a breeding site for threatened albatrosses and other seabird species that are being killed by mice, there is an urgent need to eradicate mice from the island. A detailed feasibility plan (Parkes, 2016) suggests that mice can be eradicated using aerial baiting. This follows the now well-established approach of using helicopters fitted with GPS guidance systems and under slung bait-distribution buckets to spread brodifacoum-laced pellets across the entire island over a relatively short period, to ensure that all rodents have access to the poison bait. Such operations, pioneered on New Zealand's offshore islands, have a good track record in recent years with 21 of 22 operations around the world targeting mice being successful in the last decade (DIISE, 2015). However, the operation on Marion Island will be an order of magnitude larger than any previous island eradication targeting mice only (cf. Springer, 2016; Martin & Richardson, 2017). This will require the deployment of poison bait with a high level of accuracy given the small home ranges of mice relative to rats (Parkes, 2016).

The South African Department of Environmental Affairs is planning to mount an eradication attempt on Marion Island in the austral winter of 2021. This is timed to follow a planned eradication of mice on Gough Island led by the United Kingdom's Royal Society for the Protection of Birds in the winter of 2020. Gough Island, part of the UK Overseas Territory of St Helena, Ascension and Tristan da Cunha, is one of the world's most important seabird breeding islands. It is the site where mice were first appreciated to pose a significant risk to breeding seabirds (Cuthbert & Hilton 2004; Wanless, et al., 2007), and experiences very high levels of chick mortality in several species, including the Tristan albatross (globally Critically Endangered), Atlantic petrel (*Pterodroma incerta*) (Endangered) and Macgillivray's prion (*Pachyptila macgillivrayi*) (Endangered) (Davies, et al., 2015; Dilley, et al., 2015). Despite these impacts, the island still supports some 12 million breeding seabirds of 22 species and is regarded as a top-priority island for rodent eradication world-wide (Hilton & Cuthbert, 2010).

At 65 km^2, Gough will be the largest island where an eradication has been attempted targeting mice alone (mice were eradicated from 129 km^2 Macquarie Island (Australia), but they occurred at lower densities than on Marion due to the presence of black rats (*R. rattus*) on the island (Springer 2016; <http://www.parks.tas.gov.au/?base=13013>). Planning for the Gough Island eradication has involved more than a decade of research to ensure the highest probability of success (e.g. Angel & Cooper, 2006; Brown, 2007; Parkes, 2008; Wanless, et al., 2009; Cuthbert, et al., 2011a; Cuthbert, et al., 2011b; Cuthbert, et al., 2014; Cuthbert, et al., 2016). At 290 km^2, Marion Island is almost five times larger than Gough Island, but the terrain is less rugged, and the presence of a largely un-vegetated interior above 800 m with few, if any, mice in winter makes an eradication attempt at Marion less challenging in some regards (Parkes, 2016). The intention is to commence the operation during early winter, when mouse numbers are falling due to lack of food and cold conditions, increasing the likelihood of all animals consuming bait (see Parkes, 2019, for further details on the crucial decision of 'when to bait' on Marion). Mice also cease breeding on Marion from late May to August, reducing the chances of semi-independent young in the den failing to encounter bait (Parkes, 2016). Winter also coincides with the period of lowest numbers of brown skuas and giant petrels (*Macronectes* spp.) present on the island, which might be killed accidentally by either primary or secondary poisoning.

Mitigation plans will be needed to reduce the impacts on resident scavenging species (Wanless, et al., 2010). At this stage, the intention is to keep approximately 100 lesser sheathbills (*Chionis minor*) in captivity during the eradication attempt, given the moderate level of mortality of snowy sheathbills (*C. albus*) during the rodent eradication at South Georgia (Martin & Richardson, 2017). The Prince Edward Islands are home to an endemic subspecies of sheathbill *C. m. marionensis*, but nearby Prince Edward Island houses a substantial population of this subspecies and could be used to re-establish birds on Marion Island. Kelp gulls (*Larus dominicanus*) also are resident scavengers at Marion Island, but they may be less susceptible to non-target poisoning (Martin & Richardson, 2017). Given the small population size (Table 1) and difficulty of catching and maintaining captive birds, there is currently no plan to mitigate impacts on this species. Gulls are thought to move freely between Marion and Prince Edward Island, so immigration should aid the recovery of the Marion population after the eradication.

The eradication on Marion Island was stimulated by the donation of US$100,000 and the three helicopters used in the South Georgia rodent eradication by the Mamont Foundation to the South African Department of Environmental Affairs in early 2017. South Africa has a weather station on Gough Island, and will assist this eradication effort through the provision of accommodation (including possible refurbishments on the island), the hosting of the eradication team from its Cape Town harbour, and assistance with transportation. In return, the equipment used and expertise developed during the Gough eradication will be transferred to South Africa for use in the planned Marion eradication. The programme on Marion Island will be spearheaded by the Department of Environmental Affairs' Working for Water programme – Africa's biggest conservation programme focusing on the control of invasive species. Working for Water is already managing eradication projects against eight invasive vascular plant species on Marion Island, and the possible eradication of one introduced invertebrate, the rough woodlouse (*Porcellio scaber*), is being assessed (D. Muir). The South African Government is budgeting for this programme (with an initial budget of about US$2.2 million). It will seek to raise co-funding, including through a crowd-funding initiative being led by BirdLife South Africa, a non-governmental organisation.

Eradicating rodents from islands is an effective, long-term conservation management action, provided robust biosecurity measures are put in place to minimise the likelihood of any reintroductions. The South African National Antarctic Programme has imposed stringent quarantine measures on all vessels and materials going to the Prince Edward Islands (and Gough Island) since the early 1990s. These include fumigation of the resupply vessel prior to each voyage, use of rat guards on all hawsers when in harbour, placement of rodenticide baits at strategic points throughout the ship, and inspection of all cargo before being opened ashore (DST-NRF Centre of Excellence for Invasion Biology, 2014).

ACKNOWLEDGEMENTS

Logistical and financial support for scientific research on Marion Island was provided by the South African Department of Environmental Affairs through the South African National Antarctic Programme (SANAP), the National Research Foundation, the University of Cape Town and the Agreement on the Conservation of Albatrosses and Petrels. The support of BirdLife International, BirdLife South Africa, the Mamont Foundation, the Royal Society for the Protection of Birds and the FitzPatrick Institute of African Ornithology at the University of Cape Town, is gratefully acknowledged.

Improving the efficiency of aerial rodent eradications by means of the numerical estimation of rodenticide density

Grupo de Ecología y Conservación de Islas, A.C. Ave. Moctezuma 836, Zona Centro C.P. 22800, Ensenada, Baja California. <evaristo.rojas@islas.org.mx>.

Abstract Invasive rodents are present on approximately 80% of the world's islands and constitute one of the most serious threats to island biodiversity and ecosystem functioning. The eradication of rodents is central to island conservation efforts and the aerial broadcast of rodenticide bait is the preferred dispersal method. To improve the efficiency of rodent eradication campaigns, the generation of accurate and real-time bait density maps is required. Creating maps to estimate the spatial dispersion of bait on the ground has been carried out using traditional GIS methodologies, which are based on limiting assumptions and are time intensive. To improve accuracy and expedite the evaluation of aerial operations, we developed an algorithm for the numerical estimation of rodenticide density (NERD). The NERD algorithm performs calculations with increased accuracy, displaying results almost in real-time. NERD describes the relationship between bait density, the mass flow rate of rodenticide through the bait bucket, and helicopter speed and produces maps of bait density on the ground. NERD also facilitates the planning of helicopter flight paths and allows for the instant identification of areas with low or high bait density. During the recent and successful rodent eradication campaign on Banco Chinchorro in Mexico, carried out during 2015, NERD results were used to enable dynamic decision-making in the field and to ensure the efficient use of resources.

Keywords: aerial dispersal, bait density, invasive species, rodenticide

INTRODUCTION

Island ecosystems are vulnerable to the threat posed by invasive species due to the combination of high levels of endemism and isolation, coupled with smaller population sizes (Loope & Mueller-Dombois, 1989; D'Antonio & Dudley, 1995; Reaser, et al., 2007). Invasive rodent species such as *Rattus rattus* are particularly harmful to island ecosystems. Worldwide, invasive rodents are found on more than 80% of the world's islands and their high potential for dispersal indicates that this number is on the rise (Russell, et al., 2008; Harris, et al., 2012). The presence of invasive rodents on islands can lead to rapid population decreases of both flora and fauna and the extirpation of endemic species (Towns, et al., 2006; Medina, et al., 2011) as invasive rodent species begin to dominate communities (Angel, et al., 2009; Towns, et al., 2013). Island biodiversity is not only affected by the presence of invasive rodents; in cases where rodent invasion is severe, key island ecosystem functions and services are often lost (e.g., Towns, et al., 2006). Island ecosystems are unable to recover while rodents are present; as such, the first step to restore ecological functioning and island biodiversity is the eradication of invasive rodent species via the dispersal of rodenticide (Towns & Broome, 2003; Harris, et al., 2012).

The aerial-based dispersal methods of rodenticide bait via helicopter are preferable to ground-based methods in many circumstances (Towns & Broome, 2003; Broome, et al., 2014). Aerial bait dispersal strategies are designed to cover large areas rapidly, reduce the complications associated with complex topography, and target potential refuge sites (Towns & Broome, 2003; Howald, et al., 2007). The evaluation of the effectiveness of aerial rodenticide dispersal is informed by bait density maps that show the spatial variation of bait on the ground (Broome, et al., 2014). Traditionally, bait density maps have been created with *in situ* measurements or from GPS helicopter trajectories although there are challenges associated with both methods. To obtain *in situ* measurements, quadrat bait density sampling is carried out on the ground and requires a substantial investment of both time and human resources. The effectiveness of this method depends on the topography, accessibility, and climate of the island at the time of sampling, in addition to existing time constraints and available manpower. In contrast, the spatial estimation of bait density from recorded GPS helicopter trajectories is time intensive and can be imprecise as it is based on several untested assumptions, the principal one being that the bait density remains constant within the treated polygon.

We have developed a method for the numerical estimation of rodenticide density (NERD) that improves upon the aforementioned methods. NERD creates bait density maps using GPS helicopter trajectories but is not constrained by the assumptions of traditional GIS analysis. NERD does not assume that bait density is constant within the treated polygon nor is it time intensive. Results from NERD are both automatic and instantaneous, allowing for modifications to helicopter flight plans during an ongoing eradication. During helicopter refuelling, GPS data from the helicopter are downloaded into NERD and bait density maps are returned in minutes.

The NERD algorithm combines two models. The first model estimates the mass flow rate as a function of the bait bucket aperture diameter and the second model describes the bait density profile perpendicular to the flight path of the helicopter. By combining the two models, bait density on the ground is estimated as a function of the aperture diameter of the bait bucket and the speed of the helicopter.

In this paper, we present the first field implementation of NERD on the island of Banco Chinchorro, Mexico, a small false atoll in which rodents were most likely introduced during the 19th century (Samaniego, et al., 2017).

METHODS

Study site

Banco Chinchorro is comprised of four flat keys that create a false atoll measuring 0.5–539 ha, located in the Caribbean Sea approximately 35 km off the coast of Quintana Roo, Mexico, and is classified as both a Biosphere Reserve and Ramsar site (CONANP, 2000; 2006; Samaniego, et al., 2017). Banco Chinchorro presents a wet tropical climate and is primarily covered with mangrove vegetation, composed of *Rhizophora mangle*,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 47–50. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Laguncularia racemosa, *Avicennia germinans*, and *Conocarpus erectus*, and has tropical trees such as *Thrinax radiata*, *Bursera simaruba*, and *Tournefortia gnaphalodes* (Samaniego, et al., 2017). The island provides habitat for a number of crab species, the American crocodile (*Crocodylus acutus*) and the seabird *Fregata magnificens* (Samaniego, et al., 2017). Prior to eradication efforts, the invasive rodent (*Rattus rattus)* occurred at densities from 6.5–47.9 rats/ha on Cayo Centro to 25.3–102.5 rats/ha on Cayo Norte Major (Samaniego, et al., 2017). The extensive mangrove presence on Banco Chinchorro and the presence of the *C. acutus* makes ground-based evaluation methods of bait density both hazardous and ineffectual.

Relationship between density, mass flow rate, and helicopter speed

The combination of the two models comprising NERD is presented. Here, we show that the function $\sigma(x,y)$ used to represent superficial bait density (kg/m²) complies with the following equation

$$\int_{-\frac{w}{2}}^{+\frac{w}{2}} \sigma(x)dx = \frac{\dot{m}}{s}$$

where $\dot{m}$ is the bait flow (kg/s), s is the speed of the helicopter (m/s) and w is the swath width (m).

We set the origin of a Cartesian coordinate system on the middle point of the bottom side of a rectangle with base w and height δy. This way, the bottom side is found at $y = 0$, the top side at $y = \delta y$, the left side at $x = -\frac{w}{2}$, and the right side at $x = +\frac{w}{2}$. The rectangle represents one dispersion cell.

After the helicopter completes a pass, in each point (x,y) of the dispersion cell, a superficial bait density is obtained $\sigma(x,y)$. In instances where two or more dispersions cells overlap, we simply add the density from each cell to get the total density on the overlap. The definition of the superficial bait density of mass m indicates that $\sigma(x,y) = \frac{dm}{dA}$. Rewriting the superficial density substituting dA by $dydx$ and integrating along the dispersion cell, it follows that

$$\delta m = \int_{-\frac{w}{2}}^{+\frac{w}{2}} \int_{0}^{\delta y} \sigma(x,y)dydx. \qquad (1)$$

Assuming superficial density is uniform with respect to the helicopter's flight path, represented in Fig. 1, equation (1) becomes

$$\frac{\delta m}{\delta y} = \int_{-\frac{w}{2}}^{+\frac{w}{2}} \sigma(x)dx. \qquad (2)$$

The left-hand side of the equation represents the linear bait density, which is related with the mass flow of bait from the bucket and the speed of the helicopter. A helicopter equipped with a dispersion bucket with a constant mass flow rate,

$$\dot{m} = \frac{\delta m}{\delta t} \qquad (3)$$

flies from the point (0,0) to the point $(0,\delta y)$ with a speed of

$$s = \frac{\delta y}{\delta t}. \qquad (4)$$

Combining equations (3) and (4), the linear bait density

$$\frac{\delta m}{\delta y} = \frac{\dot{m}}{s} \qquad (5)$$

is obtained.

Finally, setting equations (2) and (5) equal to each other, we obtain

$$\int_{-\frac{w}{2}}^{+\frac{w}{2}} \sigma(x)dx = \frac{\dot{m}}{s}. \qquad (6)$$

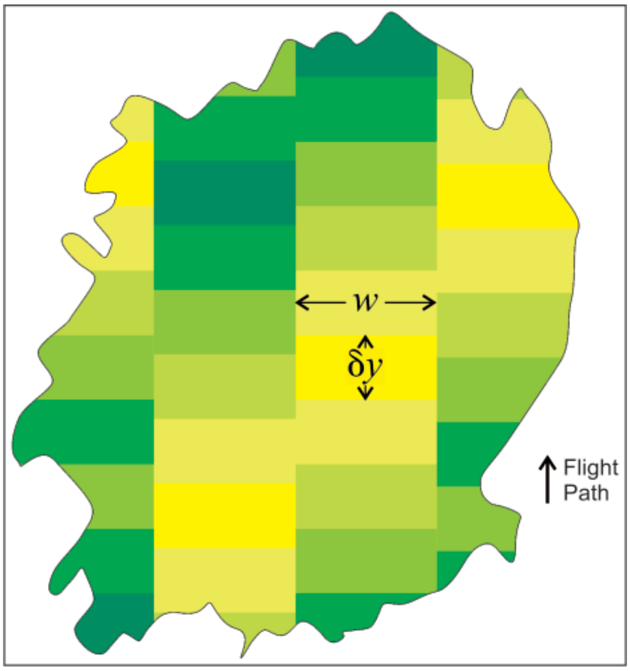

Fig. 1 Hypothetical island with bait swaths. Each vertical band represents one bait swath. Each shaded rectangle represents one dispersion cell. Shade intensity corresponds to bait density, with darker shades indicating higher densities.

Equation (6) relates the bait density on the ground with the mass flow rate and the speed of the helicopter. In order to get an explicit form of σ, a model is fitted to cross-density profiles, such as the ones shown in Fig. 2.

Simplified relationship between density, mass flow rate, and helicopter speed

The required bait density for the successful eradication of an invasive species on an island is determined by evaluating the ecosystems present and the biology of the target species. Once this density has been determined, NERD can be used to estimate the aperture of the bait bucket needed for the eradication operation in question and to plan helicopter flight paths. During the planning phase of an eradication campaign, prior to arriving on the island, a simplified relationship between density, mass flow rate, and helicopter speed is used where bait density is assumed to be constant along and across the flight path of the helicopter.

Assuming density is independent of x, i.e. σ does not change perpendicular to the flight path, equation (6) can be easily solved to obtain

$$\sigma = \frac{\dot{m}}{s \cdot w}. \qquad (7)$$

To write equation (7) as a function of the aperture diameter of the bait bucket, we express the mass flow rate of bait as a function of the aperture diameter, $\dot{m}(d)$. To do this, the bait in the bucket was weighed and the time required to empty the bucket was measured and repeated using several aperture diameters (Fig. 3).

The resulting three-dimensional model,

$$\sigma(d,s) = \frac{\dot{m}(d)}{s \cdot w} \qquad (8)$$

is shown in Fig. 4.

An implementation of this model can be found at <*http://github.com/IslasGECI/nerd*>.

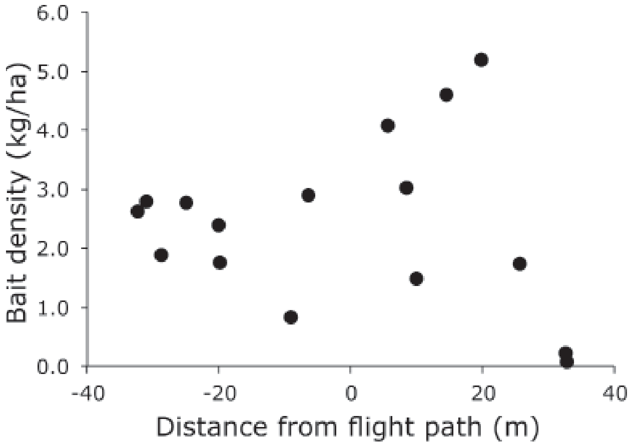

Fig. 2 Bait density profile perpendicular to the flight path of the helicopter during a test flight in Oxnard, CA in 2013. Each black dot shows the bait density measured within a quadrat.

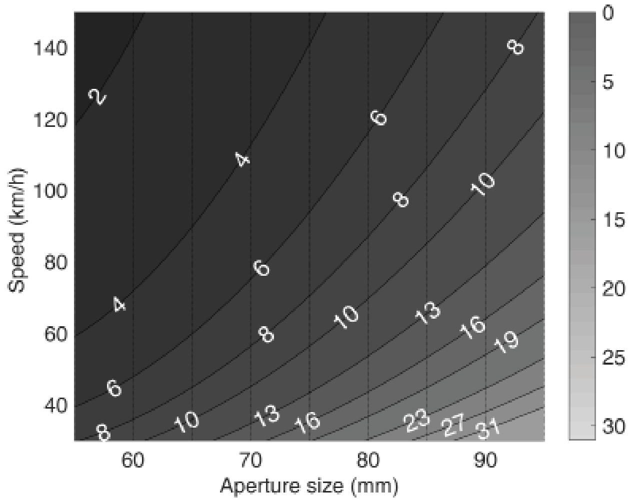

Fig. 4 Surface bait density σ (kg/ha) as a function of aperture diameter d (mm) and speed s (km/hr). The horizontal axis shows the aperture diameter of the bait bucket and the vertical axis shows the speed of the helicopter. The resulting bait density on the ground is shown in white superimposed numbers and in the second vertical grayscale axis.

RESULTS AND DISCUSSION

NERD was used to plan and carry out the 2015 eradication campaign on Cayo Centro of Banco Chinchorro. Given the desired helicopter speed, NERD was used to determine the aperture of the bait bucket and the flight paths of the helicopter required to achieve the desired bait density within the target polygon. The results of the 2015 rodent eradication campaign on Banco Chinchorro are detailed by Samaniego et al. (2017). During the course of the eradication campaign, NERD was operated by two people and generated an updated bait density map multiple times each day providing instantaneous visualisations of the current state of bait application over the island, such as the map shown in Fig. 5. These visualizations provided feedback in real time, allowing for helicopter course corrections and promoting the efficient use of rodenticide bait.

Fig. 5 shows the final bait density map estimated with NERD for the eradication campaign. From this map, it is apparent that all terrestrial areas of Banco Chinchorro were estimated to be covered with at least 60 kg/ha of rodenticide, which was the target bait density for this campaign. The colormap of Fig. 5 indicates bait density on the ground (kg/ha), with warmer colours corresponding to lower bait densities. The large red polygons that appear on the map represent inland lagoons, which were not covered with rodenticide bait excepting a few swaths that correspond to the presence of sandbars within the lagoons. Around these lagoons, manual bait placement was carried out by a team of field operatives. The maps generated by NERD were also used by this team to ensure even bait coverage and avoid excess bait application. Overall, few areas in Fig. 5 show bait densities near 100 kg/ha, indicating that helicopter flight paths were rarely redundant. Furthermore, any small isolated areas of low bait density were always surrounded by areas with target bait densities of at least 60 kg/ha.

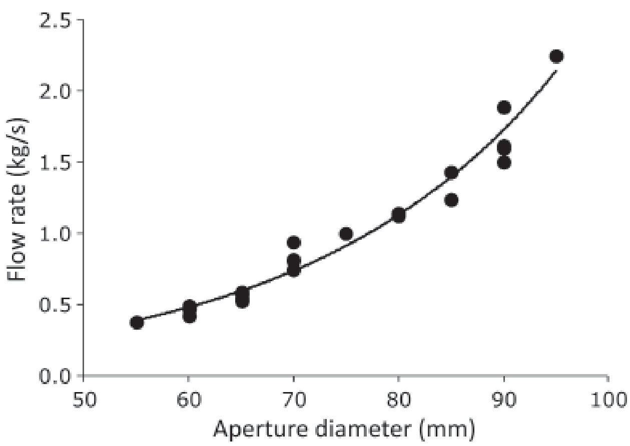

Fig. 3 Mass flow rate (kg/s) as a function of aperture diameter d (mm). Each dot represents a calibration event and the black curve is the quadratic model fitted to the data.

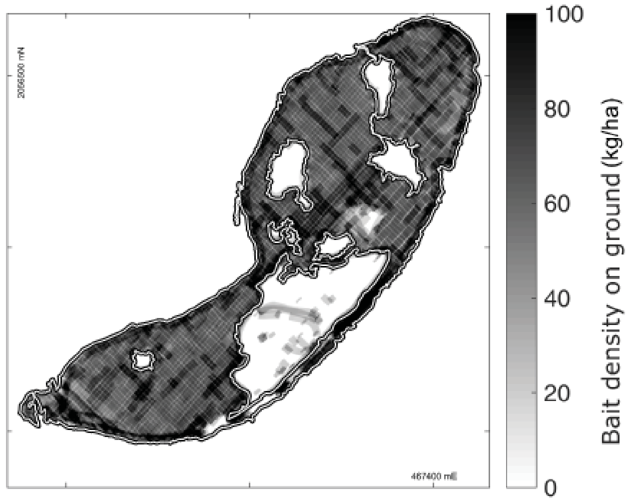

Fig. 5 Estimated bait density (kg/ha) resulting from the aerial operation of the rodent eradication campaign in Banco Chinchorro, Mexico, during 2015.The shade bar on the right indicates predicted bait density on the ground (kg/ha), with lighter shades indicating lower densities. The large white polygons show the location of inland lagoons.

The information provided by NERD was indispensable to the eradication campaign on Banco Chinchorro and allowed for immediate decisions to be made regarding not only the aerial dispersal of rodenticide bait, but also for the manual placement of bait on the ground. Until now, efforts to generate bait density maps have been inefficient and results were often not available until after the end of an eradication campaign. NERD provides information in real time, enabling dynamic decision making in the field and ensuring the efficient use of resources.

Abstract Invasive black rats (*Rattus rattus*) were successfully eradicated during 2012 from Pinzon Island in the Galapagos archipelago using the rodenticide brodifacoum. Potential exposure to brodifacoum in Pinzon tortoises (*Chelonoidis ephippium*), Pinzon lava lizards (*Microlophus duncanensis*) and Galapagos hawks (*Buteo galapagoensis*) was mitigated by captive holding of subpopulations. This was successful for all species during and shortly after baiting, however mortality of Galapagos hawks occurred post-release, likely due to the persistence of residual brodifacoum in lava lizards. Since 2013, Pinzon tortoise hatchlings are surviving in-situ for the first time in at least 120 years and the eradication of black rats is expected to have significant benefits for at least 15 other island-endemic species.

Keywords: brodifacoum, endemic species, eradication, *Rattus rattus*, restoration

INTRODUCTION

Islands are centres of endemism and endangerment, with about one-fifth of the world's threatened amphibians, one-quarter of the threatened mammals and more than one-third of the threatened birds being endemic to islands (Fonseca, et al., 2006). Invasive non-native species are major extinction drivers, with predators like rodents being particularly damaging (Bellard, et al., 2016; Doherty, et al., 2016). Four rodent species (*Rattus rattus, R. norvegicus, R. exulans, Mus musculus*) have been introduced to islands holding 88% of all insular critically endangered or endangered terrestrial vertebrates (TIB Partners, 2014). Invasive rodents cause population declines and extinctions of insular flora and fauna and interrupt ecosystem processes with negative cascading effects (Fukami, et al., 2006; Towns, et al., 2006; Jones, et al., 2008; Kurle, et al., 2008). To recover endangered populations and restore ecosystem processes, invasive rodents on islands are increasingly targeted for eradication, with at least 650 eradication attempts of introduced *Rattus* spp. populations to date (Russell & Holmes, 2015). Eradication of invasive mammals from islands results in positive responses by native species with few exceptions (Jones, et al., 2016).

Pinzon Island (1,815 ha), in the Galapagos archipelago, is uninhabited and is entirely within the Galapagos National Park. Pinzon endemics include three reptiles (Pinzon Island tortoise (*Chelonoidis ephippium*), Pinzon lava lizard (*Microlophus duncanensis*), Pinzon leaf-toed gecko (*Phyllodactylus duncanensis*)), six land snails (*Bulimulus duncanus, B. eschariferus ventrosus, B. pinzonensis, B. pinzonopsis, B. prepinguis, Bulimulus* sp. undescribed), and six insects in the orders Homoptera and Hemiptera. Thirteen species considered threatened by the IUCN are present, such as marine iguanas (*Amblyrhynchus cristatus*), Galápagos hawk (*Buteo galapagoensis*), land snails and the cactus *Opuntia galapageia*, along with several species of unassessed conservation status (IUCN, 2015).

The island was most heavily used by whalers harvesting tortoises in the early to mid-1800s and it is during this period that black rats (*R. rattus*) were most likely introduced, with specimens first collected in 1891 (Patton, et al., 1975). Black rats are the only invasive mammals that successfully populated the island. On visiting Pinzon Island in 1903, Rolland Beck noted "We… captured altogether nearly thirty live tortoises…. We were much chagrined, however, at finding no very small specimens, but soon came to the conclusion that the large rats, of recent introduction, and now common everywhere on the island, eat the young as soon as they are hatched" (Beck, 1903 p. 174). Heavy predation by black rats on eggs and hatchlings saw a halt of recruitment into the tortoise population for over a century, leaving fewer than 65 old tortoises that had survived human harvesting efforts (MacFarland, et al., 1974; Jensen, et al., 2015). In response, a 'head-starting' programme was initiated nearly 50 years ago. This entailed collecting eggs or recently hatched individuals from nests on-island, transporting them to the Galapagos National Park's centre on Santa Cruz Island where hatchlings were reared ex-situ until 4–5 years old, at which time they were repatriated back to Pinzon Island (Jensen, et al., 2015). Elsewhere in the Galapagos Archipelago, invasive black rats have been implicated in the extinction of native rodents, declines and extirpations of sea- and land-bird populations and other fauna (Cruz & Cruz, 1987; Steadman, et al., 1991; Dowler, et al., 2000). By consuming seeds and seedlings they impede vegetation regeneration and alter forest dynamics, affecting entire ecosystems (Clark, 1981). Impacts on invertebrates have not been quantified in the Galapagos Archipelago but likely occur based on reports from elsewhere (e.g. Towns, et al., 2006).

Conservationists attempted to eradicate black rats from Pinzon Island in 1988 utilising rodenticide bait dumps (coumatetralyl powder combined with rice in paper bags) and hand broadcast of baits containing brodifacoum and coumatetralyl (Cayot, et al., 1996; Harper & Carrion, 2011). The project was unsuccessful, although rodents were not detected for nine months after the operation (Cayot, et

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 51–56. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

al., 1996). This rodent suppression resulted in recruitment of Pinzon tortoises, anecdotal reports of increases in the abundance of juvenile marine iguanas, populations of Pinzon lava lizards and Galapagos doves (*Zenaida galapagoensis*), and decreases in populations of short-eared owl (*Asio flammeus galapagoensis*) and Galapagos hawks (Muñoz, 1990; Cayot, et al., 1994; Cayot, et al., 1996). A cessation of predation of Pinzon tortoise hatchlings by black rats was recorded, however an 80% predation rate by native Galapagos hawks occurred for two years after the eradication attempt (Morillo Manrique, 1992). Ambitious for its time, this failed eradication attempt set back rodent eradications in the archipelago for the next three decades, with the exception of attempts on just a few small (<20 ha) islands (Harper & Carrion, 2011).

Large-scale feral pig (*Sus scrofa*), goat (*Capra hircus*) and donkey (*Equus asinus*) eradications were implemented in the Galapagos Archipelago throughout the late 1990s and 2000s (Cruz, et al., 2005; Carrion, et al., 2007; Carrion, et al., 2011) renewing interest in large-scale rodent eradications. In 2007, an international workshop laid out a plan for developing capacity and confidence to eventually eradicate rodents from inhabited Floreana Island (17,253 ha) with complexity and scale being increased at each step (CDF & GNPS, 2007). Later in 2007, North Seymour Island (184 ha) was hand baited with wax blocks containing brodifacoum, successfully eradicating black rats (Harper, et al., 2011). In 2011, the first aerial broadcast of brodifacoum baits in South America eradicated rodents from Rabida and 11 other islands totalling 705 ha (Campbell, et al., 2013). Pinzon (1,815 ha) and Plaza Sur (12 ha) islands were originally considered within the group of islands to be targeted along with Rabida but their operations were delayed to allow trials to be conducted for increasing certainty of non-target risks to tortoises and for pilot mitigation strategies for Galapagos hawk (Campbell, et al., 2013). As part of the Rabida project, 20 Galapagos hawks were kept in captivity and released once the risk of mortality from rodenticide poisoning was considered past (Campbell, et al., 2013).

Here we describe the successful eradication of invasive black rats from Pinzon Island and the measures taken to mitigate negative impacts of rodenticide bait application on non-target wildlife.

METHODS

Site description

Pinzon Island, located in the centre of the Galapagos Archipelago, has a maximum elevation of 458 m and approximately 18 km of rocky coastline with steep cliffs on the southern and north-western coasts. Large lava blocks dominate the slopes of Pinzon. There are two craters at the centre of the island. The vegetation is xerophytic and there are no permanent bodies of water. Two small islets, each of approximately 0.4 ha in size, lie close inshore. Pinzon has no terrestrial visitor sites and is more than 10 km from any other island with invasive rodents, making unassisted reinvasion highly unlikely.

Baseline genetic sampling of rodents from Pinzon

In 2011, black rats were trapped, euthanised and samples taken (n=89) for future genetic analyses in case rodents were detected after the eradication attempt. If this occurred, as island populations of black rats can be differentiated in the Galapagos (Willows-Munro, et al., 2016), genetic samples from the pre- and post-eradication attempt could be compared to help determine whether reintroduction or eradication failure occurred (Abdelkrim, et al., 2007).

Bait application

As with previous rodent eradications in the archipelago, bait application was timed for the last three months of the dry season (October–December), when rat breeding ceases and their numbers are at a minimum, after a typical six-month dry-spell (Clark, 1980). Bait type used was ‘Brodifacoum 25D Conservation’ (Bell Laboratories, Madison WI). Baits were 2.5 g compacted crushed grain pellets of 13 mm diameter, containing 25 µg (25 ppm) of brodifacoum per kg of bait, blue dye and pyranine biomarker, a non-toxic, odourless and tasteless dye that fluoresces green under UV light. Bait was applied in two aerial applications 23 days apart at an average rate of 6.72 kg/ha for the first application (15–17 November, 2012) and 4.85 kg/ha for the second application (8–9 December, 2012; Fig. 1). Pre-eradication trials in 2010 had determined that target application rates of 6 kg/ha followed by 3 kg/ha ensured bait was available in all habitats for at least four days. It had been planned to have bait applications 7–10

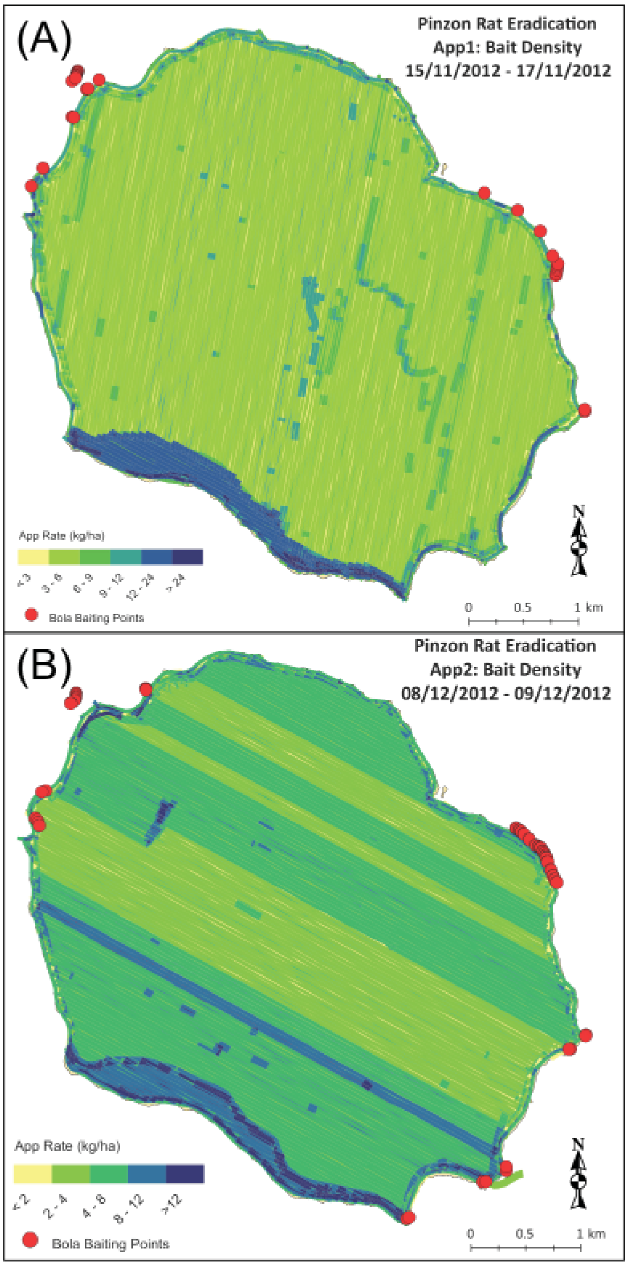

Fig.1 Bait density (kg/ha) maps of Pinzon Island from (A) first, and (B) second bait applications. Circles indicate where baits in paper bags were applied (bola baiting points).

days apart, however a pregnant rat was reported after the first bait application, prompting a decision to extend the duration between applications to maximise the probability that all rats would be exposed to bait (Keitt, et al., 2015).

An experienced pilot flew the helicopter (Eurocopter AS350-B2, France) guided by GPS, pre-programmed flight lines and light-bar (Tracmap flight unit, New Zealand). The helicopter was fitted with a custom agricultural style bait spreader bucket (CSI Helicopters, New Zealand) that was used to spread bait systematically over Pinzon Island (Fig. 1). Pre-programmed flight-lines 40 m apart provided a 100% overlap for inland areas, as previous bucket calibration indicated the bucket had an 80 m effective baiting swath width. Interior flight-lines ran coast-to-coast, with lines starting and ceasing 40 m inside of the coast to minimise the amount of bait entering the marine environment. Interior flight-lines were flown approximately north–south on the first application and east–west on the second. Two flight-lines were flown around the coast. The 'outer' coastal swath was flown along the coastline with a deflector attached to the bucket, providing 40 m unidirectional sowing towards the inland, to minimise bait entering the ocean. The inner coastal swath was carried out with the standard bucket, 60 m inland from the coast, thereby achieving a 50% overlap with the outer coastal swath. Sections of cliff over 50° slope on the southern side of the island were treated as a separate block to achieve twice the bait application rate of the interior, which is considered best practice (Broome, et al., 2014). GPS tracks were inspected periodically throughout each application. Any gaps identified in bait coverage were then baited in subsequent flights the same day.

Hand-baiting was conducted around the on-island camp, temporary hawk aviaries and one islet. The second islet was baited by hand from the helicopter using paper bags with 10 baits in each to achieve target application rates. Any areas along the coast that may not have received bait due to extreme steepness, overhangs, and deep cut gullies were also hand baited with bait in paper bags. Bait availability plots (25 m × 1 m; n=10) were used to monitor bait persistence after each aerial application at points from the coast to the highlands on the northern side of the island. Plots contained the number of pellets that corresponded to the bait application rate for each application. Each bait pellet was marked with a pin flag, which was removed as pellets were consumed. Plots were checked daily between the first and second applications and for 13 days following the second application.

Two boats acted as a floating base during helicopter baiting operations. One boat, fitted with a helicopter landing platform, also acted as the helicopter refuelling station. The second boat was fitted with a wooden platform from which bait was loaded into the bait spreader bucket as the helicopter hovered to one side.

Non-target species

Brodifacoum is the most commonly used toxicant for rodent eradications on islands and has the highest success rate (DIISE, 2016). Although an effective rodenticide, brodifacoum is highly toxic to mammals and birds, is known to persist in tissue containing vitamin K epoxide reductase (Eason, et al., 2002) and therefore presents risks to non-target wildlife through primary and secondary pathways of exposure (Broome, et al., 2015). Reptiles are considered to be less susceptible to brodifacoum (Weir, et al., 2015) but may also present a secondary exposure pathway to their predators.

An *a priori* non-target risk assessment which included Pinzon wildlife was conducted in 2010 (Campbell, 2010). A revised assessment (Fisher & Campbell, 2012) incorporated a suite of new information from the 2011 rodent eradications, and captive feeding trials used to assess risk of brodifacoum exposure in giant tortoises, lava lizards, geckos and snakes (Fisher, 2011a; Fisher, 2011b). Lava lizard samples were taken from Rabida Island before and after bait application to assess the incidence and persistence of residual brodifacoum in lava lizards but all these samples perished when a freezer was unplugged. Population-level impacts of brodifacoum applications were assessed for lava lizards and land birds using a before-after control-impact study design on Rabida, Bartolome, Bainbridge #3 and Beagle Sur islands, with Pinzon acting as a control. Based heavily upon the 2012 non-target risk assessment the Galapagos National Park Directorate and other partners determined that mitigation actions should be conducted for Pinzon tortoise, Galapagos hawk, Pinzon lava lizard, lava gull (*Larus fuliginosus*) and endemic land snails. Mitigation plans were developed for each taxon (Cunninghame, 2012; Cunninghame, et al., 2012; Oberg & Campbell, 2012; Parent & Campbell, 2012) except tortoises. Mitigation plans for lava gulls and land snails were not implemented. Lava gulls were not present on Pinzon Island during operations, and in searches undertaken before bait application all snails found were estivating so would not be exposed to bait.

Fifteen adult Pinzon tortoises were brought into captivity two years prior to baiting operations, housed on Santa Cruz Island and returned in good health two years after the rodent eradication was complete. Forty Pinzon lava lizards were taken into captivity prior to baiting and were maintained in enclosures on Pinzon Island. Termite larvae were provided as food every other day. Ten days after the second application the potential for bait consumption by lava lizards, as determined by bait degradation plots, was determined to be minimal and all surviving individuals were released near their capture sites.

Sixty hawks were taken into captivity on Pinzon Island, most prior to baiting operations, held in purpose-built aviaries and maintained on diets of goat meat, day-old chicks and (prior to baiting) rats. All hawks were ringed and genetic samples taken for future study. Four additional hawks were captured, ringed, and treated with injectable (intramuscular) vitamin K_1, however due to limited aviary space they were released. Three hawks were identified, but never captured. Captive hawks were released 12–14 days after the second aerial application of bait. Telemetry transmitters were fitted to 32 hawks before release.

Confirmation of eradication

Efficacy of rat detection methods was demonstrated prior to the eradication. Corrugated plastic chew cards with peanut butter (Oberg, et al., 2014), visual sightings, and signs of activity (prints, faeces, gnawed seed pods) readily indicated rodent presence across Pinzon Island. In January 2015 (25 months after the second bait application), these same methods were used to confirm black rat eradication with 1,140 chew cards deployed for at least 54 days, spaced at 25 m intervals along a trail network covering the island.

RESULTS

Baiting operations successfully applied bait across the island at the desired rates, as determined by helicopter GPS, baiting rate and effective swath width being overlaid on island maps (Fig. 1). Monitoring conducted more than two years after bait applications did not detect invasive rodents on Pinzon Island. None of the 1,140 chew cards deployed had rodent sign, while nearly 100% of chew cards placed pre-eradication did. Seed pods of *Acacia* spp. were intact and showed no sign of rodent damage across the island.

Based on this evidence we conclude that black rats were eradicated from Pinzon Island.

Bait availability plots indicated that after the first application (6.3 kg/ha) the average remaining density across all plots was above 2 kg/ha until day three (2.07 ± 1.75 kg/ha) and did not drop below 1 kg/ha until day 12 (0.9 ± 1.04 kg/ha). One plot had no bait available on day four; tortoises were observed consuming the baits. When the second application occurred, the average bait density remaining was approximately 0.5 ± 1.14 kg/ha. Bait availability plots for the second application (4.2 ± 1.19 kg/ha), indicated average availability remained above 2 kg/ha until day seven (2.7 ± 1.64 kg/ha), and less than 1 kg/ha remaining at day 12 (0.99 ± 1.67 kg/ha). Individual plots went to zero within two days due to Pinzon tortoises consuming bait.

Consumption of bait by Pinzon lava lizards and Pinzon tortoises was observed at higher rates than anticipated and evidenced by faeces containing blue dye, however no mortality in these species was observed in the wild. Additionally, mitigation efforts were successful at maintaining a separate population of Pinzon lava lizards and Pinzon tortoises as insurance in the case of any unexpected mortality in wild populations. Two lava lizards escaped captivity and five captive lizards died (survival rate of 87%).

All captive Galapagos hawks survived captivity and were released in healthy condition. Between 12 and 170 days after release, mortality of 22 tracked Galapagos hawks was recorded (Rueda, et al., 2016). Necropsy of four of these birds showed signs of anticoagulant toxicosis, with 379 ppb brodifacoum measured in one hawk liver (Rueda, et al., 2016). Monitoring of live-caught Pinzon lava lizards also showed residual brodifacoum in liver, for at least 850 days after bait application (Rueda, et al., 2016). The fate of 28 released hawks remains unknown, but they likely died. The remaining Pinzon Island Galapagos hawk population (n=10) was recaptured, placed into captivity in June 2013 and treated with Vitamin K_1, while toxicological monitoring of Pinzon lava lizards continued (Rueda, et al., 2016). These captive Galapagos hawks from Pinzon Island, representing 15% of the original population, were released when risk was considered acceptable in July and August 2016 with telemetry and GPS transmitters. Within three months of release, Galapagos hawks from Pinzon Island had nests with eggs. As of April 2018, nine nesting attempts have resulted in five healthy chicks, two nest failures, one unknown outcome and one pending (P. Castaño, unpublished data 2018). These and related events will be reported in greater detail elsewhere. Galapagos hawks continue to be monitored on Pinzon Island, as does toxicological monitoring in Pinzon lava lizards.

The eradication of black rats and actions taken to mitigate non-target impacts on Pinzon Island cost an estimated $1,501,000 (2013 US dollars). Cost breakdown estimates include planning ($101,000), implementation ($909,000), non-target species management ($101,000) and indirect costs ($390,000) (Holmes, et al., 2015).

DISCUSSION

Recovery of native and endemic species due to the successful eradication of invasive black rats from Pinzon is already evident, with ongoing monitoring expected to reveal further biodiversity gains. Pinzon tortoise hatchlings are now surviving in the wild for the first time in over 120 years (Tapia Aguilera, et al., 2015). With natural recruitment now occurring the Pinzon tortoise head-starting may soon no longer be required (Jensen, et al., 2015). Land-bird surveys in early 2018 found two species (cactus finch *Geospiza scandens*, Galapagos rail *Laterallus spilonota*) never before recorded from the island (Fessl, et al., unpublished data 2018). Endemic land snails also appear to be on the increase, indeed a new species of land snail was discovered two years post-eradication in permanent snail monitoring plots on the island and is currently being described (C. Parent, unpublished data 2015). With a major threat now removed, threatened land snails and other species may now be eligible for down-listing from the IUCN Red List. Similarly, on Rabida Island, two years after invasive Norway rats (*Rattus norvegicus*) were eradicated, two island endemic land snails that were considered extinct for over 100 years were rediscovered (Campbell, et al., 2013; C. Parent, unpublished data 2012). Also, on Rabida Island, a leaf-toed gecko was found post-eradication in late 2012 (Campbell, et al., 2013). The only known geckos from Rabida were recorded from subfossils estimated at more than 5,700 years old, which were classified to genus only (Steadman, et al., 1991). Although the specimen was identified at the time as the archipelago endemic *Phyllodactylus galapagensis* (W. Tapia Aguilera pers. comm. 2013), a recently proposed taxonomic split divides *P. galapagensis* into four species by major islands, including Pinzon (Torres-Carvajal, et al., 2014). Future analyses including samples of geckos from Rabida Island may also see a unique species identified for that island.

Eradication of black rats from Pinzon Island was arguably a cost-effective conservation action at US$827 / ha, resulting in the removal of a significant threat for at least 15 Pinzon Island endemic species, several archipelago endemic species and 12 IUCN threatened species. The negative impact of this conservation action on Pinzon's population of Galapagos hawks is expected to be short-term, with breeding already underway on the island. However, without additional mitigation actions this population may have been lost due to secondary poisoning, potentially requiring a translocation to re-establish Galapagos hawks on Pinzon Island. Longer-term impacts will only be discovered in time.

The persistence of brodifacoum residues in Pinzon lava lizards for at least 850 days was unexpected (Rueda, et al., 2016) and, as it was unknown at the time, was not considered within *a priori* risk assessments. Ingestion of lizards carrying residual brodifacoum for prolonged periods was likely a significant contributor to unpredicted and unexpectedly high mortality of released Galapagos hawks (Rueda, et al., 2016). The use of a prescribed duration for captive holding was, in hindsight, an error. Future mitigation efforts should use biological criteria (e.g. bait availability, sentinel animals) relevant to the pathways being managed to determine when captive held or translocated non-target species be released after brodifacoum bait has been used for rodent eradication.

Pinzon is currently the largest island in the Galapagos to be freed of invasive rodents, and the fourth-largest island globally to be eradicated of black rats (behind Macquarie, Rangitoto and Australia Islands; DIISE, 2016). Continuing on, as suggested in the original roadmap (CDF & GNPS, 2007), the next island in the Galapagos archipelago being targeted for rodent eradication is Floreana Island, nearly an order of magnitude larger than Pinzon, with 160 human inhabitants, pets, livestock, surface water and a suite of wildlife species that are expected to require mitigation actions (Island Conservation, 2013). Floreana Island represents significant challenges but also major opportunities for incorporating social well-being targets in invasive species eradication projects, as well as biodiversity targets to benefit 55 IUCN threatened species and creating the conditions for the reintroduction of 13 species extirpated by invasive species.

Removing non-native invasive rodents from islands is a proven approach to protecting endemic biodiversity (Jones, et al., 2016), and anticoagulant rodenticides are currently the most reliably effective method to achieve this. Until alternative rodent-specific methods become available (Campbell, et al., 2015), practitioners will have to become increasingly skilled at mitigating risks to non-target species related to rodent eradications to ensure the conservation benefits of this powerful tool are maximised.

ACKNOWLEDGEMENTS

We thank Galapagos National Park Directorate and Island Conservation staff for assisting in planning, logistics, and the field work conducted to implement this project. L. Cayot, J. Flanagan, J. Gibbs, C. Parent, P. Parker, T. de Vries, and staff from project partner organisations provided information relevant to developing or assisted in developing mitigation plans for non-target species. G. Harper and D. Brown assisted in operational planning. New Zealand Department of Conservation's Island Eradication Advisory Group and Island Conservation's Eradication Advisory Team provided peer review of earlier drafts of plans. Thanks to the editors and two anonymous reviewers for constructive feedback on earlier drafts of this manuscript.

Financial support

The work described here was supported by Galapagos National Park Directorate, Island Conservation, The Leona M. and Harry B. Helmsley Charitable Trust (IC), Bell Laboratories (IC), The David and Lucile Packard Foundation (IC), The Raptor Center at the University of Minnesota, Morris Animal Foundation (Grant D14ZO-061; TRC), Galapagos Conservancy (IC) and the Charles Darwin Foundation. The Galapagos Invasive Species Fund (IC) supported development of this manuscript. This work was carried out as part of management operations of the Galapagos National Park Directorate.

Abstract A pilot project for the eradication of beavers (*Castor canadensis*) in Tierra del Fuego started as part of a bi-national agreement, signed between Argentina and Chile, to restore the affected environments. The project covers nine pilot areas of different landscapes and land tenures in the Argentinian part of Isla Grande de Tierra del Fuego. We report on the results from operations in the first of the pilot areas. From October 2016 to January 2017, ten trappers (named restorers for advocacy purposes) used body-grip traps, snares and an air rifle, in a first phase, which included 2,237 trapping nights and 1,168 trap-sets. Shooting efforts were not monitored. Traps were set for 1,401 trapping-nights and caught 175 beavers at a success rate of 12.5% (captures per trap night). Snares were set for 936 snare-nights and caught 22 beavers at a success rate of 2.3%. Seven beavers were shot. Most beavers (65%) were removed during the first week of trapping in the different watercourse sections. Stopping trapping for a week or more did not increase efficiency. From March to May 2017 restorers removed 24 survivors and/or reinvaders, including 10 from two previously untrapped colonies. Capture efficiency for this removal period was low for body-gripping traps but not for snares. The sex ratio of catches was 47% females to 53% males. The age structure of catches was 15% kits, 29% yearlings, 51% adults, with 4% not aged. An estimated total of 41 colonies was trapped, giving an average of 5.6 animals per colony. After nominal eradication was declared by restorers, 154 camera trapping nights were deployed to assess eradication success. Nine cameras (of 26 cameras used) detected beavers. Therefore, eradication was not achieved using the methods and efforts in the first part of the pilot study. This highlights the need for more effort or the application of different techniques or trapping strategies. For example, daily checking of traps may cause the animals to be cautious so, the next step in the programme will involve exploring alternative trapping methods to reduce disturbance.

Keywords: Argentina, *Castor canadensis*, eradication programme, management, pilot study, trapping

INTRODUCTION

North American beavers (*Castor canadensis*) are semi-aquatic and territorial rodents. They live in family groups generally composed of two breeding adults, two yearlings and two kits; the yearlings are forced to leave the natal colony by the age of two (Lizarralde & Escobar, 1997; McTaggart & Nelson, 2003). The family group controls a group of adjacent dams, defending its territory from other beavers. Each family group can build one or more lodges (although they may also den in the river banks) and share a single food cache.

In 1946, 20 beavers were introduced from Canada to Tierra del Fuego, South America (Pietrek & Fasola, 2014), with the aim of developing a fur industry. Beavers found extensive suitable habitats, high availability of food, lack of predators and unoccupied territory (Lizarralde, 2004). These features allowed beavers to spread quickly throughout Tierra del Fuego (Skewes, et al., 2006; Anderson, et al., 2009). Several impacts on the environment of Tierra del Fuego were reported and it was suggested that beavers caused the largest landscape-level alteration to the region since the Holocene (Anderson, et al., 2009). The most obvious impacts are the reduction of the riparian vegetation due to their activities, which includes the building of at least 70,000 dams in Argentinian Tierra del Fuego (Eljall, et al., 2016), affecting at least 31,000 ha of forests, grasslands and peat bogs (Henn, et al., 2016), as well as the fen areas (Westbrook, et al., 2017). The beech forests of Tierra del Fuego are not adapted to the impact of beavers, so their impacts are long lasting (Anderson, et al., 2009). Their dams also limit the dispersal of native fish and the water in their dams changes the benthic communities, modifying the macroinvertebrate assemblages by engineering changes to the fluvial and riparian environment (Anderson, et al., 2006). Beavers also modify the dynamics of the streams by altering sedimentation (Vazquez, 2002; Martin, et al., 2015). Last, but no less important, beavers impact the economy by flooding roads and culverts, and affecting ranching activity, reducing pastures by flooding as well as affecting fences.

Attempts to control beavers by commercial hunting during the 1990s and 2000s failed. Beavers were detected in continental South America in the 1990s (Skewes, et al., 2006; Wallem, et al., 2007; Schiavini, et al., 2008; Anderson, et al., 2009), although recent dendrochronological evidence takes their arrival date to 1968 (Graells, et al., 2015). The presence of beavers in the continent raised alarm about the possibility of their dispersal through the greater American continent. In view of these issues, Argentina and Chile started, in 2005, to discuss a change in strategy.

Eradication was deemed as feasible (Parkes, et al., 2008), and adopted as a strategy by Argentina and Chile in 2008, after signing a bi-national agreement for the restoration of the southern ecosystems affected by the beaver (Malmierca, et al., 2011). At present, both countries are performing pilot projects, funded by the Global Environment Facility (GEF) and national counterparts. The pilot project in Argentina is under the umbrella of the major project "Strengthening the Governance for the Protection of Biodiversity through Formulation and Implementation of the National Strategy for Invasive Exotic Species" GEF Project ID 4768. The project runs from 2015 to 2019, covering nine pilot areas of Tierra del Fuego.

The objectives of the project (Schiavini, et al., 2016) are essentially to answer questions raised during the feasibility study: building capacity, learning about technical and organisational challenges of the process, showing the environmental benefits of beaver removal, and deciding the next steps between the two countries.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 57–63. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Several research priorities and questions in relation to the eradication of beavers are expected to be answered by the pilot project:

- How much effort is needed to eradicate beavers and to declare eradication on a small scale?
- What factors affect effectivity of trapping? The tools used? The sequence of deployment? Learning by beavers to avoid traps?
- What is the effort demanded for active surveillance to avoid reinvasion?
- How to develop passive surveillance from society?
- Is the bureaucracy able to accommodate the dynamics of eradication projects?
- Are any beavers found, after nominal eradication is declared, likely to be survivors or reinvaders?
- Does the environment recover in a short time frame after beaver removal?

The nine Argentinian pilot areas cover an area of 1,017 km^2, with a range of 14–238 km^2 (Fig. 1). In this paper, we report the results of operations achieved in the first pilot area, Esmeralda-Lasifashaj, and discuss the challenges revealed for the larger major project.

MATERIALS AND METHODS

The Esmeralda-Lasifashaj area (54 km^2) belongs to the ecological region of the forest range (Collado, 2007). The landscape represents a U-shaped valley with the valley bottom covered with *Sphagnum* peat bogs and poorly drained mires (Figs 2 and 3). Slopes are covered with southern beech forests (*Nothofagus* spp.) with the vegetation line reaching about 700 m altitude. The main valley is surrounded by eight lateral valleys. The area is open to reinvasion as it has no geographical boundaries that limit beaver dispersal, mainly from the west and east. However, it was proposed as a pilot area for several reasons: it is located only 20 km from Ushuaia city, is

used by the public for recreation and tourism, and the area holds a permanent cross-country ski trail, which is affected by beavers. For these reasons, the area was selected as a way of showing the environmental, social and economic benefits of removing beavers.

The dams and lodges built by beavers are so conspicuous that they can be identified in satellite images. During the planning process, beaver dams and lodges were mapped using Google Earth and integrated with the dams identified by Eljall, et al. (2016). Then, 363 locations of beaver activity were loaded into the GPS units used during the operation (Garmin eTrex 20x), to be used as a general guide for moving through the terrain to the areas impacted by beavers.

The skills of the personnel involved in hunting should include not only good trapping skills, but also the ability to spend several days in the field in the harsh weather of Tierra del Fuego and deliver good trapping data, essential for assessing trapping efforts and eradication success. Good, traditional trappers work with a focus on yield, while personnel needed for eradication need to "look for the last animal". With this change in focus, 10 people were selected and trained from a group of 39 people interviewed. The training was performed by our own personnel, staff from the National Parks Administration and from the volunteer fire brigade. Training included the use of trapping tools, data recording and first aid in the field. The final selection included a combination of people with previous trapping skills and people with good outdoor abilities and a willingness to learn. Hunters are publicly called "restorers" as a way of helping to advocate for the final objective of the project, i.e. building the correct conditions for environmental restoration by means of beaver eradication.

The trapping equipment and tools were purchased with advice from the Animal and Plant Health Inspection Service of the USA, who also provided a handbook for best-practice management. Two main tools are being tested, body-gripping traps and non-powered cable devices (snares), complemented with a PCP air rifle. The group was commanded by a chief of operations and assisted by a logistics officer.

The spatial and temporal progression of trapping differs from traditional trapping operations, where hunters deploy their tools progressively through the landscape, usually in a regular or grid mode. Given that the trapping target is located along watercourses or sectors of poor drainage such as edges of peatlands, trapping effort follows these landscape features. For planning purposes, the pilot area was divided into sectors that brought together groups of sections of channel or activity detected during planning. Watercourse sections were trapped inside sectors until "nominal" eradication was achieved, when trappers moved to another watercourse section. After nominal eradication of a sector, operations progressed to another sector.

At the watercourse section scale, trapping was made according to decisions made by each restorer. A "trap-set" is a trap (either a body-gripping trap or a snare) set at a particular location and for a number of consecutive trapping nights. Traps are usually set along watercourses and near dams with beaver activity denoted by the girdling of trees, fresh beaver trails, freshly gnawed branches in front of the dams, castor mounds, and /or accumulation of submerged tree branches with leaves. Traps are also set either in trails or slides made by beavers or in purpose-made openings at the front of the dam. The limits of beaver colonies are not always evident. However, during fall and winter, family groups gather at one lodge, so colonies are more easily distinguishable. During spring and summer, young animals disperse from their natal colonies, so the movement of animals leads to colony boundaries being confused. Also, traps can be set in the same place for more than one night. After a number of trapping nights, hunters noticed a reduction in their trapping efficiency, and at some point, they decided that a "nominal" eradication was achieved in this watercourse section and moved to another section. As a result, data recording is quite different from some other hunting and trapping operations, where hunters either traverse a landscape searching for their prey, or traps are set up more permanently at sites or along transects or grids.

The records of trapping and yields attempted to reflect the operation in great detail. An account of each trap set and its subsequent outcome (set, capture, activation without capture, not activated, removed) was recorded every day, taking into account the use of both the body-gripping traps and snares, with each one requiring daily checks for humanitarian reasons. Each trap had a unique number for identification. For data recording, an application was built into Cybertracker software (Steventon, 2017), allowing us to build a database with a record of each trap (set, revision and retirement, with or without capture), as well as ancillary data (e.g. location of placement, use of attractant). The application is available upon request, or at <http://cybertrackerwiki.org/index.php?title=Community_applications>. For data recording, we used an outdoor rugged tablet (Boolean A71, Boreal Technologies Inc). The database can be transferred to Spreadsheets or to any GIS system, as Cybertracker software can export shapefiles. Restorers also carried a GPS unit for tracking their activity.

Operations ran from October 24, 2016 to January 31, 2017 in the first phase. From March 2 to May 15, 2017 (Fig. 4), the area was checked again to remove survivors/invaders. Restorers worked mostly daily, during blocks of five days or four trapping nights, commuting each day from Ushuaia to the pilot area that is traversed by a National Route highway. When restorers worked on the lateral valleys, they camped for between three and five days. A Robinson R44 helicopter was used to search for dams in specific areas (Johnston & Windels, 2015) and to transport personnel and equipment to lateral valleys. Two colonies were left untrapped until the survivors-reinvaders removal phase, as they were used by tourist operators during the summer. Tour operators agreed as this would be the last time they would be using these colonies for their tours.

Trapped animals were aged in the field, based on external measurements, as kits, yearlings or adults, and were sexed by detection of the baculum. Samples were stored for accurate age determination, the breeding status of females and for future assessment of the accuracy of genetic tools to distinguish survivors from new invaders in areas free of beavers.

For verification of eradication, an independent team visited a sample of the watercourse sections, as restorers declared the "nominal" eradication, between December 12, 2016, and May 24, 2017. Twenty-six camera traps were set in front of artificial castor mounds with beaver lure at a 1–2m distance from the camera and no more than 1m from the water body. Each camera was placed at a height of between 20 and 40 cm from the ground to capture full images of beavers, and operated, on average, six days, with a range of 3–10 days. Cameras were located both in the main valley and in all the lateral valleys.

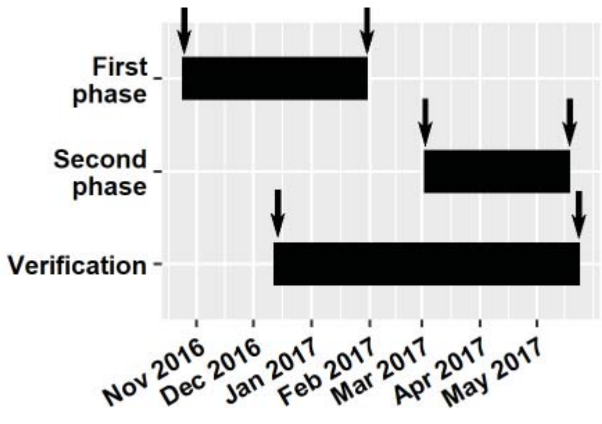

Fig. 4 Gantt chart including the first and second eradication step (the arrows mark the first and last capture) and the period of camera-trap vigilance (the arrows mark the first and the last detection).

As operations took place during spring and summer, territorial limits were difficult to assess. The total number of colonies was estimated based on the spatial distribution of catches following Johnston & Windels (2015). The Esmeralda-Lasifashaj area was divided into 18 sectors for data analysis. All statistical analysis was performed in Infostat (Rienzo, et al., 2016).

A monitoring plan measuring the environmental benefits of removal of the beavers is being developed by independent groups. The monitoring includes assessment of the of trees that will not be subject to beaver cutting after beaver removal, water quality, macroinvertebrate diversity, metabolism of the watercourse and fish diversity.

RESULTS

Mop-up phase

From October 2016 to January 2017, restorers walked 2,930 km over the area (Fig. 5). For logistic purposes, a helicopter was flown for nine hours. Trapping nights were derived from trapping records by summing up trap revisions and retirements. An additional 5% was added to the effort for the offset for traps that were not checked daily (based on an analysis of a subset of data).

Body-gripping traps were deployed in 715 trap sets, yielding 1,401 trapping nights. Snare traps were deployed in 453 trap sets, yielding 936 trapping nights. This represents a total of 2,337 trapping nights with 1,168 sets. Each trap operated on average 1.97 nights with a range of one to four nights. Rifle effort was not monitored, as it was employed in an opportunistic fashion. A total of 197 beavers were removed by trapping; 175 with body-gripping traps and 22 with snares, together with seven individuals that were shot (Fig. 6). The trapping efficiency was 12.5% for body-gripping traps and 2.3% for snares, giving an average efficiency of 9% for trapping.

The capture efficiency for each day of the working blocks was assessed. For example: during the first day of the working block the main activity was setting traps; during the second day of the working block there were 443 reviews or removals and 46 catches, which gives an efficiency of 10.4%; on the sixth or seventh day, very little field work was performed. This analysis was then limited to reviews and retirement of traps from Tuesday to Friday. Using a test of more than two proportions (Zar, 2010), the null hypothesis of the difference of proportions revealed no differences in catch efficiency over the different days of the week (χ^2 statistic, p=0.152, df=3). Therefore, restorers did not reduce trapping efficiency through cumulative disturbance by working consecutive days in a watercourse segment, since the efficiency was similar between the days of the working block. Another explanation might be that even though beavers are more "relaxed" or “naïve” to trapping early in the week (i.e. Tuesdays), restorers gradually perform better in a particular area during the week, compensating for the increasing caution of beavers with improved trapping sets.

The effect of disturbance from hunting over the weeks was also assessed, checking if leaving a section of the watercourse without trapping for a week after trapping for one or two weeks increases the trapping efficiency by reducing the awareness of traps by the beavers. The scarce data available for this analysis revealed no positive effect by leaving a watercourse section without traps. The first week of trapping in the watercourse´s section yielded 65% of the beavers, giving an average capture efficiency higher than the efficiency of the rest of the trapping days (10.3% and 9% respectively; p <0.0001, difference of proportions of Infostat). The capture efficiency did not differ between the main valleys and the lateral valleys, comparing the 10 channel sections of the main valley with the six channel sections of the lateral valleys (p=0.88).

A total of 151 traps (289 trapping nights) were set with attractant (beaver hormone, food lure): 142 traps (263 trapping nights) set with attractant, six traps (13 trap nights) with attractant added after the first review and three traps (13 trap nights) with attractant added after the second review. These 151 traps produced 13 catches (289 trap nights), giving an efficiency of 4.5%. If only beaver lure was considered, there were 10 catches in 89 traps (163 trapping nights), giving an efficiency of 6.1%.

The sex ratio of catches did not differ from 1:1 (p=0.26, 45% females vs 52% males, 3% unsexed). Also, the

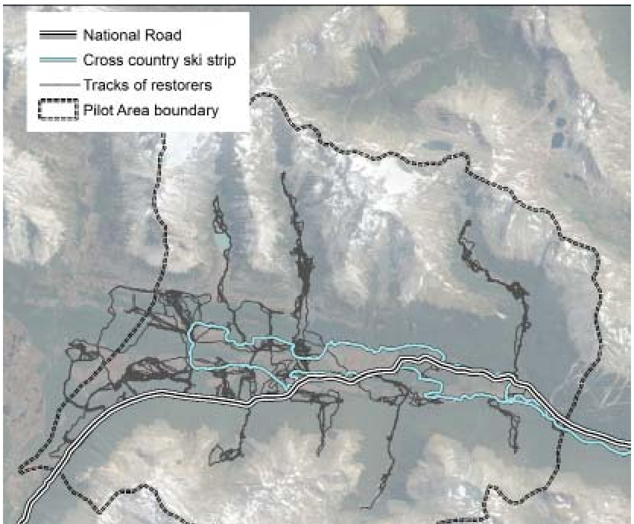

Fig. 5 Tracks recorded by restorers in the pilot area Esmeralda-Lasifashaj. Some tracks were not recorded due to failure of the GPS units.

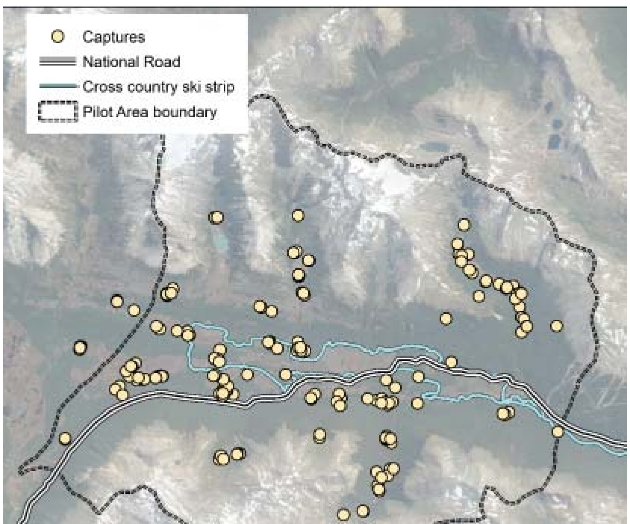

Fig. 6 Catches recorded for the pilot area Esmeralda-Lasifashaj

proportion of females did not differ between body-gripping and snares (difference of proportions = 0.003; p≈1). The age assessment made by restorers revealed an age structure of 15% kits, 29% yearlings and 51% adults (4% not aged), with similar proportions of age classes between body-gripping and snare traps (p=0.21). During the first days of trapping along each watercourse section, 83% of the sections yielded females while 50% of them yielded males (marginally significant difference, p=0.043).

Survivors/reinvaders removal phase

During this phase, restorers walked 380 km deploying 735 trap nights (529 body-gripping and 206 snares). This represented 23% and 31% of the previous walking and trapping effort respectively. Twenty-four animals were removed (22 with body-gripping traps and two with snares, Fig. 6). From them, 10 animals came from the two colonies left untrapped during the mop-up phase, and therefore 14 animals should be considered survivors-reinvaders. The main valley provided most of the captures (83%), although most of the trapping effort was focused there (83%).

Capture efficiency was 3.97% for body-gripping traps and 0.97% for snares. Trapping efficiency, compared with the first phase, was lower for body-gripping traps (p<0.0001), but not for snares (p=0.20).

One of the two colonies originally left untrapped yielded six males (one adult, four juveniles and one kit), one female and one animal of unidentified sex. The second colony yielded two males (one juvenile and one kit) and two females (one adult and one kit).

The survivors/reinvaders captured consisted of 10 males (six adults, three juveniles and one kit), six females (four adults and two juveniles) and two animals of unidentified sex. Five sites provided only males in this phase (including a site with only three males). Attractant was used in only seven of the sets, therefore the outcome was not analysed due to the low sample size.

Population assessment

Analysis of the spatial distribution of catches concluded that 41 colonies were trapped (plus a few recolonised sites). The average number of beavers per colony was 5.6, although this may exclude offspring, presumably dead inside dens (see Discussion). The survivors/reinvaders came from what we identified as 11 different colonies. As beavers were dispersing during the time of operations, it is difficult to compare the age/sex of the beavers caught during the mop up with those captured during the survivor/reinvader phase.

Non-target catches

Trap specificity was 90%. Non-target catches were recorded only during the first phase. One culpeo fox (*Lycalopex culpaeus*), and one upland goose (*Chloephaga picta*) were released alive. Native species killed included two spectacled ducks (*Speculanas specularis*), three unidentified ducks and two upland geese (*Chloephaga picta*). Exotic species captured included 10 muskrats (*Ondathra zibethicus*) and one mink (*Neovison vison*) which were killed and one grey fox (*Lycalopex griseus*) which was released alive.

Eradication verification phase

The 26 cameras yielded a total of 154 camera trapping nights. Nine cameras detected beavers after a period between zero to five days (average two days), and 17 cameras did not detect animals after a period of between three and 10 days (average six days). In addition, two persons walked 155 km to check for signs of presence/absence at the same time that the cameras were set. The last beaver detection was confirmed on 24 May, 2017, nine days after the last capture. Later in the year, from August to October, surveys for survivors/reinvaders were planned to continue.

DISCUSSION

This is the first eradication attempt for beavers from one area in a short time frame. The finding of survivors/reinvaders has two explanations, not mutually exclusive. First, operations may not have reached the last individuals. Second, the lack of physical barriers may ease the movements of dispersing beavers from neighbouring colonies. There had been two previous attempts at beaver removal (Schiavini, et al., 2016). The first attempt took place in the Tierra del Fuego National Park, where a sustained control plan aimed to reduce the size of the beaver colonies was followed by their complete removal from 2,000 ha in 2011. The second attempt took place in the provincial protected area of Reserva Provincial Corazón de la Isla in 2014, where beavers were removed from 4,900 ha in two months, although the project was discontinued for financial reasons and this area has been included as one of the pilot areas to be treated in the near future.

The estimated efficiency of body-gripping traps (12%) was lower than the 22% reported by Lizarralde, et al. (1996) for Tierra del Fuego. However, it must be noted that the first estimate derives from tests for trapping aimed at performance-oriented catches per number of captures. In contrast, the complete removal of animals from one area explains the lower trapping efficiency reported here. Results from the next pilot areas will allow us to have a broader view of the calculation.

The original trapping set and reviewing approach required daily checking of traps. The presence of people walking every day over the dams and dens, and in the vicinity of colonies, can make beavers more “cautious”, affecting the likelihood of removing the last animals. The potential of beavers “learning” from disturbance and becoming wary (*sensu* Morrison, et al., 2007) is a problem for efficient eradication operations. Initial data analysis did not reveal the cumulative effect of the presence of the restorers in the capture efficiency. Neither did it find beneficial effects of not setting traps for a number of days. Because part of this pilot area was subject to different intensities of trapping over the years, animals from there may already have been cautious to human disturbance. However, capture efficiency did not differ between areas with more historical trapping effort (the main valleys) and areas less accessible to trapping (the lateral valleys), suggesting a lack of “memory” from previous trapping disturbance in the area.

The next trials will give us a chance to answer the questions raised above, and explore alternative trapping effort schemes – for example, the exclusive use of body-gripping traps. This lethal tool would allow us to leave traps unattended for several days, reducing the likelihood of disturbance. However, the size and weight of body-gripping traps limit the number of traps a person can transport and manage during a day, and the trade-off is that trapping effort would be overestimated by this approach. Nevertheless, the benefits of eradication would overcome the uncertainty associated with estimating the eradication effort.

The unexpectedly small number of kits present in the catch may be because they were too young to leave the dens. The trapping effort coincided with much of the breeding season. Also, the lodges were not destroyed as part of the management process because we wanted to avoid the escape of animals from their colonies. Consequently, the most likely scenario is that kits remained in the den and starved after the mother was captured. This poses a potential constraint on the timing of future eradication attempts if animal welfare issues are considered. Although the sex ratio of the capture was even overall, females outnumbered males by 1.66:1 ($p = 0.043$) early in the trapping of each watercourse section, when 83% of females were caught. These numbers support the idea of greater mobility of females outside the lodges due to their maternal duties.

Trapping efficiency was lower during the survivor/reinvader removal phase than during the first phase. This is to be expected due to fewer remaining animals, and/or because they may have "learnt" to be more cautious. However, it is expected that reinvaders would not be as cautious as survivors. More data are needed to explore this issue. During the mop-up phase we could not identify family colonies accurately from the spatial distribution of catches, and consequently we could not discriminate survivors from reinvaders based on their sex and/or age. It is expected that genetic analyses would assist in identifying survivors from reinvaders.

Of the 28 individuals captured during the survivor/reinvader phase, 18 came from colonies previously trapped; 10 males, six females and two of undetermined sex. In five sites only males were captured, and three males were captured at one site. Most of the females were captured at the same site next to males. The sex ratio of captures for this phase did not differ significantly from 1:1 ($p=0.3$), although male catch seemed to be larger. This could be a reflection of greater male dispersion from neighbouring areas, following source–sink dynamics.

Analysis of the spatial distribution of catches indicated that 41 colonies were trapped, plus a few recolonised sites. These values are in agreement with previously known colony densities for the area. Lizarralde (1993) reported 4.72 colony sites/km, defining a colony site as "a pond, or series of ponds used by a colony of beavers throughout the year or years", different than the usual definition of a colony, that refers to a family group living in a series of ponds and sharing a common food cache. Lizarralde & Escobar (pers. comm. 2000) reported, for 1998 and 1999, densities of 0.91 and 0.45 active colonies/km for the Olivia River and of 0.67 and 0.52 colonies/km for the Lasifashaj River, respectively. Schiavini, et al. (2016), reported densities of 0.42 and 0.37 colonies/km for the Olivia and Lasifashaj rivers in March 2010.

The estimated number of beavers per colony (5.6 individuals/colony) may underrepresent kits for the reasons explained above. On the other hand, since trapping occurred during a period of high juvenile mobility, the total catch is likely to overestimate the number of individuals per colony, since it would include animals from colonies neighbouring the pilot area.

Eradication was not achieved during operations in this first pilot area since beavers were detected by trap-cameras during the verification phase and the removal and revision work continued after the month of May. The main reasons are likely to be that the area is open to reinvasion and that trapping took place during a time of high juvenile dispersal. In view of these preliminary results, a large-scale eradication programme in the Isla Grande de Tierra del Fuego (48,000 km^2), must consider the spatial progression of the operations, adjusted to the possibility of reinvasion of the area under management and to the biological cycle of beaver dispersal. Large-scale operations should be carried out either in larger areas, covering areas with physical barriers for reinvasion, and/or restorers should cover the landscape in a more structured way. It is expected that the experience gained in the rest of the trial will allow us to adjust the strategy.

ACKNOWLEDGEMENTS

Towards a genetic approach to invasive rodent eradications: assessing reproductive competitiveness between wild and laboratory mice

M. Serr[1,2], N. Heard[1] and J. Godwin[1,2]

[1]Department of Biological Sciences, N.C. State University, Raleigh, NC, USA. <meserr@ncsu.edu>. [2]Genetic Engineering and Society Center, N.C. State University, Raleigh, NC, USA.

Abstract House mice are significant invasive pests, particularly on islands without native mammalian predators. As part of a multi-institutional project aimed at suppressing invasive mouse populations on islands, we aim to create heavily male-biased sex ratios with the goal of causing the populations to crash. Effective implementation of this approach will depend on engineered F1 wild-lab males being effective secondary invaders that can mate successfully. As a first step in assessing this possibility, we are characterising genetic and behavioural differences between *Mus musculus* strains in terms of mating and fecundity using wild house mice derived from an invasive population on the Farallon Islands (MmF), a laboratory strain C57BL/6/129 (t^{w2}), and F1 wild-lab offspring. Mice with the 't allele' (t^{w2}) have a naturally occurring gene drive system. To assess fertility in F1 wild-lab crosses, t^{w2} males were paired with wild-derived females from the Farallon Islands (MmF). Results of these matings indicate litter sizes are comparable but that weaned pup and adult wild-lab mice are heavier in mass. Next, we initiated tests of male competitiveness using larger (3 m^2) enclosures with enrichment. We introduced both an MmF and a t^{w2}-bearing male to two MmF females to assess mating outcomes. Preliminary results of these experiments show none of the offspring carried the t-allele. However, performing the same experiment with F1 wild-lab males instead of a full lab background resulted in 70% of offspring carrying the t^{w2} allele. This indicates that F1 wild-lab males may be able to successfully compete and secondarily invade. It will be important in subsequent experiments to determine what characteristics contribute to secondary invasion success. More generally, a better understanding of characteristics contributing to overall success in increasingly complex and naturalistic environments will be critical in determining the potential of a gene drive-based eradication approach for invasive mice on islands.

Keywords: competition, gene drive, invasive rodents, reproductive fitness, secondary invasion

INTRODUCTION

Invasive rodents are a key biodiversity threat for the majority of the world's islands and eradication campaigns are often employed to prevent loss of island endemics (Howald, et al., 2007; Campbell, et al., 2015). These eradications employ rodenticides and have been successful in eliminating invasive rodents from over 400 islands (DIISE, 2017). Rodenticides, however, have a higher failure rate with mice (*Mus musculus*), as opposed to rats (*Rattus* spp.) (MacKay, et al., 2007) and their use on inhabited islands presents severe logistical challenges. Additionally, rodenticides are not species-specific and present animal welfare concerns (Campbell, et al., 2015). These challenges have created a compelling need for alternative approaches to rodent eradication.

One potentially promising approach to eliminating invasive mice from islands would be to bias offspring sex ratios by genetically engineering mice that produce only one sex of offspring. Pairing this approach with a genetic drive mechanism to spread this trait in an invasive mouse population would be critical. Key first steps are to understand the processes of reproductive competitiveness and the capability of an introduced mouse to introgress into established island populations, a process we are terming 'secondary invasion'. The phenomenon of secondary invasions and multiple introductions has been documented in invasive brown anole (*Anolis sagrei*) populations with evidence that secondary invasions may be frequent and can add genetic variation to existing invasive populations (Kolbe, et al., 2004). This secondary invader phenomenon in house mice, however, is less well understood and genetic evidence suggests variation in how this occurs across islands. Some studies suggest that secondary invaders may be frequent (Berry, et al., 1991; Bonhomme & Searle, 2012) while others suggest instead only single primary invasions (Hardouin, et al., 2010; Gabriel, et al., 2015). For rodent eradications these secondary invaders would be carrying the gene drive and spread of this construct through the population would be necessary for this approach to be effective.

The development of the CRISPR/cas9 genome editing technology has recently revolutionised genetic engineering capabilities (Barrangou & Doudna, 2016). This has increased interest in genetic pest management approaches first conceptualised by Burt (2003) and built upon by other authors more recently (Sinkins & Gould, 2006; Esvelt, et al., 2014). Many of these approaches centre on gene drives, systems in which a genetic construct producing a desired phenotype (e.g., sex ratio manipulation, sterility) is preferentially inherited by offspring. These are considered 'selfish' genetic elements because the majority of offspring will inherit the genetic construct and it therefore could spread quickly through a population (Lyttle, 1991). In mice, a naturally occurring gene drive is found on chromosome 17 and is termed the t-allele (Silver & Buck, 1993). The t-allele bearing sperm impact the motility of non-t bearing sperm and this leads to an inheritance rate of greater than 90% for the t-allele (Bauer, et al., 2005; Baker, 2008). Homozygosity of the t-allele (t/t) is typically lethal, but this is not true of the variant form termed the t^{w2} allele, although homozygosity does cause sterility (Levene & Dunn, 1961).

A gene drive-based approach to eradication could use either a naturally occurring drive or a synthetic drive based on CRISPR/Cas9 and functional drives with this technique have now been demonstrated in mosquitoes, flies, and yeast (Harris, et al., 2012; DiCarlo, et al., 2015; Gantz & Bier, 2015); see also early contributions by Craig, et al. (1960) and Hamilton (1967). Theoretically, by biasing offspring sex ratios heavily towards males, reproduction could be impaired and populations reduced. One way this could be done would be to use the *Sry* gene. The *Sry* gene is the key male determining factor in mammals and is sufficient to start the cascade of events leading to male development (Hacker, et al., 1995). Placing the *Sry* into an autosome induces development that is phenotypically male in mice that are genotypically XX (Koopman, et al., 1991). Inserting *Sry* into a naturally-occurring gene drive such as the t-allele or a synthetic drive based on

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 64–70. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

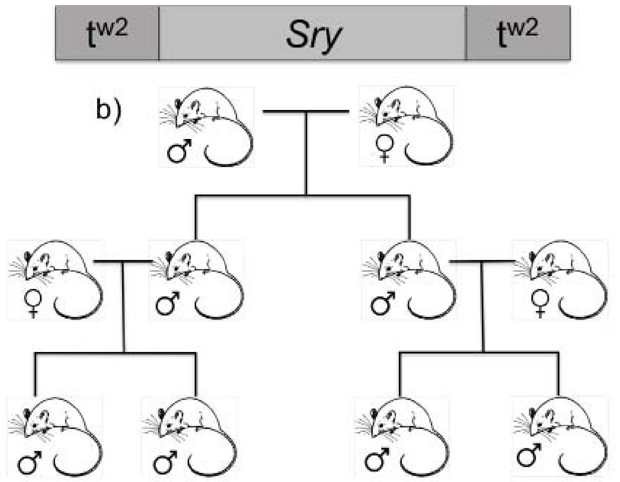

Fig.1 Depiction of the *Sry* gene inserted into the t^{w2} gene drive accompanied by a depiction of how the population would bias to be all male.

CRISPR/Cas9 should create the potential for reduction of an invasive mouse population by reducing and ultimately potentially eliminating production of fertile females (Fig. 1; Backus & Gross, 2016; Piaggio, et al., 2017; Prowse, et al., 2017). A synthetic gene drive using CRISPR/Cas9 could theoretically be employed in a similar way to ensure all offspring inherit a feminising gene.

Regardless of the genetic mechanism employed, the reproductive competitiveness and relative fitness of gene drive carriers are likely to be important in determining the success of any genetic approach to reducing invasive mouse populations. Assessing reproductive competitiveness is the focus of this study. Since mice introduced with a gene drive mechanism would essentially be secondary invaders into an established invasive mouse population, it is important to better understand processes affecting introgression into established demes. Mice are social animals and dominant males will often hold and defend a territory (i.e. deme) that provides reproductive access to reproductive females while subordinate males do not (Bonhomme & Searle, 2012). How incoming mice are able to successfully integrate into island demes is not clear. If a gene drive approach was used, then the incoming males would need to compete with the resident island males for females. Competition and aggression tend to occur between male mice when there are limited territories (Gray & Hurst, 1998). Mouse populations living non-commensally on islands can instead exhibit an 'island syndrome' where they show important differences with commensal populations. These can include increases in body mass and, importantly in the context of this study, lower levels of aggression (Adler & Levins, 1994; Gray & Hurst, 1998; Cuthbert, et al., 2016). In the 1980s, a study was conducted by capturing house mice on the Orkney island of Eday (commensal) and releasing them onto the Isle of May, which was uninhabited by humans but had an established population of non-commensal wild house mice (Berry, et al., 1991). This study followed the spread of genetic markers unique to Eday and found that these alleles moved quickly through the Isle of May population (Berry, et al., 1991; Jones, et al., 1995). Differences in aggression may relate to whether the mice are living commensally or not, with evidence indicating that commensalism and perhaps increased density favours more aggressive individuals (Berry, et al., 1991; Gray & Hurst, 1998). Overall, the limited studies to date have strongly suggested that island mice may not be as competitive as their mainland/commensal counterparts (Mackintosh, 1981; Berry, et al., 1991; Gray & Hurst, 1998).

Secondary invader success may also depend on female mate choice (Jones, et al., 1995). In terms of female mate choice, there is evidence that females prefer the scent of foreign males and are more likely to mate with unrelated males (Roberts & Gosling, 2003; Frynta, et al., 2010). Importantly, however, there is also evidence of female choice favouring non-t haplotype carrier males or males carrying a different t-haplotype variant (Lenington et al., 1994; Manser, et al., 2015; Sutter & Lindholm, 2016). The relative fitness of gene drive carriers will be a critical determinant of effectiveness for this approach. Fitness costs have been documented with other forms of the t-allele (Carroll, et al., 2004; Lindholm, et al., 2013), but have not been examined for the t^{w2} variant to our knowledge. Information about the t-allele presence on islands and modelling of population dynamics would help us further understand the transmission of the Sry/t^{w2}gene drive in island mouse populations (Backus & Gross, 2016).

Central questions

A critical aspect of exploring gene drive eradication techniques for island rodents is that the gene drive originates in a mouse strain with a standard laboratory background that is amenable to manipulation. Laboratory mice, however, have been inbred and housed in non-hierarchical social conditions for generations (Morse, 2007; Fawcett, 2012) and they have also undergone both deliberate and inadvertent selection under these captive conditions (Fawcett, 2012). It is encouraging to note, however, that wild-type behaviour can be restored quickly by backcrossing with wild-derived mice to create wild-lab crosses (Chalfin, et al., 2014). The central goals of this study are to one i) confirm that a gene drive mechanism can be bred into a wild background and ii) assess whether key reproductive measures such as litter size, pup weight, and adult weight are impacted in F1 and F2 wild-lab mice. We also present preliminary findings regarding the success of laboratory and F1 wild-lab males in competitive mating situations.

MATERIALS AND METHODS

Strains of mice

These studies employed several different strains of mice. A primary laboratory strain is C57BL/6J referred to as (B6) mice. B6 mice are the most common strain of lab mice and are easily manipulated genetically (Silver, 1995). Compared to other laboratory strains B6 mice are considered more defensive and aggressive in response to perceived threats (Blanchard, et al., 2009). A second strain was donated from the Threadgill lab at Texas A&M University. These mice are of a mixed C57BL/6J and a 129S1/SvlmJ (B6;129) background (hereafter referred to as "lab" strain) and carry the t^{w2} variant of the t-allele. The t^{w2} variant stems from a wild background but was brought into laboratory stocks in 1946 (Dunn & Morgan, 1953). These mice are not transgenic (no *Sry* inserted) and so heterozygotes produced are either male or female. The t^{w2} allele is inherited by 95% of offspring in matings with a t^{w2}/+ sire (Kanavy & Serr, 2017). To maintain t^{w2} mice, B6 females are mated to males heterozygous for the t^{w2} allele (t/+). The wild-derived mice (MmF) we use are derived from wild progenitors captured on Southeast Farallon Island, which is part of the Farallon National Wildlife Refuge, located about 30 miles off the coast of California near San Francisco (Farallon, 2013). Invasive mice are the only terrestrial mammals on the island currently (Schoenherr, et al., 1999; Farallon, 2013). These mice show annual cyclic population variation with peak densities in late summer and early fall. MmF mice do not carry the t allele (Threadgill, pers. comm. 2013).

Some of the highest mouse densities ever recorded in non-commensal habitats are seen on Southeast Farallon Island at over 1300/ha (490/acre) (Farallon, 2013; Newser, 2013). Their diet consists primarily of invertebrates (Jones, et al., 2006). The Farallons mice pose direct threats to an endemic invertebrate and indirect threats to native seabirds. The USFWS plans for a future mouse eradication with rodenticide (Farallon, 2013). We established a colony of wild-derived Farallons mice (MmF) at NCSU in 2013 and they are now 8th generation derived from the wild. These Farallon mice serve as the 'island mouse' model being used to form demes for testing the ability of secondary invaders to establish and mate successfully.

All experiments were conducted under an approved Institutional Animal Care and Use Committee protocol at North Carolina State University between 2015–2017. Mice were maintained in a temperature-controlled greenhouse with natural lighting and conditions suitable for reproduction year round. Animals were fed *ad libitum* with 5058 LabDiet® and daily health and welfare checks were performed. To test if mating between wild-derived MmF females and laboratory males occurred pairs of lab males with wild-derived MmF females were created and housed in 29 cm wide × 40 cm long × 19 cm high standard laboratory cages. Each cage contained aspen bedding, natural cotton, a 15 cm PVC tube and black oil sunflower seeds for enrichment. Mice were housed in this manner with weekly cage changes. To minimise disturbance, mice were transferred over to a clean cage using a 15 cm PVC pipe whenever possible. Pups were weaned at the mouse standard of 21 days +/- 3 days (Silver, 1995) and the litter size, sex and weight of the pups in grams were recorded. In addition, an ear punch or tail snip was taken for genotyping. Pups were then weighed as adults and their weight in grams was collected for nulliparous individuals between the ages of 70–140 days.

Tests of male competition were conducted in semi-natural enclosures. The size of these 'arenas' is 3 m^2, closely approximating the size of those used by Slade, et al. (2014). To allow for formation of hierarchies and nesting, we added enrichment and complexity in the form of sand, bricks, plastic blocks ('Legos') supporting multilevel clear Plexiglass structures, galvanized wire mesh (1.25 × 1.25 cm mesh size), cardboard boxes and cardboard egg cartons, and PVC pipes for environmental complexity. For trials, all mice were placed into the arena at the same time. Males were either weight matched to within 1 g (~5% of body weight) or age matched within 8–10 weeks. All mice used in the arenas were nulliparous and sexually mature. Coloured ear tags as well as Clairol 'Just For Men' Black Hair dye® was used to identify males. Trials included combinations of MmF and t^{w2} males as well as MmF and F1 wild-lab males. At the start of each trial, both males and two non-related MmF females were placed into the arena and filmed for one hour. During this hour, we counted the number of bouts, chases and attempts to copulate, or time in proximity with females, as a means of assessing dominance. Animal welfare checks and monitoring for pups were performed daily. Any pups born in the enclosures were weaned at the standard of 21 days and a tissue sample was collected for genotyping.

To confirm the presence of the t^{w2} haplotype, we used a modified protocol where we amplified a portion the Hba-ps4 (alpha-globin pseudogene-4) locus (Schimenti & Hammer, 1990). The procedure uses a 'dirty' DNA extraction developed by one of our collaborators at Texas A&M University (Kanavy, pers. comm. 2016). Tissue is collected and either a 2–3 mm tail snip or a 2 mm ear punch is used. The 'dirty' DNA extraction buffer contains (50 µl 5 M NaOH, 4 µl 0.5 M EDTA, and 10 ml sterile water). 100µl of extraction buffer is then added to the tissue sample and incubated at 95°C for 20 minutes. After vortexing and cooling 5 µl of 1 M HEPES is added. The sample is then centrifuged at 6,000 g for five minutes and 40 µl of DNA is extracted from the top. DNA electrophoresis of PCR products shows a distinct band at 198 bp for wildtype mice (+/+) while t^{w2} homozygotes (t/t) display a band at 214 bp and heterozygotes (t/+) show the presence of both bands.

Statistical analyses were conducted using JMP® Pro 12.2.0 (SAS) where 1-way ANOVAS were used for adult weights and litter sizes. A mixed model ANOVA with the fixed effect of litter size was used to separate litter size from pup weight to compare pup weights. Next, post-hoc analyses including orthogonal contrasts and Tukey's HSD tests were used to identify group differences. Litter sizes and weights are presented as mean ± SEM.

RESULTS

Adult weights were taken for males and females. Sample sizes for males were as follows: B6 (33), t^{w2} (24), MmF (53), F1 (21), and F2 (22). For females sample sizes were: B6 (19), t^{w2} (25), MmF (44) and F1, (23). The average day of age that adult male weights were measured at was the following: B6=80.43± 21.95; t^{w2} =90.43±27.65; MmF 92.63±34.90; F1 93.03±19.46; and F2 89.48±28.27. Similarly, for females the average day of age that the adult weight was taken was: B6 91.24±28.99; t^{w2} 88.66±24.09; MmF 89.20±36.14; and F1 82.25±38.15. Adult weights varied by strain and sex, $F_{8,257}=28.35$, $p<0.0001$. In addition, t^{w2}carrying males (t^{w2}, F1, F2) were larger than MmF males, $F=58.00$, $p<0.0001$. Similarly, t^{w2} carrying females (t^{w2} and F1) were larger than MmF females, $F=7.75$, $p=0.0058$ (Fig. 2). Due to space restrictions for husbandry, not enough F2 adult females had been reared to allow calculation of a meaningful average for this group.

While litter size varied across strains $F_{5,141}=4.59$, $p<0.0007$, MmF, F1 and F2 wild-lab mice had litter sizes that were comparable (Fig. 3). Sample sizes for litter size were as follows: B6 (27); t^{w2} (20); MmF (45); MmF/B6 (19); F1 (21); and F2 (20). There were no differences detected in the sex ratios for pups born, nor in the time of gestation (data not shown).

Weaning weight was measured with a mixed model ANOVA with litter size being a fixed effect. The samples are as follows: B6 (18); t^{w2} (14); MmF (44); MmF/B6 (20);

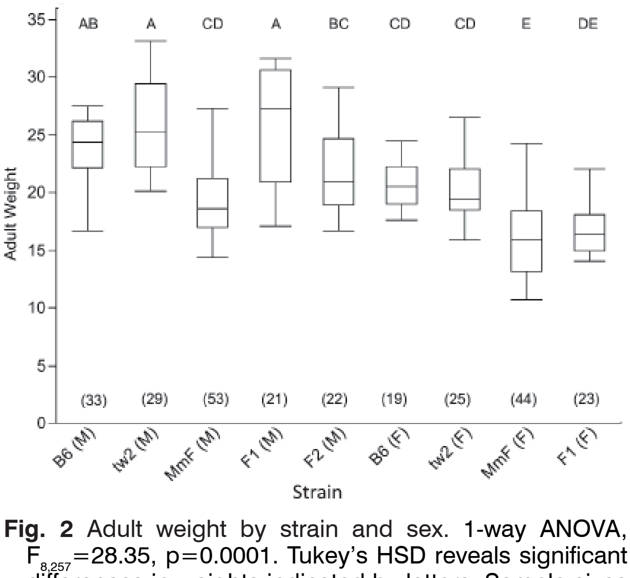

Fig. 2 Adult weight by strain and sex. 1-way ANOVA, $F_{8,257}=28.35$, $p=0.0001$. Tukey's HSD reveals significant differences in weights indicated by letters. Sample sizes are indicated in parentheses.

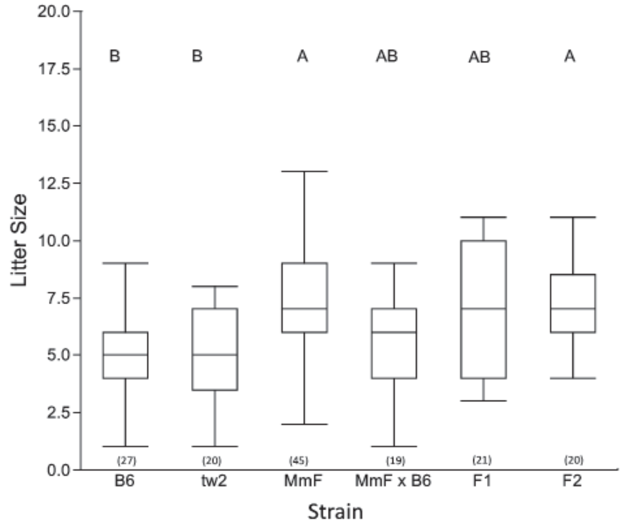

Fig. 3 Litter size by strain 1-way ANOVA, $F_{5,141}=4.59$, $p=0.0007$ indicates significant differences in litter size across strains. Tukey's HSD reveals significant differences in weights indicated by letters. Sample sizes are indicated in parentheses.

F1 (13); and F2 (20). Pup weaning weight was significantly different across strains ($F_{133,383}=13.922$, $p=0.0001$) and the highest weaning weights were found in F1 wild-lab F2 and F1s respectively (Fig. 4). Highest mean weights at weaning were 10.46± 0.40 g (F1) and 9.82± 0.33 g (F2).

In the arenas, preliminary trials of male competition between t^{w2} males (laboratory strain) and MmF males revealed no t^{w2} transmission based on genotyping (three trials with 35 pups total). The t^{w2} male initially appeared behaviourally dominant. He pursued females and chased the MmF male away, but on subsequent days was subordinate and tended to stay on top of the feeder out of view of the MmF male. Preliminary trials with MmF males and F1 wild-lab males (eight trials, 47 pups) revealed strongly contrasting results and a 70% transmission rate of the t^{w2} allele. Here, five of the eight litters did carry the t^{w2} with 31 of 33 pups from these litters confirmed. The F1 wild-lab males appeared to be behaviourally dominant throughout the trial in the same five trials where t^{w2} pups were produced.

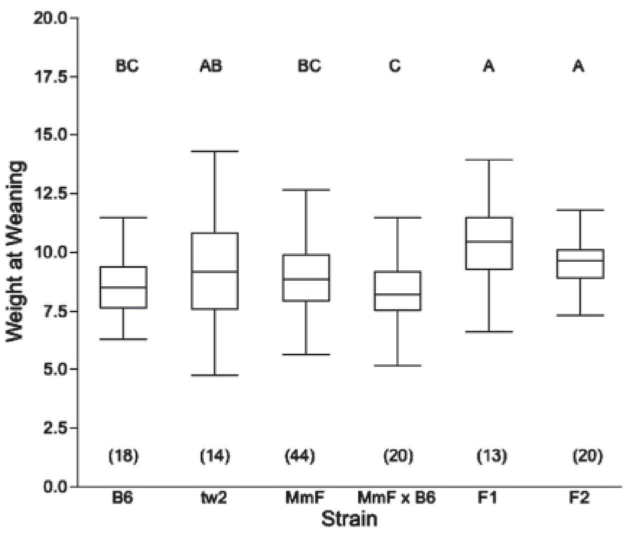

Fig. 4 Weaning weight with fixed effect of litter size Mixed Model, strain $F_{5,119}=4.98$, $p=0.0004$., litter size $F_{1,117}=12.46$, $p=0.0006$. Tukey's HSD reveal significant differences in pup weights across strains, which is indicated by letters. Sample sizes are indicated in parentheses.

Dominance was again based on initiation of chasing or fighting with the MmF male and by time spent pursuing or mating with females. When subordination did occur, the subordinate males appeared to place themselves so as not to be visible to the dominant individual. Behavioural results are ongoing and were beyond the scope of this manuscript.

DISCUSSION

Relative fitness of gene drive carriers is likely to be critical in determining the success of this approach (Burt, 2003; Manser, et al., 2015; Backus & Gross, 2016). Carriers of gene drive constructs would need to be successful in reproduction and reproductive competition if a genetic approach to invasive rodent eradication is to be effective. This work establishes some key initial conditions for this success. First, lab mice and wild mice can breed and produce viable litters. Second, while litters of the common lab background t^{w2} mice were smaller than those of wild-derived mice under the more naturalistic conditions used in this study, the F1 wild-lab litters were of comparable size to those having two wild-derived parents. Preliminary results also suggest F1 wild-lab males may have strong potential for reproductive success, a likely prerequisite for initial introgression of gene drive constructs into an island population.

This work established that wild-derived Farallon females will mate with laboratory males in standard cages and at similar frequencies to those seen in matings with wild-derived males (M. Serr, unpublished data). This was an initial but critical step in assessing reproductive output across strains and in F1 wild-lab mice. Furthermore, results indicate that both F1 wild-lab and F2 wild-lab backcrossed mice have litter sizes that are not different statistically than those of Farallon mice. This is important in terms of fitness and exploring the effectiveness of using the Sry/t^{w2} haplotype technique. It is also important to note that the reverse holds true, as wild-derived MmF males will mate with B6 and t^{w2} females in standard laboratory cages although sample sizes are not adequate for statistically meaningful comparisons. Results for pup weights indicate F1 and F2 wild-lab pups have the greatest weight at weaning and that this trend continues for adult males. Body size affects male competitiveness in mice (Cunningham, et al., 2013; Ruff, et al., 2017) with evidence suggesting that in semi-natural enclosures male mice of intermediate weight have the highest fitness (Ruff, et al., 2017). Matching mice based on body size for our experiments helps rule out this confounding factor, but for a potential gene drive release it could be beneficial for the drive-bearing mice released to weigh more than their wild counterparts.

Preliminary results from experiments in our larger arenas examining competition suggested a surprising pattern. Arena trials between MmF and t^{w2} males suggest the wild-derived MmF males are dominant to pure laboratory strain males, preventing transmission of the t^{w2} allele. Interestingly, however, weight-matched F1 wild-lab males carrying the t^{w2} allele appear more competitive and behaviourally dominant to MmF males. Consistent with this observation, we find a 70% transmission rate of the t^{w2} allele in arena trials analysed thus far. In addition, of the three trials where the F1 wild-lab male was not dominant MmF litter sizes were small with two of the three litters only having two pups each. This suggests that F1 wild-lab males are strong competitors and that females will mate with F1 wild-lab males even when both male types are present. It will be important to conduct further arena trials to assess this competitiveness with greater sample sizes and also assess the competitiveness of F2 wild-lab males. Other reproductive comparisons we are conducting include measuring testes weights. Testes weight is correlated to total sperm count in mice (Le Roy, et al., 2001). Testes weight can also predict dominance and mating success, as mice with higher testicular weight are more likely to initiate mating with females and attack behaviour towards conspecific males (McKinney & Desjardin, 1973). Finally, nesting behaviour and the temperature of nests will be important to examine across wild-derived, laboratory and F1 wild-lab mice as anecdotal observations suggest poor nest construction by laboratory mice. This could be important too because in cooler environments studies have indicated that nest building behaviour, thermoregulation, and fitness are correlated (Bult & Lynch, 1997).

Our results suggest that F1 wild-lab males could be efficient secondary invaders. This would be generally consistent with other studies from island populations (Jones, et al., 1995; Bonhomme & Searle, 2012). However, the situation may be different for females. Introduction of mice from a commensal population on the Isle of Eday to the Isle of May did not lead to the spread of mitochondrial DNA markers, which are maternally inherited. These results were in contrast to those for a Y-chromosome marker and suggested females were unable to secondarily establish while males did (Jones, et al., 1995). Studies from other islands have corroborated these results in suggesting no integrations of new maternal haplotypes from later-arriving females (Searle, et al., 2009; Gabriel, et al., 2010; Jones & Searle, 2015). This apparent male-female asymmetry in secondary establishment ability, however, has not been experimentally tested. One approach to addressing this apparent asymmetry is having records of detailed behaviour in more naturalistic arena settings. We have designed and implemented a Radio Frequency Identification (RFID) system for tracking mouse movements. RFID tracking allows collection of detailed behavioural records and works well with wild house mice (Weissbrod, et al., 2013; Auclair, et al., 2014). Behavioural measures include time spent at nest boxes, running wheels and food. With this information we can assess the number of visits, the timing of visits, the number of interactions and time in social contact with one another (König, et al., 2015; Lopes, et al., 2016).

A second approach is to test the ability of different strains to establish dominance in a standard test termed resident-intruder paradigm. A previous study used this approach to compare competitive behaviour in house mice from the Isle of Eday and the mainland, finding the island mice were significantly less aggressive (Gray & Hurst, 1998). Expanding trials to increasingly complex naturalistic experimental arenas should give insight into the relative abilities of male and female mainland mice to secondarily invade and therefore genetically introgress into an island population.

Other factors that could influence the potential success of an eradication effort include mate-choice and tolerance of island conditions. Mate-choice factors known for mice include odorant cues such as urinary proteins and ultrasonic vocalisations (Hurst & Beynon, 2004; Blanchard, et al., 2009; Musolf, et al., 2010). Island conditions and climate, in particular, could be important influences on the success of introduced mice (Berry, 1992). The island syndrome for rodents predicts increased body mass and decreased aggression (Adler & Levins, 1994; Gray & Hurst, 1998; Cuthbert, et al., 2016). In addition, the island syndrome in rodents is often associated with high population densities, increased reproductive output, and increased survival rates on islands (Adler & Levins, 1994). Mice are able to adapt to new conditions and islands (Anderson, 1978; Bronson & Pryor, 1983) and this adaptation could be critical for fitness, although any construct would presumably be introgressed into an island genetic background relatively quickly as it spread. The population genetic structure of the mice already present on an island would be critical for a synthetic gene drive, but other factors including the rate of inbreeding, ratio of reproductive males to females, and age structure of the mouse population(s) might also prove important. These are also likely to impact spread of either a synthetic or natural drive like the t-haplotype considered here. In regions with seasonality and temperature variations, mouse populations often undergo a 'boom and bust' cycle, as seen in the Farallon Islands, where the populations can erupt only to die off with changes in temperature. The timing of release of secondary invaders will likely be important in these situations (Singleton, et al., 2005; Farallon, 2013; Backus & Gross, 2016). Both natural and sexual selection could influence the number of drive carrier mice that would be required for eradication success. A study by Backus & Gross (2016) modelling the Sry/t^{w2} gene drive found that the relative fitness of the mice carrying the gene drive determined whether multiple releases would be required. Similarly, Prowse, et al. (2017) modelled synthetic gene drives and found that a sex reversing drive would require multiple releases to achieve eradication success.

The concept of reducing invasive mouse populations through release of genetically-modified mice is still in the early stages of development. Many key issues will need to be addressed to determine whether this is a feasible approach. We have shown that an island-derived wild strain will mate with t^{w2}-carrying laboratory males and produce comparable litter sizes to those of wild–wild matings. Promisingly, we also see that pup-weaning weights are larger for F1 and F2 wild-lab mice and that F1 wild-lab males may be stronger competitors in semi-natural enclosures. A key future step will be to scale up trials in arena size and environmental complexity. Larger enclosures could be used with greater numbers of mice to test whether a gene drive can spread under controlled and biosecure, but naturalistic conditions. Finally, beyond the technical issues discussed above, social license for any environmental releases would be crucial (NASEM, 2016). As gene drives are a new technology still in development, input from the relevant publics and regulatory authorities will be very important moving forward and this input is also likely to lead to additional interesting and important questions that developers will need to address.

Abstract Aerial broadcast application is currently one of the most common methods for conducting rodent eradications on islands, particularly islands greater than 100 ha or with complex and difficult topography where access by ground teams is difficult. Overall, aerial broadcast applications have a high success rate, but can be burdened by logistical, regulatory, and environmental challenges. This is particularly true for islands where complex shorelines, sheer terrain, and the interface with the marine environment pose additional risks and concerns. Using data collected during ten eradication projects we investigate the influence that operational realities have on broadcast applications. We tested the association between the amount of bait used and island size, topography, and the desire to reduce bait application into the marine environment and then compared planned bait application to actual bait application quantities. Based on our results, islands of decreasing size and increasing coastal complexity tended to use more bait than anticipated and experienced greater variability in localised bait densities. During operations, we recommend analysing flight data to identify treated areas with localised bait densities that fall below the target application rate. We recommend that areas with low localised bait densities may result in biologically significant gaps that should receive an additional application of bait based on project risk variables such as target home range size, non-target bait competitors, and alternative foods. We also recommend a common language for discussing aerial broadcast applications and where future work can be done to improve operational decision making.

Keywords: bait density, gaps, geographic information systems (GIS), island invasives, operational monitoring

INTRODUCTION

History of aerial broadcast applications

One of the primary principles for rodent eradication is ensuring sufficient bait is distributed to every potential rodent home range, so that every rodent is exposed to bait for long enough to cause mortality (Bomford & O'Brien, 1995; Howald, et al., 2007). The aerial application of rodenticide is one of the most common and effective ways for eradicating rodents from islands (Holmes, et al., 2015). Aerial broadcast techniques were first developed in the 1980s and methodology and principles were developed over several decades as lessons learnt were applied to projects of increasing size and complexity (Towns & Broome, 2003). The first aerial applications relied on the use of modified "monsoon" fire-fighting buckets slung beneath a helicopter and flown by eye or guided by ground personnel. These early projects were often successful in removing rodents, despite difficulty in controlling application rates and the need to use hand spreading to fill gaps (Garden, et. al., 2019). The advent of specialised mechanical spreading buckets to control bait application rates and distribution, and global positioning systems (GPS) to guide pilots along straight flight paths and record bait spread, revolutionised aerial application techniques (Garden, et. al., 2019). These changes allowed rodent bait to be delivered with far greater precision over much larger areas, resulting in the successful removal of rodents from islands larger than 10,000 ha (Campbell 11,300 ha; Macquarie 12,800 ha; and South Georgia 108,700 ha) (Broome, 2009; Russell & Broome, 2016; Martin & Richardson, 2017).

Aerial application principles

It is impossible to predict where all rodent home ranges are and, because rodents are highly tolerant of a wide range of habitat types, the whole island must be assumed to support rodents, and the entire island is ultimately treated. Bait application rates are set to ensure that bait is readily available in all potential rodent home ranges and target bait application rates are often informed by bait availability trials (Pott, et al., 2015) or rates used on similar islands that were previously successful (Broome, et al., 2014). These rates are conservatively selected to ensure enough bait for all the rodents on the islands while accounting for loss and uptake by non-target competitors, like land crabs, that reduce the amount of bait rodents are exposed to (Pott, et al., 2015).

In general, one bait application rate is targeted across an entire island because stratification increases complexity and the risk of gaps in bait coverage (i.e. areas where some rodents may not be exposed to bait), increasing the risk of eradication failure (Keitt, et al., 2015). Subsequently, projects are generally designed to use parallel flight lines with 50% overlap between lines and additional parallel flights along the coast to reduce the risk of gaps. Projects may apply additional bait on steep cliffs because they have a larger surface area (3D) than planar area (2D), resulting in un-even bait distribution from bait falling downslope (Broome, et al., 2014).

Challenges in aerial application

There are technical limitations of helicopters and mechanical bait spreaders in applying bait over an entire island. Operational realities, like wind, flight speed and turning capabilities of the helicopters, steep terrain, and unevenness of bait pellet distribution from the mechanical spreader can impact bait placement on the ground, leading to potential gaps in coverage. To ensure sufficient coverage the pilot must reapply bait over potential gap areas, resulting in locally increased bait densities where this additional application partially overlaps with previous flight lines. Additional complications arise when areas need to be excluded from aerial application, such as human habitation, inland water features or the marine environment. These operational constraints tend to increase the total amount of bait needed because additional overlapping flight lines are required to ensure no gaps in coverage exist along edge boundaries.

When trying to eradicate a rodent population, planning tends to focus on targeting the worst-case scenario,

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 71–78. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

ensuring that there are no gaps, meaning that bait overlaps with the smallest known home range. However, it is not well understood if applying less bait could constitute biologically significant gaps where reduced bait availability within a rodent's home range decreases the likelihood of a rodent being exposed to a lethal dose. The potential risks posed by biologically significant gaps may be particularly relevant on tropical islands, which tend to have more non-target bait competitors and alternative food sources (Holmes, et al., 2015), or when targeting multiple rodent species.

These challenges have generally led to an "over-engineering" approach to project design under the perception that more bait increases the likelihood of eradication success (Cromarty, et al., 2002); however, higher bait use has trade-offs, such as increasing risk to non-target species (Parkes, et al., 2011). We sought to improve existing knowledge of what constitutes an 'optimal' bait application rate, and what is a biologically relevant gap in baiting. We examined ten projects to 1) understand factors influencing the difference in bait use between what was planned and what happened on the ground, and 2) characterise localised bait application rates amongst these ten projects to further understand what may constitute a gap. Specifically, we asked:

What are the differences in total bait used between three baiting scenarios and what physical and operational factors are associated with these differences?

How does localised bait application rate vary and how do areas estimated to be below the target application compare to rodent home range size?

METHODS

Aerial application terminology

The *target application rate* is the desired rate of bait deployment, in mass per unit area (e.g. kg/ha), to be applied across the island. The target application rate is usually based on bait availability trials and is set to maintain bait availability for a certain period. The *average application rate* is the total amount of bait distributed over an island divided by the area of the island, in bait mass per unit area, and is generally used for comparing eradication projects.

In general, bait is applied via a modified fertiliser bucket underslung from a helicopter that distributes bait either 360 degrees (*full swath*) or 180 degrees (*half swath* or directional) from the bucket. Each bucket throws bait pellets a certain distance as a function of bait product size and weight and the speed of the distribution spinner. The *swath width* is the effective distance that baits are consistently sown, which is conservatively set during calibration trials and less than the maximum distance the bucket can throw bait.

The *flow rate* is the rate, in mass per unit time (i.e. kg/sec), at which bait is distributed by the bucket. This may be controlled in a variety of ways, depending on the mechanics of a bucket, but is often controlled manually with *aperture discs* that vary in size to restrict how much bait can enter the spinner.

A bucket's *sow rate* is the rate, in mass per unit area (e.g. kg/ha), that bait is distributed from the bucket and is a function of the helicopter's *flight speed* and the bucket's *flow rate.* In general, a faster *flight speed* will decrease the *sow rate* while a larger *aperture disc* will increase the *sow rate.*

Using a GPS unit, bait is generally spread in parallel *flight lines* employing planned *overlap* between flight lines to reduce the possibility of gaps in bait coverage. When using overlap the *sow rate* must be reduced to achieve the desired *target application rate* (i.e. using a planned 50% overlap buckets would require a sow rate of 5 kg/ha if the target application rate was 10 kg/ha). In areas where multiple flight line *swaths overlap* localised *bait densities* achieved on the ground, in mass per unit area (e.g. kg/ha), may be higher than the *target application rate,* and where planned *overlap* does not occur *bait densities* may be lower – resulting in *undertreated areas.* The GPS unit assists helicopter pilots during bait application by indicating deviance from the desired flight line and displaying the current flight speed.

Supplemental bait is additional bait needed to fill unplanned *gaps*, *undertreated areas*, or areas that require additional treatment like steep cliffs or preferred habitat. *Contingency bait* is bait held in reserve to replace spoiled bait and is generally intended to be left unused at the end of an operation.

Data from aerial broadcast eradication projects

Between 2008 and 2016 aerial baiting data were collected and analysed across ten different rodent eradication projects representing a variety of different island habitats, sizes, strategies, outcomes, and regulatory environments (Table 1). We used these data for our analyses.

For each operation, an aerial baiting plan was developed to estimate the total amount of bait required to complete the operation. High resolution satellite imagery (<1 metre per pixel) was acquired and used to estimate the island area by digitising along the mean high-water mark at a scale of 1:2,500. Treatment area estimates were generated by calculating the area from hypothetical parallel flight lines over the island with 50% overlap, using an estimated effective swath width, and a single directional coastal boundary swath, at half the estimated effective swath width, along the coastline. For the nine projects with the most conservative regulatory guidelines that restricted bait entry into the marine environment, the start and end of the parallel flight lines were brought in from the coast by half of the estimated effective swath width, and an additional coastal overlap buffer was estimated that overlapped with the ends of the interior flight lines and the coastal swath.

On several operations, areas were identified for supplemental treatment (e.g. steep cliffs) or exclusion from aerial treatment (e.g. inland bodies of water, human habitation) and treatment areas were calculated based on the operational parameters. Steep cliff areas were estimated by acquiring Digital Elevation Models (DEM) with a resolution of 30 metres per pixel or better. Slope estimates were calculated based on the DEM and used to identify areas for additional treatment. Exclusion zones were treated like the coastal edge, with flight line ends starting and stopping at least half the effective swath width from the exclusion boundary and a half swath flown around the exclusion boundary to minimise gaps.

To estimate the total amount of bait required per application treatment, area estimates were multiplied by the sow rates required to achieve the target application rate on the ground.

Aerial bait tracking

During each operation, a tracking worksheet was completed that recorded detailed information about each bucket load including: helicopter departure time, helicopter arrival time, bucket type, disc size, bait placed in the bucket, bait returned in the bucket, and cumulative area treated as recorded by GPS (TracMap Ltd., Otago, New Zealand iOS 1.7.2). For each bucket load the amount

of bait used and area treated were calculated and used to estimate the sow rate achieved. The sow rate information was relayed to project management and the pilot to inform decisions about adjusting disc size or flight speed to ensure a consistent sow rate.

Flight line data were downloaded from the GPS unit and treatment polygons (spatial representations of where bait was spread) were estimated by buffering the flight lines based on the effective swath width calculated during operational bucket calibration. Using the helicopter times from the tracking worksheet and the times recorded in the flight line GPS data, the recorded sow rates were assigned to treatment polygons (now spatial representations of where bait was spread and at what rate it was applied). GIS-derived bait density estimates were calculated by dissolving overlapping treatment polygons into new non-overlapping polygons and summing the sow rates of the overlapping parts. Bait density estimates and flight line maps were reviewed to identify gaps or undertreated areas.

Factors associated with difference in planned and actual bait amounts used

To evaluate what factors were associated with the total bait applied during an aerial operation, aerial baiting data from the ten projects, comprising 17 different island blocks, were collated (Table 1). In some cases, an island block comprised of multiple treatment units (i.e. motu or small islets) that were treated collectively. There were three projects where multiple island blocks were treated as independent units. Ten exploratory factors thought to be associated with differences in aerial bait applications were collected for each application (Table 2). Only the first application for each island block was analysed as they were the most comparable because the amount of bait applied during the second application could be influenced by the amount of bait used during the first application, bait availability monitoring data, or the use of supplemental bait.

These ten factors were compared against two response variables, referred to as bait use scenarios: 1) the percent change between the bait amount in a hypothetical uniform scenario, where bait is evenly distributed across an island, and the planned amount of bait to be used (Δuniform.planned); and 2) the percent change between the planned amount of bait and the actual amount of bait used (Δplanned.actual) (Fig. 1). The variable 'Δuniform.planned' represents the change in bait required between a uniform application and what was planned to account for physical island characteristics and strategy decisions such as reducing bait into the marine environment. The variable 'Δplanned.actual' represents the difference between what was planned and what happened on the day due to operational realities, such as unexpected deviations in sow rates and flight path.

We used Spearman's rank correlation to explore relationships between variables we thought may influence planning (Δuniform.planned) and how the reality of the day affects the plan (Δplanned.actual). To minimize the chance of Type I error resulting from multiple pairwise tests, we chose to test four variables (elevation, size, coastline, and flight lines) for correlation with the two bait use scenarios and penalized the p-value by a factor of 8 ($P<0.0006$). The remaining explanatory variables were expressed as boxplots and compared with exploratory statistics.

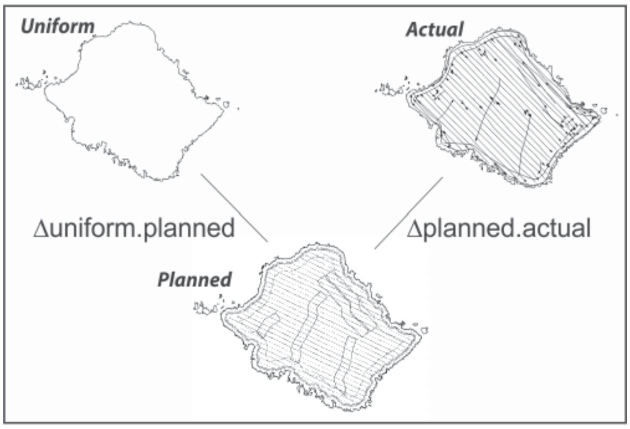

Fig. 1 Examples of bait use scenarios used and normalised percent change, delta, in bait use between scenarios. Uniform represents bait needed in an even distribution of bait across island area, planned represents bait needed based on predicted flights paths and overlap, and actual represents bait used.

Table 2 Explanatory physical and operational characteristics evaluated.

Physical characteristic	**Definition**
Country	Country operation was implemented in
Habitat	Tropical or temperate
Island type	Volcanic or coral atoll
Max. elevation	Maximum elevation in meters as a proxy for steep terrain
Size	Size of area to be treated (km^2)
Coastline	Length of coastline to be treated (km)
Operational characteristic	**Definition**
Target rate	Minimum application rate expected to be achieved on the ground, in some cases the coast and interior had different expected rates. The lowest expected rate was selected
Number of flight lines	The total number of flight lines flown
Supplemental treatment	Cliff, coast, or none to represent areas that received additional treatment above the target application rate
Coastal overlap buffer	True or false if the coastal overlap buffer strategy was employed to reduce bait into the marine environment

Variability in bait densities achieved

To evaluate the distribution of bait densities (kg/ha) we used GIS-derived bait density estimates from the 17 island blocks. For each island block, the area and estimated bait density of each polygon representing the bait density achieved on the ground from overlapping swaths was exported. Polygon areas representing areas smaller than 100 square meters (0.01 ha) were excluded as they were smaller than what is commonly considered a significant gap. For each island block, a bait density distribution was calculated to represent the total amount of island area treated at each bait density rate (e.g. 10 ha at 5 kg/ha) by summing the areas of treatment polygons at each bait density rate. To normalise bait density distributions across island blocks, values were represented as a percentage of the target application rate (e.g. 50% = half, 100% = target rate, 200% = twice target) and areas as a percentage of the total island area treated.

RESULTS

Factors associated with differences in planned and actual bait amounts used

The 10 projects analysed most often occurred in tropical regions (7 projects, 14 of 17 island blocks) and ranged in size from 8–2,900 ha, and 5–430 m in elevation. Target application rates ranged from 6 to 80 kg/ha, supplemental baiting used in seven island blocks, the coastal buffer overlap strategy used in 10 island blocks, and the number of flight lines flown spanned 9–1096.

On average, 20% more bait than the uniform scenario (Δuniform.planned) was planned for, and 16% more bait was used than planned (Δplanned.actual). The variables Δuniform.planned and Δplanned.actual showed no associations with the four factors investigated (elevation, size, coastline length and the number of flight lines) (Table 3). Median results of the 17 island blocks were 380 hectares, 214 flight lines, 80 m in elevation, and an 18 km coastline. Although no statistical correlation was evident among the island blocks and these factors, those blocks below the median showed a mean Δuniform.planned that was two to three times greater than blocks above the median, suggesting that compared to larger islands in our sample, planning on smaller islands typically identified proportionally more bait than a uniform distribution. The same trend is evident for Δplanned.actual with mean values for islands blocks below the median being one and a half times greater than above the median, showing that among our sample, smaller islands used proportionally more bait than planned for, compared to larger islands. Of the 14 tropical island blocks, five were on coral atolls, and these generally had a higher number of flight lines (M = 474.6, SD=215.1), compared to volcanic islands (M=121.1, SD=110.5).

Three island blocks conducted in the United States (Desecheo 2012, 2016, and Palmyra) had a negative Δplanned.actual, putting less bait on the ground than planned. The 10 blocks using the coastal buffer overlap strategy to reduce bait into the marine environment showed, on average, lower Δuniform.planned and Δplanned.actual compared to blocks that did not use this strategy.

Analysis of bait density estimates

On average, 5.1% (SD=3.8) of total island area received less than 50% of the target application rate and 0.8% (SD=1.6) of total island area received more than 400% of target (Fig. 2). The GIS derived bait density estimate polygons representing these areas had an average size of 0.12 ha (SD=0.2) and 0.03 ha (SD=0.04), respectively. Bait density estimates from each island block are shown in Fig. 3. Bait density estimates of less than 75% of the target application rate were visually compared against grids representing conservative minimum (0.01 ha) and average (0.1 ha) rodent habitats on tropical islands based on available literature (Fig. 4).

DISCUSSION

Factors associated with differences between planned and actual bait amounts used

From a statistical perspective, the sample size we used is considered small (n=17), and less than ideal because it was opportunistically collected (and not experimentally collated). From a conservation practitioners perspective, the opportunity to compare 17 different island blocks consistently is rare, and a positive example of collaboratively working to answer questions relevant across the island restoration field. A key result from our investigation is that projects planned to use 20% more bait than the hypothetical uniform application and used 16% more bait than planned, suggesting that simply estimating bait quantities by multiplying island area by target application rate is insufficient to judge how much bait will be needed. On average, the percent change between the planned amount of bait and actual bait used was less than the percent change between the hypothetical uniform

Table 3 Spearman's correlation and p-value of factors thought to influence bait use. Factors were considered associated with changes in bait use if Rho > 0.3 and p-value<0.006. Negative numbers represent a negative association (i.e. as one factor increases the other decreases) and positive numbers a positive association (i.e. as one factor increases so does the other).

amount of bait and actual bait used, suggesting that the aerial bait plans were more accurate at forecasting bait use but still underestimated actual bait required.

In general, smaller islands and islands with shorter coastlines, less elevation, or fewer flight lines planned to use, and actually used, a higher percentage of bait than projects on larger islands or those with more topography or flight lines. This suggests that small islands use proportionally more bait and that projects with fewer flight lines are more complex. While coastline length and maximum elevation were likely not differentiated enough from island size to detect a significant difference, the four-fold increase in the number of flights flown on tropical coral atolls, which have two coastal edges (lagoon and ocean), compared to volcanic tropical blocks suggests coastal complexity needs to be factored into planning. While the number of flight lines is also related to size, projects with fewer flight lines also have less room for error and could experience greater variability in bucket sow rates. Small islands may be able to improve bait applications, and reduce unplanned bait use, by employing strategies to increase the number of flight lines flown such as flying the parallel flight lines twice per application at half the target rate.

Perhaps the most interesting result was that projects implemented in the United States were the only projects, on average, to use less bait than planned. The United States has a complex regulatory environment, and aerial broadcasts are required to stay below permitted application rates. When implementing an eradication, projects in the United States had to balance the desire to achieve the desired target application rate with not exceeding the permitted application rate. Striking this balance resulted in projects using less bait than planned, particularly when the desired target rate was close to the permitted rate. This suggests that regulators should be involved early in the planning process so that regulatory approval can be sought to maximise project success. A single permitted application rate, such as the one designated on the bait product registration in the United States, is not necessarily appropriate for every project and, when appropriate, projects should develop site-specific operational strategies using the best available science. Regulatory bodies should review these strategies and recommended application rates on a case by case basis.

Bait application variability and consequences

It is noteworthy that, on average, 5% of the total island block area had bait density estimates less than half of the target application and 0.4% had bait density estimates greater than four times the target application rate (Fig. 2). This suggests a relatively high degree of precision in balancing the risk of failure (i.e. low localised bait densities) with unintended environmental impacts (i.e. high localised bait densities). Comparing the distributions of bait densities, larger (> 100 ha) single unit island blocks (i.e. those treated as a single contiguous unit: Antipodes, Desecheo, Hawadax, Pinzon, and Rabida) generally tended to have less bait density variability, with more than 60% of total island area near the target application rate, compared to smaller islands (< 100 ha) or island blocks consisting of multiple treatment units (Galapagos Islets, Gambier, Palmyra, Plaza Norte, Temoe, Tenarunga, Vahanga, and Wake) with less than 50% of total island area near the target application rate (Fig. 3). This is logical given that large or single unit island blocks have longer flight lines with which to "settle" into consistent sow rates and a smaller coast to size ratio resulting in fewer overlapping flights. Island blocks with multiple treatment units, particularly tropical coral atolls (Palmyra, Temoe, Tenarunga, and Vahanga), tended to have a higher percentage of total island area with localised bait densities more than twice the target application. These tropical coral atolls have more coastline for their size than other similarly sized islands, and thus the consequences of the flight line overlap necessary to minimise the chance of gaps near the coastline (i.e. higher localised bait densities) are more pronounced. This result underscores the trade-offs of ensuring complete coverage along complex coastlines.

Examinations of the two failed projects (Desecheo in 2012 and Wake) suggested low bait densities as one of the potential reasons contributing to failure (Derek Brown, pers. comm.). The bait density distribution of the failed 2012 Desecheo project shows a larger proportion of the island experienced localised bait densities less than half the target application rate during the first application (7.7%), compared to similar islands. Desecheo had a high abundance of non-target bait competitors (up to 833 crabs/ha) and bait availability plots in one habitat showed bait availability reaching zero within two to three nights (Will, et al., 2019). It seems likely that areas with localised bait densities less than half the target application rate would have experienced even less bait availability. On Wake, the bait density distribution shows a smaller proportion of the island achieved less than half the target application rate (1.4%) compared to similar islands, but bait density maps also show fewer flight lines extending up to the coastal edge and the presence of bait gaps on the beaches between the mean high-water mark and predominant vegetation. These observations may be instructive in improving the quality of future bait applications, suggesting that future applications consider applying additional bait (i.e. reapply) in areas with bait densities identified to be less than the target application rate and consider minimising the amount of untreated coastal edge on tropical coral atolls. These are areas where bait availability may be much less than expected and may not be immediately obvious when inspecting flight line maps. It is impossible to know if these improvements would have resulted in successful eradication attempts on Desecheo in 2012 and on Wake, but they would have removed questions about the quality of bait coverage as a possible contributor to eradication failure.

What is a significant biological gap?

Comparing actual bait densities achieved to the hypothetically smallest potential home range size can be instructive in informing risk tolerance for future operations. Rodent home ranges are highly variable, but amongst *R. rattus* have been recorded ranging from 0.012 to > 10 ha (Shiels, et al., 2016; Harper & Bunbury, 2015). It is in the smaller home ranges, particularly for breeding female rodents, where localised deficiencies in bait density present the highest risk of a rodent not being exposed to a lethal dose of bait (i.e. undertreated areas). We considered any areas that achieved less than 75% of the target application rate to be undertreated, which were generally the result of flight line deviation and were small (<0.1 ha) and irregularly-shaped (hundreds of meters long and <20 m wide). Despite their size and shape, these undertreated areas were still large enough to encompass most, if not all, of an assumed 0.01 ha potential minimum home range, but a minority of an assumed 0.1 ha average home range (Fig. 4). This suggests that, at the extreme, localised deficiencies in bait density could make bait less available than expected in entire potential rodent habitats where rodents have small home ranges.

Whether localised bait density deficiencies (i.e. undertreated areas) constitute biologically significant gaps is largely a consequence of toxicology, rodent biology and island ecology, and is project dependent. Ultimately, projects should anticipate that localised deficiencies in bait density are almost inevitable and determine what risk they pose to project success based on site specific conditions. In the presence of alternative foods and non-target bait competitors, or on islands targeting species with small home range sizes or multiple rodent species, areas that receive less than the target application rate could result in insufficient bait availability and constitute biologically significant gaps that pose a risk to project success. Where biologically significant gaps are a concern, project managers can either choose to increase the target application rate to increase the localised bait density of undertreated areas or set area size and application rate thresholds (i.e. 0.1 ha or larger with a bait density less than half the target application rate) to reapply bait.

Improving aerial application data analysis

Although GIS-derived bait density estimates provide a useful metric for identifying gaps or undertreated areas, they do have limitations and assumptions. A key limitation is they are not a direct measure of bait on the ground, and where possible on-ground measures of bait density, particularly with adequate sample size, can improve these data. Further, GIS-derived bait density estimates assume a) that flight speed is constant along the length of a flight line, b) bait pellet distribution across a swath is even, and c) wind has no impact on bait spread. A novel model called the Numerical Estimation of Rodenticide Dispersal (NERD) models these assumptions to generate a probability density function describing bait density and was successfully implemented on several projects in Mexico (Rojas-Mayoral, pers. comm.; Samaniego-Herrera, et al., 2017). These sorts of novel models are highly appropriate on high risk islands targeting species where smaller rodent home ranges may be anticipated (e.g. tropical islands where breeding may be expected). However, regardless of the analysis method used, managers are advised to trust in the broader rodent eradication principles and exercise caution to avoid overanalysing baiting data.

RECOMMENDATIONS

In summary, we propose the following recommendations to improve the planning and implementation of aerial broadcast applications for eradications.

Use high-resolution satellite imagery to estimate island size. Accurate estimates of operational area will improve estimates of the amount of bait needed and reduce the risk of having insufficient bait or the cost penalties of transporting and disposing of too much bait.

Create predicted flight plans to inform planning and estimate bait requirements. Multiplying island area by target rate is not an accurate estimate of bait needed. Including flight line overlap between parallel swaths and at the coastal boundary will improve accuracy of bait total estimates, reducing the chance of having too little bait. Additionally, predicted flight plans are useful in communicating the desired strategy.

Projects should plan for small islands to use more bait than anticipated and islands with complex coastlines to experience greater variability in bait densities. Coral atolls with lagoons have two coastal edges, which increases complexity, and should plan to use more bait and experience more areas of high localised bait densities. Small, complex projects should plan on ordering additional bait to treat gaps and compensate for areas of unplanned overlap.

Managers of projects on small islands should consider modifying operational strategies to reduce using additional bait. Increasing the number of flight lines by flying the island twice per application (with sowing rates adjusted to achieve the target rate), reducing the amount of bait in the bucket per load to reduce the percentage of island covered per flight, or conducting additional calibration runs to ensure consistency should be considered.

Projects should seek site-specific regulatory approval that maximises project success. A single permitted application rate is not sufficient to maximise success for all projects. Where appropriate, application rates should be tailored to site-specific conditions and be informed by the best available science. Additionally, to ensure clarity, projects should seek site-specific approval to implement predicted flight plans that describe the application rates and strategy needed to maximise project success. This is particularly relevant for projects implemented in the United States.

Use bait density estimates to identify areas treated below the target application rate. Tracking sowing rates achieved per load and assigning them to flight line data improves the understanding of bait coverage and allows managers to identify undertreated areas. Novel or high-risk projects should also consider using more fine scale bait density modelling approaches like NERD (Rojas-Mayoral, pers. comm.).

Projects should set gap size tolerances and application rate thresholds to match project risk variables. Clarify in advance of the project what constitutes a biologically relevant baiting gap based on what is known about the target species, island habitat, topography, and presence of non-target bait competitors. It is highly likely that a broadcast application will result in less than expected bait availability in the smallest potential rodent home ranges. For rodents with small home ranges, or tropical islands with high densities of non-target bait competitors, alternative food sources, or multiple rodent species a smaller gap size or higher application rate threshold may be warranted.

ACKNOWLEDGEMENTS

We would like to acknowledge implementation partners BirdLife International, Coastal Conservation, Island Conservation, New Zealand Department of Conservation, Parque Nacional Galápagos, Parks Canada Agency and the Council of the Haida Nation, SOP Manu, The Nature Conservancy, U.S. Air Force, U.S. Fish and Wildlife Service and many funders for their dedication to planning and conducting rodent eradication projects, without which this work would not be possible.

It's not all up in the air: the development and use of ground-based rat eradication techniques in the UK

E.A. Bell

Wildlife Management International Ltd, P.O. Box 607, Blenheim 7201, New Zealand, <biz@wmil.co.nz>.

Abstract Eradication techniques using ground-based devices were developed in New Zealand in the early 1970s to target invasive rodents. Since then, different bait station designs, monitoring tools and rodenticide baits have been developed, and changes in field techniques have improved and streamlined these operations. The use of these techniques has been taken around the world to eradicate rodents from islands. Eradication technology has moved rapidly from ground-based bait station operations to aerial application of rodenticides. However, regulations, presence of and attitudes of island-communities and presence of a variety of non-target species precludes the aerial application of rodenticides on islands in many countries. As such, ground-based operations are the only option available to many agencies for the eradication of invasive rodents from islands. It is important to recognise that the use of ground-based operations should be a valid option during the assessment phase of any eradication proposal even in countries that can legally apply bait from the air; in many instances the use of ground-based techniques can be as economic and rapid. The use of ground-based operations can also facilitate opportunities for in-depth monitoring of both target and non-target species. Using examples of the techniques and developments used in five ground-based rat eradication operations from the UK demonstrates how these methods can be used safely and successfully around the world, even on islands in the order of hundreds of hectares and those with communities.

Keywords: bait station, ground-based, inhabited, island, rodenticide

INTRODUCTION

Albeit unanticipated, the eradications of rats from Rouzic Island, France in 1951 and Maria Island, New Zealand in 1960 were the first successful rat eradication operations on islands anywhere in the world (Towns & Broome, 2003; Lorvelec & Pascal, 2005; Howald, et al., 2007). These unintentional eradications spurred efforts in New Zealand to develop and perfect eradication techniques (Cromarty, et al., 2002; Thomas & Taylor, 2002; Towns & Broome, 2003). Between 1965 and 1986, New Zealand wildlife managers, ecologists and scientists used a range of experimentally designed operations to determine the best methods to consistently, successfully eradicate rats from islands (Cromarty, et al., 2002; Towns & Broome, 2003). Seabirds and other native species on islands are particularly vulnerable to invasive mammal species, particularly rats. The eradication of invasive mammals is considered the first step in island restoration and the subsequent recovery of native species and biodiversity. Since these early ground-based operations, rats (*Rattus rattus, R. norvegicus, R. exulans*) have been successfully eradicated from over 400 islands ranging in size from 1 to 12,850 ha, around the world, using the full gamut of methods and technology (Moors & Atkinson, 1984; Atkinson, 1985; Towns & Broome, 2003; Howald, et al., 2007; Jones, et al., 2008; Parks & Wildlife Service, 2008; Parks & Wildlife Service, 2014, DIISE, 2015). Of these rodent eradications, the largest ground-based rat eradication operation, was on Langara Island in British Columbia at 3,100 ha, and the largest ground-based rat eradication in the United Kingdom (UK) was on the Isle of Canna at 1,300 ha (Taylor, et al., 2000; Bell, et al., 2011; DIISE, 2015).

Techniques and technology developed in those early eradications have since moved on from ground-based hand-broadcast and bait station operations to aerially-applied rodenticide operations and these have now been used across the globe. Advances in, and alterations to, techniques and tools have streamlined ground-based operations. Lessons learnt from each eradication have improved the next operation. However, in several countries, including the United Kingdom (but excluding the United Kingdom Overseas Territories), methods to eradicate rats are restricted to ground-based methods. The presence of critical non-target species, sensitive habitats, island communities and legislative requirements have restricted methods and tools for island eradications in these countries. This paper describes the history and development of ground-based rat eradications using bait stations in the United Kingdom using five eradication operations as examples and covers lessons learnt and how local communities have been involved.

INVASIVE *RATTUS* SPECIES ON UK ISLANDS

Both black (*Rattus rattus*) and brown (*R. norvegicus*) rats are present in the UK (Nowak, 1999; Long, 2003). Black rats were presumed to have been introduced by the Romans (c. 110 AD) and the brown rat via shipping between 1720 and 1728 (Thomas, 1985; Corbet & Southern, 1977; Yaldwen, 1999; McCann, 2005; Parslow, 2007). Brown rats were first recorded in the Isles of Scilly in 1728 after several shipwrecks occurred that year (Thomas, 1985; Parslow, 2007). Although the brown rat displaced the black rat throughout most of the UK, black rats can still be found in a small number of locations, particularly port cities such as London, Edinburgh and Falmouth (Matheson, 1962; Bentley, 1959; Twigg, 1992; Long, 2003). The brown rat is still present on 56% of UK islands over 100 ha (Long, 2003).

Rats are known to have very detrimental effects on seabird populations through predation and competition for food and habitat, causing local and global extinction of birds on islands throughout the world (Moors & Atkinson, 1984; Atkinson, 1985; Courchamp, et al., 2003; Towns, et al., 2006; Jones, et al., 2008; Bell, et al., 2016). The eradication of introduced predators from islands has become one of the most important tools in avian conservation in recent times and, with an initial investment, significant long-term restoration benefits such as increased productivity and population increases of seabirds and other native species as well as the establishment of new seabird species can be achieved. The eradication of rats from seabird islands is recognised as a prerequisite for the restoration of seabird populations (Atkinson, 1985; Moors, et al.,1992).

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 79–87. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Seabird populations on many UK islands have been recorded in decline and in at least four cases rats have been identified as one of the contributing factors for these declines (Campbell, 1892; Brooke, 1990; Mitchell, et al., 2004; Brooke, et al., 2007; Swann, et al., 2007; Dawson, et al., 2015; Hayhow, et al., 2017). Many species such as puffin (*Fratercula arctica*) which is listed as threatened due to their declining population status (IUCN, 2017), Manx shearwater (*Puffinus puffinus*) and the European storm petrel (*Hydrobates pelagicus*) may have limited distribution due to the impacts of, and predation by, rats (Heaney, et al., 2002; Mavor, et al. 2008). Currently, the majority of the UK puffin and all European storm petrel populations nest on rat-free islands (Mavor, et al. 2008, Ratcliffe, et al., 2009). The protection and enhancement of UK seabird breeding habitat has been recognised as an important conservation priority, including under international conservation agreements (Brooke, et al., 2007; Ratcliffe, et al., 2009; Dawson, et al., 2015; Thomas, et al., 2017a).

Rat eradications have occurred on over a dozen islands around the UK with brown rats being the most common target species (Bell, et al., 2011; Thomas, et al., 2017a; Bell, et al., 2019a; Pearson, et al., 2019). Black rats have been targeted on Lundy Island and the Shiant Isles (Lock, 2006; Appleton, et al., 2006; Thomas, et al., 2017a; Main, et al., 2019). Many of the eradications have occurred on islands with permanent staff or the presence of small communities (Bell, et al., 2011; Bell, et al., 2019a; Pearson, et al., 2019). These operations demonstrate how ground-based eradication techniques can be utilised on both inhabited and uninhabited islands around the UK.

Pre-1998: the early eradication operations

Despite an early attempt to eradicate rats from Ailsa Craig in 1925, the first documented successful rat eradication did not actually occur in the UK until 1968 on Cardigan Island in Wales (RSPB, 1924; RSPB, 1925a; RSPB, 1925b; Johnstone, et al., 2005; Thomas, et al., 2017a). This makes the UK the first country to intentionally undertake a rat eradication operation anywhere in the world. Four other rat eradications occurred between 1968 and 1998; Inchgarvie (Firth of Forth), Scotland in 1990, Ailsa Craig, Scotland in 1991, Handa Island, Scotland in 1997 and Puffin Island, Wales in 1998 (Ratcliffe & Sandison, 2001; Zonfrillo, 2001; Zonfrillo, 2002; Johnstone, et al., 2005; Stoneman & Zonfrillo, 2005; Thomas, et al., 2017a). Warfarin was the primary active ingredient used in each of these eradications with difenacoum used as a secondary option in the Puffin Island rat eradication (Ratcliffe & Sandison, 2001; Zonfrillo, 2001; Zonfrillo, 2002; Stoneman & Zonfrillo, 2005). All of these early eradications used ground-based methods, but focused on applying bait in holes, burrows, under rocks and vegetation and in isolated wooden bait stations or under inverted fish bins, rather than in a systematic grid pattern (Ratcliffe & Sandison, 2001; Zonfrillo, 2001; Zonfrillo, 2002; Stoneman & Zonfrillo, 2005; Thomas, et al., 2017a).

This method of baiting made it difficult to monitor bait consumption by rats and non-target species. There were no accurate records of bait take by rats or other species from any of these operations (Ratcliffe & Sandison, 2001; Zonfrillo, 2001; Zonfrillo, 2002; Stoneman & Zonfrillo, 2005; Thomas, et al., 2017a). Monitoring was limited: in most cases it didn't occur; used chewsticks across the island immediately following the eradication (it has been noted that chewsticks can be difficult to interpret sign accurately); or was determined by the recovery of the seabird or rat populations without any quantifiable measures (Zonfrillo, 2001; Ratcliffe, et al., 2009; Thomas, et al., 2017a). In the case of Inchgarvie and Puffin Islands eradication was not confirmed until years after the operation. Unfortunately, there have been recent reports of rats on Inchgarvie and rats reinvaded Handa in 2012 (Thomas, et al., 2017a).

The later operations (post-1999)

The use of toxins and the risks these presented to non-target species and the environment led to the development of Best Practice and Standard Operating Procedures for eradication operations in New Zealand in the 1990s and these documents are revised as new techniques and tools are developed (Cromarty, et al., 2002; Broome, et al., 2011). Robust protocols for eradication operations included detailed planning, operational requirements, implementation protocols, monitoring guidelines and biosecurity requirements (Cromarty, et al., 2002; Broome, et al., 2011). These best practice and standard operating techniques developed in New Zealand were followed and adapted during the UK eradications undertaken by Wildlife Management International Ltd (WMIL).

Five major eradications directed by WMIL have occurred in the UK since 1999; Ramsey Island, Wales (brown rat) in 1999/2000, Lundy Island, England (black and brown rat) in 2002–2004, Isle of Canna, Scotland (brown rat) in 2005/2006, St Agnes and Gugh, Isles of Scilly, England (brown rat) in 2013/2014 and the Shiant Isles, Scotland (black rat) in 2015/2016. In addition to these five sites, eradication attempts have also been made on Looe Island in 2006, the Calf of Man in 2012 and Caldey Island in 2015, which have not been included here because Looe Island was reinvaded by rats three years later and the Calf of Man and Caldey Island eradications are still on-going (Thomas, et al., 2017a).

These five eradications used ground-based techniques with bait stations placed out across the islands on either 25 m × 25 m, 25 m × 50 m, 50 m × 50 m, 90m × 90 m or 100 m × 100 m grids depending on the target species and type of habitat or risk areas. The smaller grid sizes (between 25 and 50 metres spacing) were used to target black rats and the larger grid sizes (between 50 and 100 metres spacing) used to target brown rats, with the smallest spacings used in high risk areas (such as around properties, seabird colonies, wharves, farms and restaurants).

A simple yet effective bait station design has been used in each of these five eradications in the UK. Although a range of commercially available lockable stations have been used in selected locations (e.g. residential homes, farm buildings, schools, etc.) during these eradications, and for on-going biosecurity to reduce the risk to the public, particularly children and the possibility of tampering with these long-term stations, the main bait stations were made from corrugated drainage pipe. This design is cost-effective and widely available. For the 1999/2000 Ramsey Island rat eradication, 500 mm lengths were used. However, these stations were found to be too short as they allowed carrion crows (*Corvus corone*) access to the bait. The stations were made longer by adding 250 mm lengths to one end. The standard length for each bait station in all subsequent eradications was 750 mm long with an access hole cut in the centre for placement of the bait (Fig. 1). This access hole is covered with a short section of drainage pipe. During the 2002–2004 Lundy Island rat eradication, crows learnt to flick the lids off the stations to reach the bait, therefore another length of wire was put around the centre of the station to hold the lid tightly in place. This "crow clip" became standard on all bait stations on any island with either carrion crows, hooded crows (*C. cornix*) or ravens (*C. corax*) present (Fig. 1).

Technological advances in GPS and GIS-linked systems helped streamline the positioning of bait stations during the grid establishment stage of eradications, as well

Fig. 1 Example of the main bait station in position with the crow clip holding the central lid in place, as used in the five ground-based eradications in the United Kingdom that were directed by Wildlife Management International Ltd. [Credit: Elizabeth Bell, WMIL]

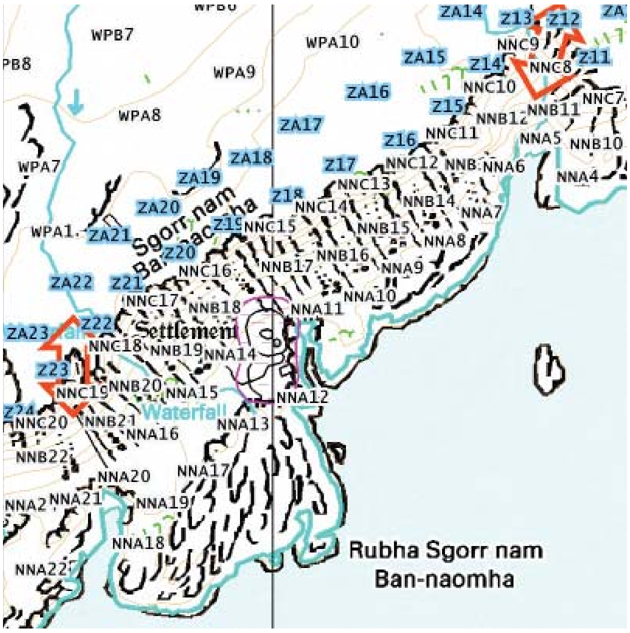

Fig. 2 An example of a detailed bait station map as used by eradication teams during the Isle of Canna operation. Where alphanumeric codes related to bait station positions (e.g. WP = West Plateau, A = line A, 9 = bait station 9; Z = Boundary line Z (two lines of stations at the top of the cliff section above the coastal slopes), 19 = bait station 19; NN = Nunnery, B = line B, 6 = bait station 6), double ended red arrows = safe access routes up or down to the coastal slope areas, pink shaded areas = important archaeological site (e.g. The Nunnery).

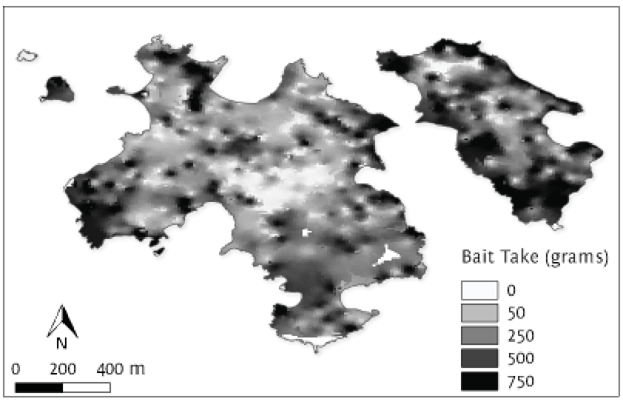

Fig. 3 Example of a heat map of bait take (g) by rats using the results from the St Agnes & Gugh brown rat (*Rattus norvegicus*) eradication.

as monitoring the level of bait take by rats and non-target species. Detailed maps can be produced for the eradication team that can give additional information such as sensitive sites like archaeological structures, location of rare plants, seabird colonies and white-tailed sea eagle (*Haliaeetus albicilla*) nesting sites and locations of access points for steep terrain where more care needs to be taken (Fig. 2). This intimate knowledge of the stations and island make it easier for the eradication team to monitor bait take by rats as the data can be linked to the specific station and activity levels can be recorded on the spatial map. These maps created by the GIS-linked database offer the team the opportunity to monitor the decline in rat numbers throughout the operation and could allow the eradication personnel to react instantly to hotspots or problem areas on the island. Specific bait take information can lead to detailed activity which shows bait take by rats throughout the operation and detailed heat maps showing complete bait take by rats at the end of an eradication (Fig. 3).

Cereal-based bait blocks (containing the anticoagulant diphacinone, bromadiolone or difenacoum) were used. Each eradication used one bait formulation as the main bait with a second option available to target ‘fussy’ (i.e. those rats that will not eat the primary bait for whatever reason) or surviving rats. This gives the option to adapt the project if rat behaviour or taste preference becomes an issue during the eradications. This has been shown to be important in certain eradications as demonstrated by the Isle of Canna brown rat eradication where the last surviving rat was targeted successfully using the alternative bait. Bait was placed loose in the bait stations for the first three weeks of the eradication operation. This allowed rats to cache bait in burrows for feeding themselves and any breeding females. Once bait take has reduced, bait is wired securely into the stations (Fig. 4) and any rat sign on these blocks is used to identify the presence of a surviving rat or monitor high risk areas, such as seabird colonies or farm buildings.

Although aerial application operations generally have a range of higher implementation costs compared to ground-based operations due to the requirement of a helicopter, sowing bucket and need for ground crew, engineer and other legal requirements for use of aircraft, the implementation time of the operation is often reduced compared to a ground-based operation. Except for the Lundy Island eradication (which took a second winter),

Fig. 4 Example of the main bait station in position showing the open bait station (with the lid off) with the bait wired in place, as used in the five ground-based eradications in the United Kingdom that were directed by Wildlife Management International Ltd. [Credit: Elizabeth Bell, WMIL]

rats were successfully targeted within 21 to 64 days (Bell, et al, 2011; Bell, et al., 2019a; Bell, et al., 2019b; Main, et al., 2019).

The use of rodenticide baits to complete eradications has enabled strong relationships to be established between bait manufacturers, eradication operators and local agencies in the UK. This has enabled open and in-depth discussions about the bait in regard to problems with formulation, taste and longevity that were identified during eradication operations. Issues such as the bait blooming (i.e. swelling and splitting after moisture on the bait) or rapidly going mouldy in the Lundy eradication were relayed to the manufacturers who altered the wax content for later operations. This meant the bait became much more robust in the damp winter conditions during the later Scottish operations, reducing the overall bait quantity required for those eradications.

European Union (EU) regulations require Bitrex™ (denatonium benzoate) or an alternative bittering agent to be added to all rodenticides to deter human consumption. Rats are not intended to be put off by Bitrex™, although research suggests that some rats can detect it even at very low concentrations, and preferentially choose bait that does not contain Bitrex™ (Veitch, 2002). Three rats actively avoided bait containing Bitrex™ on Lundy Island and, by working with the UK bait manufacturer, dispensation for a small amount of Bitrex™-free bait was obtained and was used to successfully target the rats at those sites (Bell, 2004). Despite the bait manufacturer disputing the fact that rats could detect and avoid Bitrex™ bait, they were open to experiment, assess the issue and work together with WMIL and Royal Society for the Protection of Birds (RSPB) towards a solution. Without the engagement of the bait manufacturer from the beginning of the project and open and frank discussions about the possibility of this issue with Bitrex™, the Lundy operation could have failed.

There have been recent regulatory changes to the purchase and use of rodenticides in UK. The Health and Safety Executive (HSE) require reassurance that biocide products can be used without unacceptable risk to wildlife and other non-target species and in July 2015 implemented the UK Rodenticide Stewardship Scheme. This scheme covers all rodenticide products sold to, and used by, professionals when applied outside buildings and in open areas and operates under a Code of Best Practice developed by the Campaign for Responsible Rodenticide Use (CRRU) group (CRRU, 2015). All professionals must have proof of competence at the point-of-sale for rodenticide baits (i.e. have completed certification for rodenticide control and/ or eradication by completing an approved training course) as well as comply with the best practice. These regulations generally relate to urban control operations, pest control operators and farmers, but eradication programmes must also follow these regulations. RSPB, in conjunction with CRRU, have developed an eradication-specific registered training course under the UK Stewardship Scheme.

Ground-based operations facilitate longer, wide-scale monitoring compared to aerial operations; not only using the bait itself, but also using a range of monitoring tools such as flavoured wax blocks, soap, tracking tunnels and trail cameras. Monitoring can be established at the same locations as the bait stations, as well as between the bait stations to intensify the scope of monitoring and ensure every micro-habitat is covered. Having non-toxic monitoring devices out in the open (pegged to the ground) and using a range of options gives more chance for any surviving rats to interact with at least one type of monitoring tool. This can also identify if a percentage of the rat population or rats at a specific location are avoiding the bait stations for any reason. This intensive effort can be used to detect any survivors and the operator can adapt the eradication to successfully target those last individuals. WMIL developed a range of flavoured wax blocks that have proved to be very effective in detecting the presence of surviving rats at the final stages of eradication (Fig. 5). These blocks have been freshly produced by the eradication team on-site to a standard recipe as the operation progresses. This flavoured wax recipe has been widely shared amongst the eradication industry.

This period of intensive island-wide monitoring allows the eradication operators to be much more confident that the eradication has been successful prior to leaving the island. By being able to detect and respond to surviving rats immediately, this reduces the likelihood of eradication failure (as any rat that is detected during this period can be targeted) and thus the need for a second eradication attempt (which can cost as much as the original operation). This intensive monitoring period in these five UK operations occurred for up to four months, depending on the size of the island and time required to initially target the rats during the baiting phase. Additional monitoring is completed at least quarterly for two years prior to the intensive final check phase and rat-free declaration following standard international eradication protocols for temperate operations (Broome, et al., 2011).

The use of volunteers has been an asset to these five UK eradications by giving passionate conservationists the chance to be involved in a project they feel strongly about, increasing the national (e.g. RSPB) capacity in eradication methodology, and engagement with the local communities. However, the use of volunteers can reduce the awareness of managers, decision makers and funders of the true cost and effort required to complete ground-based eradications.

The costs of these five ground-based eradications ranged from £76,000 up to £900,000, including planning, implementation, key species pre-and post-eradication monitoring, monitoring for survivors or incursions for two

Fig. 5 Examples of flavoured wax as used for monitoring in the five ground-based eradications in the United Kingdom that were directed by Wildlife Management International Ltd. [Credit: Jaclyn Pearson, RSPB]. Where the left (blue) block is aniseed flavour, centre (brown) block is chocolate flavour and right (fawn) block is peanut flavoured and each block is pegged to the ground with a piece of fencing wire and marked with a short piece of flagging tape for visibility.

years post-eradication and confirmation monitoring ('final check') prior to the declaration of rat-free status (Dr R. Luxmoore, NTS, pers. comm.; P. St Pierre, RSPB, pers. comm.; Lock, 2006).

There can be difficulty associated with accurately recording the entire costs of eradications; in many cases reported costs do not include in-kind or match funded expenses by the agencies involved (National Trust for Scotland, RSPB, etc.). In many cases, it can be difficult to accurately record these costs against the eradication operation as they relate to administration and corporate expenses.

BEST PRACTICE FOR ERADICATIONS

It has long been recognised that every island is different when it comes to planning and implementing an eradication operation. As such, although the NZ best practice gave an important starting point for the UK operations, it needed to be adapted for the local situation to become more relevant and effective, particularly in regard to local legislation and animal welfare regulations.

The RSPB, in partnership with UK-based governmental and non-governmental organisations working in island restoration, with input from international experts in this field produced The UK Rodent Eradication Best Practice Toolkit which is hosted on the Great Britain Non-Native Species Secretariat website (Thomas, et al., 2017b).

This toolkit was developed as an advisory resource to provide systematic planning and implementation protocols for ground-based rodent eradications and biosecurity in the UK (Thomas, et al., 2017b). It aims to give UK organisations technical advice on eradication methodology as well as an eradication project management framework to enable greater confidence in achieving island restoration goals in invasive rodent management projects in the UK (Thomas, et al., 2017b).

THE ROLE OF COMMUNITIES

The majority of eradications around the world have occurred on uninhabited islands and it is thought that islands with significant human populations, unreceptive communities or occurrence of livestock and domestic animals are unlikely to be feasible for rat eradication (Campbell, et al., 2015). However, because invasive species are also a problem on inhabited islands, such eradications must be considered. A lack of public awareness about invasive species impacts and misunderstanding of eradication techniques from island communities are thought to have been responsible for the opposition of proposed eradications on inhabited islands around the world (Bryce, et al., 2011). The importance of the engagement and inclusion of local communities has been highlighted in a number of recent eradication and research projects, especially in regard to risk and benefit analysis and to ensure a suitable environment for eradication projects to proceed can occur (Bryce, et al., 2011; Eason, et al., 2008). Respect for the attitudes, and safety, of local communities needs to be a priority in any eradication planned for inhabited islands. The support and agreement by the community to proceed with an eradication is vital for any project on an inhabited island. This is particularly important as access into all properties is vital to effectively carry out an eradication. Involving the residents in the concept, planning, implementation and on-going biosecurity of the island was recognised as the only way such an eradication could have occurred on the islands in the UK.

Considerations to how the community view the environment, how they think the proposed eradication will affect them and other social science considerations need to be assessed for eradications planned for inhabited islands. Most importantly, all aspects of the eradication should be discussed with the community in the early stages of the proposal. Unlike eradication operators, most members of the public do not have any knowledge of the principles and techniques of eradication, particularly in regard to rodenticide choice and operational procedures. It is important that each community member understands these aspects and how they will personally be affected by the day-to-day operational requirements.

As there were staff or small communities present at four of the five previously mentioned UK eradications, almost all recent operations undertaken in the UK have had to work closely within these communities and have had to adapt to the issues and technical challenges the presence of people has on the eradications. During each of these eradications, WMIL and the local project partner worked closely with the landowner, staff and residents to understand and address concerns and questions about the operations. Where the operation occurred on staffed islands, the decision to complete an eradication had already been made by the main project partner concerned and much of the consultation with staff on the islands had already been completed by the management prior to the operation. Resident staff were generally supportive of the eradication and often viewed the eradication operational team as temporary, but separate, staff members. In comparison to those islands with resident staff, WMIL and RSPB recognised the importance of the engagement of the 85-person resident community on St Agnes and Gugh in the Isles of Scilly and started this engagement process early for the eradication of brown rats (Bell, et al., this issue a, Pearson, et al., 2019). The success of the St Agnes and Gugh eradication (Isles of Scilly Seabird Recovery Project, IOSSRP) showed how the community-based approach that was designed to develop local networks and use existing community structures to build support for the project worked extremely well. The vision and benefits of the project were shared by the community and the residents were part of the decision-making process and management of the project.

An open and transparent operating system has worked well in all these five previously mentioned eradications in the UK. Information covering details on rodenticide type, bait station design, anticoagulant poisoning symptoms and treatment, contact numbers and project management was provided to all residents, stakeholders and interested parties. The project team was permanently present on each of the islands throughout the eradication to implement the operation, answer any questions and deal with any issues. Project updates were provided to the community and stakeholders each week, which gave the residents the opportunity to observe the operational procedures and results as the eradication proceeded. Real-time bait-take maps were provided as part of this process. A 24-hour contact telephone number was provided for immediate response to any issues that a resident may have.

BIOSECURITY

With the eradication of rats from islands, the priority is to ensure that they do not become re-established. Biosecurity is a critical aspect of any eradication and should be designed, implemented and tested prior to the completion of the eradication and departure of the eradication team. Prevention of an accidental rat reintroduction should be the primary aim. Precautions need to be taken not only in obvious situations such as with visitors or boat movements, or when high-risk items like stock feed or hay are being delivered to the island, but also when the risk may be mistakenly thought to be negligible.

The long-term legacy of these five UK eradication projects was important to the implementing agencies involved as well as the communities and agency staff on the island. As such, practical biosecurity strategies were established for the community and supporting agencies; measures that have been designed to reduce the risk of rats being reintroduced to a minimum, without being a hindrance to the daily lives of the staff, community or visitors to the island. A range of biosecurity strategies were proposed to the residents or agency staff on each island and, following discussions about the protocols of each strategy, suitable measures for each island were selected and implemented. Public awareness and education leaflets have been developed for every eradication to ensure that the public are aware of the rat-free status of each island and ways they can assist in keeping the islands rat-free. Residents and staff members from the project partners have been trained in all relevant biosecurity measures and they will maintain regular monitoring checks on the islands in perpetuity. Funding for on-going biosecurity has been provided by partner agencies and completed by staff or in the case of St Agnes and Gugh, funds will be provided by the community through fundraising and grants (Pearson, et al., 2019). In some instances, such as on St Agnes and Gugh, community coordinators will maintain liaison between the residents and the supporting partner agencies (Pearson, et al., 2019).

DISCUSSION

Rat eradications have been undertaken on islands around the world for the past 65 years and in the UK for the past 50 years. International rat eradication projects over this time have used a range of methods but most recently focused on the aerial application of rodenticides. However, due to legislative limitations upon the outdoor-use of rodenticides and application methods, and although derogations can be issued to allow aerial operations, ground-based methods are likely to remain the predominant rat eradication technique in the UK (and other European counties). Developments from five eradications in the UK have streamlined operating procedures and eradication techniques for the next eradication. Using plastic corrugated drainage pipe as the main bait station type has enabled the design to be adapted to exclude large or problematic non-target species such as rabbits and crows. The positioning of bait stations using GPS and GIS-linked systems has streamlined recording bait take by rats and non-target species and enabled this to be monitored in real time. Constant monitoring throughout the operations starting with the bait take and progressing through to using a range of monitoring devices, such as flavoured wax, allowed for each operation to adapt to deal with high risk areas or ‘fussy’ rats to maximise the likelihood of eradication success. This intensive level of monitoring allows any issues that may arise with bait to be addressed directly with the manufacturers and rectified early in the operational timeframe.

Ground-based eradications have been completed on islands ranging in size from <1 ha to 3,100 ha (Taylor, et al., 2000; DIISE, 2015). Although an island’s size and terrain may prevent a ground-based bait station operation being completed, it would be perfectly feasible to eradicate rats from even larger inhabited and uninhabited islands assuming there were enough resources (including staff and funding) and commitment and support from all involved. The feasibility assessment for any proposed eradication needs to investigate the costs and benefits of all possible methods before deciding on the final operational techniques. In many cases, a combination of aerial and ground-based operations may also be suitable or preferred by communities on large inhabited islands, as shown by recent eradication plans such as for Lord Howe Island (Wilkinson & Priddel, 2011; Walsh, 2019).

Over 85% of rat eradications around the world have been completed on uninhabited islands (n = 721 out of 820 eradications; DIISE, 2015). However, many are now either being investigated or planned for islands with resident communities (Oppel, et al., 2011; Russell & Broome, 2016; Stanbury, et al., 2017). Eradications on inhabited islands raise social, economic, conservation and technical challenges for the operation (Moon, et al., 2015). The experience in the UK shows that to ensure an island restoration project runs successfully the support and agreement from the community must be secured. The community must share the project’s vision and feel that they are one of the beneficiaries. To do this, they will need to be included and play an integral role in the decision-making process, planning preparation and implementation and management of the project. In this way, the legacy of the project will be much stronger. Those proposing the eradication need to ensure that the community is aware of the effects of invasive rats on the native biodiversity of their island and how the proposed eradication can benefit those species as well as explaining the process of the eradication operation itself. However, project partners and eradication operators also need to realise that for a number of residents the biodiversity and environmental reasons to eradicate rats may be of no interest; as such, social and economic benefits should also be outlined during the planning stages as these may be more important to the communities themselves. It is important for operators to realise that communities may not have the same understanding of eradication processes and each aspect of the project may have to be explained.

The larger the community the longer, potentially, the project managers will need to ensure that the residents are all at the same position of understanding through the various stages of the project. Archipelagos or groups of islands bring additional stakeholders and interested parties that need to be engaged compared to single islands. From my experience, ten years is not an unreasonable timescale depending upon the starting point, the value placed upon seabirds by the community and the strength of the project partnership. In my view, and in agreement with others such as Moon et al. (2015), the ongoing consultation and communication with the local community and wider stakeholder groups during any eradication is essential.

As the need to prioritise islands for restoration has increased, the requirement of understanding and quantifying the costs of eradications has also increased (Martins, et al., 2006; Holmes, et al., 2015). Although general costs for eradications can be estimated if the size of the island and target species are known, and it appears that costs increase with the size of island, there are other costs from application method, permits, non-target mitigation, and biodiversity monitoring that need to be factored into an eradication operation (Martin, et al., 2006; Holmes, et al., 2015). This information is vital to be able to accurately determine the complete costs for future eradications and it is important that project costs are reported.

The defining factors underpinning the success of the eradication operations on inhabited UK islands were the professional management of the eradication, dedicated and passionate volunteer involvement, efficient and systematic monitoring, adapting to local conditions and ensuring a community-inclusive approach.

This model of consultation, engagement and community-involvement developed on these inhabited islands eradications in the UK can offer valuable information, advice and direction for eradication operations planned on islands with larger communities in the UK and around the world. The eradication of brown rats from St Agnes and Gugh could be used as a valuable education tool to show other communities that it is possible to safely eradicate rats and implement suitable biosecurity measures to reduce the risk of reinvasion without impacting on the lives of the residents, as reported by Pearson, et al. (2019). This model, and future techniques developed during other eradications on inhabited islands, will be even more important if restrictions on application measures and outdoor-use of rodenticides expand to countries outside of the UK. It is important for eradication operators to realise that even if aerial application methods are possible at the location, the community on the island may not approve or permit that type of method. As such, the use of ground-based bait station techniques will have a vital part to play and this option should be assessed as part of any original feasibility assessment.

Island restoration on UK islands has led to the dramatic recovery of seabird populations. Manx shearwaters on Ramsey and Lundy Islands have increased nearly ten-fold in the ten to fifteen years since the eradication of brown and black rats and the recolonization of European storm petrels and other small burrowing species has been recorded after long absences (Brown, et al., 2011; Morgan, 2012; Booker & Price 2014; Bell, et al., 2019b). These types of results have helped develop a legacy for many of the projects, with the residents and agency personnel on the islands committing to and doing their part to maintain important biosecurity measures. These results can also be used to help explain the benefits of completing this type of eradication project on other islands, even those with larger communities or a complex of target species. Providing safe breeding habitat and creating and then maintaining rodent-free status at important island sites, will be an important part of the long-term legacy of protection for UK seabirds.

It is important that when eradication projects are being designed and assessed that operators and project partners factor in on-going biosecurity after the completion of the project, particularly in relation to equipment, capacity and long-term funding requirements. It is one of the most vital aspects of an eradication project and agencies must recognise the requirement that biosecurity is required *in perpetuity*. For eradications that occur on inhabited islands, this makes the engagement of, and commitment from, the communities to undertake biosecurity measures, even more important to ensure the legacy of any eradication project.

Detailed prioritisation exercises such as Brooke, et al. (2007), Ratcliffe, et al. (2009) and Stanbury, et al. (2017) have identified a number of UK and UK Overseas Territories' islands as being pre-eminent sites for rat eradication because of their importance to seabirds. Twenty of the 25 islands identified in the most recent prioritisation exercise have resident human populations which increases the challenges for any eradication proposed for those sites (Stanbury, et al., 2017). One of the most important lessons identified by completing eradication operations on inhabited islands is that the community needs to be engaged as early as possible, preferably in the concept and development process. As important, all stages of the eradication need to be completely open and transparent, with community members involved throughout the implementation of the project and into the future to ensure the sustainability of the on-going biosecurity for the island. The newly developed Best Practice for UK islands (Thomas, et al., 2017b) which has built on all the lessons learnt from these eradications that have occurred over the past 50 years in the UK should help make these future eradication operations more likely to succeed on both uninhabited and inhabited islands.

ACKNOWLEDGEMENTS

Special thanks to all the volunteers that have worked on all these UK eradications: the success and recovery of these islands is a credit to their hard work and enthusiasm. These eradications were funded and supported by RSPB, The Landmark Trust, The Lundy Company, The National Trust, Natural England, Scottish Natural Heritage, The National Trust for Scotland, EU LIFE, Defra, Heritage Lotteries Fund, WMIL and private donors. The communities and residents of St Agnes & Gugh, Isle of Canna, Lundy Island and Ramsey Island for their hospitality and support while the eradication teams were on their islands and for their on-going commitment to island biosecurity. Tom Nicolson and Adam Nicolson for their support of the Shiant Isles eradication and their commitment to on-going biosecurity. The Steering Groups for each eradication for their support and advice throughout these projects. Thanks to Paul St Pierre (RSPB) and Dr Richard Luxmoore (National Trust for Scotland) for providing the costs for the St Agnes and Gugh and Isle of Canna eradications. Thanks to Bell Laboratories, PelGar International Ltd and Syngenta Ltd for the supply of the rodenticide bait. Thanks also to Dr Alan Buckle, Dr Colin Prescott and David Rymer, Reading University, for their assistance with the resistance testing for many of these eradications. Kelvin Floyd produced Figs 2 and 3. This paper is dedicated to the memory of my father, Brian D. Bell (1930–2016), whose vision for rat-free islands to protect and enhance seabird populations, and his training in eradication techniques, has taken me around the world.

Abstract As part of the Isles of Scilly Seabird Recovery Project, and directed by Wildlife Management International Ltd, the eradication of brown rats (*Rattus norvegicus*) from the inhabited islands of St Agnes & Gugh, Isles of Scilly was completed between October 2013 and April 2014 with the assistance of volunteers, and staff from the Royal Society for the Protection of Birds, Isles of Scilly Wildlife Trust and Natural England. Bait stations with cereal-based wax blocks containing bromadiolone at 0.005% w/w were established on a 40–50 metre grid over the island. With the presence of 85 residents on the 142 ha islands, this is the largest community-based brown rat eradication globally to date. Given the fact that a community is based on these islands, community engagement and advocacy was a vital and fundamental part of the eradication. Consultation for eradication began three years prior to the operation to explain the requirements for the proposed project and to assess support, but this built on many years of wider community engagement with seabird conservation. All of the residents supported the eradication of rats and vision of the project. The consultation and inclusion of the community in decision-making and management of the Isles of Scilly Seabird Recovery Project was a critical part of the operation and key to the success of the eradication. The community took ownership of the project and has committed to the on-going biosecurity requirements following the eradication of rats. The removal of brown rats from St Agnes and Gugh was a major achievement and provided the opportunity to restore the islands' communities of seabirds and other native species. This project provided an example of the effectiveness of ground-based rodent eradication techniques on an inhabited island and the lessons learnt during this operation can be used to help proposed eradications on other islands with communities and with terrain suitable for ground-based techniques.

Keywords: brown rat, community, eradication, Isles of Scilly, *Rattus norvegicus*, St Agnes and Gugh

INTRODUCTION

The eradication of invasive species from islands has become one of the most important tools in conservation in recent times. It offers the opportunity that, following an initial investment, significant long-term benefits can be achieved. The eradication of rats is a recognised prerequisite for the restoration of many seabird colonies on islands. Rodents have been successfully eradicated from over 700 islands around the world, including at least 10 UK islands (Moors & Atkinson, 1984; Atkinson, 1985; Taylor, et al., 2000; Zonfrillo, 2001; Towns & Broome, 2003; Appleton, et al., 2006; Howald, et al., 2007; Jones, et al., 2008; Bell, et al., 2011; Parks & Wildlife Service, 2014; DIISE, 2015; Thomas, et al., 2017; Bell, 2019; Bell, et al., 2019; Pearson, et al., 2019), However, most of these islands have been uninhabited. Many consider that islands with significant human populations, unreceptive communities or occurrence of livestock and domestic animals are unlikely to be feasible for eradication (Oppel, et al., 2011; Campbell, et al., 2015; Russell & Broome, 2016; Stanbury, et al., 2017). However, an increasing number of eradications are being considered on inhabited islands and the importance of the engagement and inclusion of local communities has been highlighted in a number of recent eradication and research projects, especially in regard to risk and benefit analysis (Eason, et al., 2008; Bryce, et al., 2011; Oppel, et al., 2011). It should be noted that the greatest conservation benefit to be gained from future eradications in the UK, and in other parts of the world, is predominantly from inhabited islands (Stanbury, et al., 2017). As such, it is vital that techniques and protocols developed during eradications on islands with even small communities should be assessed, utilised or adapted for these islands with larger communities.

The Isles of Scilly are a nationally and internationally important location for seabirds, particularly Manx shearwater (*Puffinus puffinus*), European storm petrel (*Hydrobates pelagicus*) and black-backed gull (*Larus fuscus*) (Lock, et al., 2006). Both Manx shearwaters and European storm petrels are amber listed under the United Kingdom Birds of Conservation Concern threat categorisation (Eaton, et al., 2015). A partnership of organisations (Royal Society for the Protection of Birds (RSPB), Natural England (NE), Isles of Scilly Wildlife Trust (IOSWT) and Isles of Scilly Bird Group (IOSBG)) produced the Isles of Scilly Seabird Conservation Strategies 2005–2008 and 2009–2013 which described the national and international status and context of the seabird populations on the Isles of Scilly and identified priority actions and strategic goals for management. These included current and future measures to improve the available habitat for seabirds through rat control and eradication (Lock, et al., 2006; Lock, et al., 2009). St Agnes and Gugh have a number of important land areas designated for seabirds as Special Protected Areas (SPA), Sites of Special Scientific Interest (SSSI) and Ramsar (Lock, et al., 2009). The eradication of brown rats (*Rattus norvegicus*) from St Agnes and Gugh was identified as a priority in these strategies as it would remove predation pressure on Manx shearwaters and storm petrels and provide the opportunity for other seabirds to colonise the islands (Lock, et al., 2006; Lock, et al., 2009). These strategies also recognised the social, economic and health benefits for the local community (Lock, et al., 2006; Lock, et al., 2009).

The Isles of Scilly Seabird Recovery Project (IOSSRP) was established in 2010 and was managed by a coalition of

groups including RSPB, IOSWT, NE, Duchy of Cornwall (DC), the Isles of Scilly Area of Outstanding Natural Beauty (AONB) partnership and a representative from St Agnes and Gugh, with support from the IOSBG. The IOSSRP partnership identified the need to assess the possibility of eradicating brown rats from St Agnes and Gugh to protect and enhance the islands' seabirds and protect Annet from re-invasion. Annet is the most important uninhabited island for seabirds in the Isles of Scilly as it has always been rat-free (excluding an incursion in 2004, probably from neighbouring St Agnes) and holds the main populations of Manx shearwaters and European storm petrels (Lock, et al., 2006). The partnership commissioned a feasibility assessment in 2010 (Bell, 2011). A formal IOSSRP Steering Group made up of representatives from all Project Partners was established in 2012. Wildlife Management International Ltd. (WMIL) directed the eradication with the assistance of volunteers and RSPB, IOSWT and NE staff. The eradication was completed between October 2013 and April 2014 (Bell, et al., 2014). This paper covers the technical aspects of the St Agnes and Gugh brown rat eradication and complements the Pearson, et al., (this issue) paper on the community aspect of the eradication.

STUDY AREA AND METHODS

St Agnes and Gugh

St Agnes and Gugh (49.89267°N, 6.34073°W) are two islands in the Isles of Scilly archipelago off the Cornish coast, in south-west England (Fig. 1). St Agnes (105 ha) and Gugh (37 ha) are connected by a rock and sand bar at low tide (Fig. 1). St Agnes and Gugh are separated from St Mary's by a deep channel (St Mary's Sound) that is 1.1 kilometres at the closest point (via stepping stone islands) or 1.3 km from shore to shore (Fig. 1). There are 85 residents, only two of whom live on Gugh. Brown rats were accidentally introduced to the Isles of Scilly from shipwrecks in the 1700s, and were widespread and abundant across both islands, as well as many other islands in the archipelago (Matheson, 1962; McCann, 2005). Tourism is one of the islands' major sources of income, particularly between April and October.

There are approximately 40 homes on the island, but at least 150 buildings (holiday lets, farm buildings, sheds, etc.) scattered across the whole island. There are six farms (including a chicken farm and dairy), a campground, a school, a restaurant, a pub, two cafes, a post office and store. There are cattle, chickens, ducks, geese, two ponies and pigs on St Agnes. Many families have pet cats and dogs. There is a main quay where passengers and freight are landed, and a smaller slipway used mainly by residents. These factors increased the number of challenges such as providing alternative food and shelter for rats, risk to non-target species and biosecurity.

Fig. 1 Location of St Agnes and Gugh, Isles of Scilly, United Kingdom.

The main habitats on St Agnes are farmland, mainly flower farms and low intensity cattle grazing, characterised by small fields with extensive hedges and stone walls, ponds, maritime grassland, invasive *Pittosporum*, rocky shores and sandy beaches (Parslow, 2007). St Agnes and Gugh are home to the only known populations in the British Isles of a number of rare plants, including least adder's-tongue fern (*Ophioglossum lusitanicum*) (Parslow, 2007).

Rabbits (*Oryctolagus cuniculus*), Scilly shrews (*Crocidura suaveolens cassiteridum*) and pipistrelle bats (*Pipistrellus* spp.) are the only other known species of mammal found on St Agnes and Gugh, apart from livestock and pets. House mice (*Mus musculus domesticus*) were present on St Agnes and Gugh, but have not been seen in at least 15 years, though mice are still present on most of the other main islands in the Scillies (Howie, et al., 2007).

Eradication operation

The eradication programme ran from 11 October 2013 to 11 April 2014 and included establishing the bait station grid, poisoning, monitoring and biosecurity establishment. This phase took 1,593 person days. Long-term monitoring ran monthly between May 2014 and December 2015. The final check, species monitoring, and rat-free declaration ran from 6 January to 18 February 2016. This phase took 250 person-days. All IOSSRP personnel wore blaze-orange hats (with the IOSSRP logo) to be easily recognisable to the community and visitors. Each operational task was undertaken and completed as follows:

Pre-eradication

Due to the presence of a community on the island and the selected method of bait stations, different pre-eradication preparation tasks were required compared to aerial baiting methods. Preparation tasks included, but were not limited to: consultations with the community about operational techniques; timing of each aspect of the project and confirming access to land and buildings; testing rats for resistance to rodenticides; getting the community to cease using rodenticides on the island six months prior to the eradication (i.e. to prevent bait aversion, avoid rats becoming accustomed to bait and to prevent resistance); removal of waste, alternative food and harbourage (including cleaning up farm sheds and other buildings on the island); establishing waste management systems for each household and business (including provision of rodent proof wheelie-bins and compost bins); application for an extension-of-use for rodenticide use from the UK Health and Safety Executive (HSE); construction of bait stations; and delivery of all equipment to the islands.

The University of Reading completed resistance testing and DNA screening of 26 rats trapped on the islands. Of these samples, resistance (L120Q mutation) was detected in one individual (Rymer, 2013). This resistance evidence confirmed the requirement for multiple toxin and bait formulations to ensure any problem rats could be targeted successfully. An extension-of-use permission from HSE was obtained to use specific rodenticides (difenacoum and brodifacoum) at specific locations outdoors if it became necessary to target any resistant rats towards the end of the eradication.

Over 1,500 bait stations were constructed by RSPB staff and volunteers in Penzance and these and all other equipment was delivered to St Agnes in September 2013.

Bait station grid

The bait station grid was established between 12 October and 7 November 2013. Bait stations were made from 750 mm lengths of 100 mm diameter corrugated black plastic drainage pipes, wired into the ground to prevent movement by animals and/or wind. Bait was placed in the centre of the station through the access hole that is covered by an additional short section of pipe and held in place by a ‘crow clip’ (a short piece of wire wrapped around the centre of the station devised during the Lundy Island rat eradication operation which prevents the crows and gulls removing the lids (Bell, 2019)).

Bait stations were placed out on a 40 m × 50 m grid. Positions were determined by electronic Geographic Information System (GIS) and loaded onto a hand-held GPS unit. Each station was marked by a bamboo cane or flagging tape to ensure visibility in thick vegetation or poor weather.

The entire grid of 962 tube stations was positioned across the island (with an additional 74 commercial Protecta™ lockable bait stations inside all private homes, holiday rentals, public buildings and on the quay) before being individually numbered and mapped using GPS and added to a GIS-linked database (Fig. 2).

Poisoning

The main toxicant used was bromadiolone, Contrac™ (manufactured by Bell Laboratories), a 28 g, cereal-based wax block bait with 0.005% active ingredient. This bait was used between 8 November 2013–12 January 2013 and 27 January–8 March 2014 (Table 1). There were two alternative baits, both manufactured by PelGar International, available if any rats were detected that seemed to be avoiding or appeared to be resistant to the main bait: Roban Excel™, a 20 g cereal-based block bait with active ingredient difenacoum at 0.005% w/w that was used between 13–26 January 2014 (Table 1); and Vertox Oktablok II™, a 20 g cereal-based block with active ingredient brodifacoum at 0.005% w/w that was not required. Contrac™ and Roban Excel™ are dyed blue (or green/blue) to be less attractive to birds (Caithness & Williams, 1971; Hartley, et al., 1999; Weser & Ross, 2013), thus helping to further reduce risks to non-target species.

The poisoning operation commenced on 8 November 2013 and continued through to 8 March 2014. Baits were present in each station throughout the poisoning programme and replaced as required; when eaten by rats, by non-target species such as invertebrates and/or damaged by weather. Between 8 and 18 November 2013 there were eight blocks of bait in each station. This was reduced to four blocks between 19 and 25 November 2013 and reduced again to two blocks from 26 November 2013 to 26 January 2014 (Table 1). After 27 January 2014, only one block of bait was placed in each station. Existing undamaged bait blocks were left in the stations and the extra blocks were removed. All waste and partially eaten bait was collected

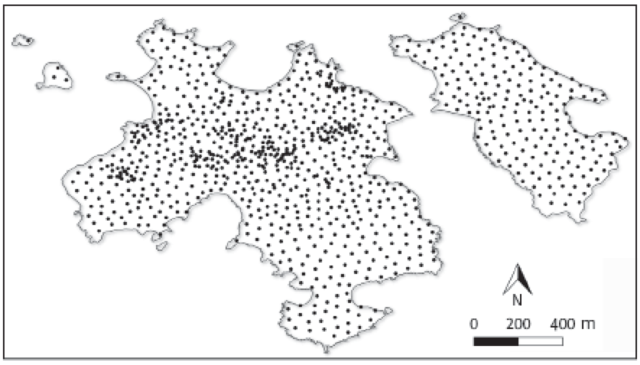

Fig. 2 Bait station grid on St Agnes and Gugh, Isles of Scilly. Bait station positions are marked by a black dot.

and incinerated in a high temperature incineration facility at the end of the operation.

Bait was loose in the stations between 8 and 25 November 2013 (so that rats can take bait back to their burrows to feed nursing females or young) and after 26 November all bait was wired into the stations (which could be used to confirm the presence of rats due to teeth marks being recorded on partially eaten blocks in the stations) (Table 1).

Excluding the stations in the houses (which were checked once a week), all other bait stations on St Agnes and Gugh were checked and serviced at intervals between one to seven days (a total of 56 bait checks over 120 days) depending on the stage of the operation (Table 2). To present the data on bait-take gained from these varied bait station checks we grouped the data into 27 periods or checks (mean (±SEM) = 1.9 ± 0.2 days between checks, range 1–7 days) shown as days from baiting (Fig. 3).

Bait-take was recorded in field notebooks by bait station number and the species believed to have consumed

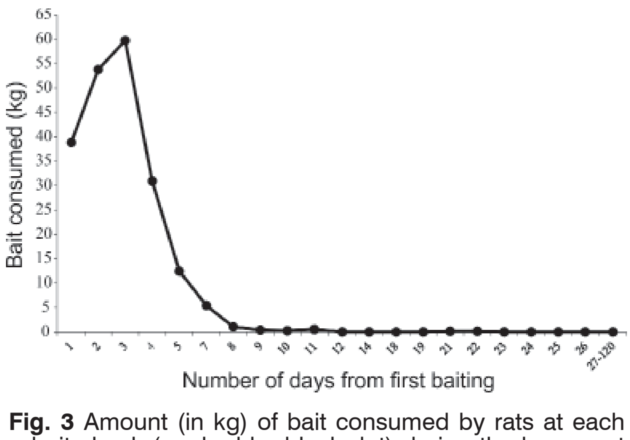

Fig. 3 Amount (in kg) of bait consumed by rats at each bait check (marked by black dot) during the brown rat (*Rattus norvegicus*) eradication on St Agnes and Gugh, Isles of Scilly.

Table 1 Baiting regime during the brown rat (*Rattus norvegicus*) eradication on St Agnes and Gugh, Isles of Scilly, United Kingdom.

Date	Bait type	No of blocks	Bait loose or wired into station
8–18 Nov 2013	Contrac™ (bromadiolone)	8	Loose in station
19–25 Nov 2013	Contrac™ (bromadiolone)	4	Loose in station
26 Nov 2013 to 12 Jan 2014	Contrac™ (bromadiolone)	2	Wired into station
13–26 Jan 2014	Roban Excel™ (difenacoum)	2	Wired into station
27 Jan to 8 Mar 2014	Contrac™ (bromadiolone)	1	Wired into station

or removed the bait. These data were entered into a GIS-linked database and maps showing active stations were produced in real-time to enable the team to effectively monitor bait-take activity and target any "hot spots".

Searches for carcasses were completed during all checks. Any carcasses that were found, were collected, necropsied to determine cause of death (where possible) and incinerated to reduce risk for non-target scavengers. It was expected that very few rat carcasses would be found on the surface as most rats die underground in their burrows. Five rat carcasses were found on the surface during the Lundy Island rat eradication and three during the Isle of Canna rat eradication (Bell, 2004; Bell, et al., 2006). Any non-target species that were collected during the operation were also necropsied and assessed for anticoagulant poisoning (i.e. blood in body cavity, bruising, discolouration of organs). Non-target species have been affected during other eradications: 77 non-target species' carcasses (greater black-backed gull *Larus marinus*, carrion crow *Corvus corone*, house sparrow *Passer domesticus*, short-eared owl *Afio flammeus* and rabbit *Oryctolagus cuniculus)* were found on the surface during the Lundy Island rat eradication and seven non-target species carcasses (wood mouse *Apodemus sylvaticus*, and pygmy shrew *Sorex minutus*) were found during the Isle of Canna operation. Of these, only 15 showed evidence of anticoagulant poisoning and the remainder had died of starvation (rabbit, shrew) or either natural (short-eared owl, crow) or unknown causes (greater black-backed gulls) (Bell, 2004; Bell, et al., 2011).

Monitoring

Three distinct periods of monitoring were undertaken as the project progressed. Intensive monitoring using 2,500 stations at 25 m spacing was carried out from 19 November 2013 to 8 March 2014 to detect rats surviving through the poisoning phase. This was followed by a 21-month period of long-term monitoring using 87 biosecurity stations and six rodent motels (wooden boxes designed to provide an attractive, alternative 'burrow' for rats during an incursion) from 9 March 2014 to 5 January 2016. These biosecurity stations were established at high risk areas on the island; around the coast, at the quay and other boat landing sites and at seabird breeding sites (Bell, et al., 2014). The final monitoring check, using 448 stations, was carried out between 6 January and 18 February 2016 (Bell & Cropper, 2016). WMIL and RSPB staff and volunteers carried out the intensive and final checks and IOSSRP staff, St Agnes and Gugh residents and volunteers maintained the long-term monitoring. Monitoring stations consisted of materials attractive to rats that would also clearly show teeth marks (e.g. chocolate, peanut or coconut flavoured wax, candles and soap), tracking tunnels and trail cameras (Bushnell™). All were individually numbered and any evidence of activity (e.g. teeth marks or foot prints) was recorded in field notebooks by station number and the species believed to have consumed or marked the monitoring item.

Monitoring items were placed inside and outside each station as well as halfway between each station during the intensive monitoring phase and final monitoring check. During these monitoring phases, each monitoring site was checked regularly 3–5 times a week (depending on weather), either separately or – during the poisoning phase – together with the poisoning bait station grid. Monitoring items were placed inside the biosecurity stations only during the long-term monitoring phase and these were checked monthly. Checks for active rat runs and activity at high-risk sites (i.e. stone walls, farms, seabird colonies, etc.) were also undertaken throughout all three monitoring phases. Any rat and non-target species sign found on any monitoring detection device at any stage of the monitoring phase was recorded and added to the database.

RESULTS

Bait acceptance and take

Bait acceptance was excellent with no evidence of bait avoidance. Green/blue rat droppings appeared within three days and rats accounted for 203.6 kg of Contrac™ bait taken (estimated 1,600–2,500 rats).

The bait-take pattern was typical of other rat eradication campaigns (Thomas & Taylor 2002; Bell, et al., 2011). It was very high in the immediate days after original baiting (checks 1–3) and dropped to a relatively low level eight days after original baiting (check 8) (Fig. 3). A small increase was recorded at day 21 after the original baiting (check 15) but dropped away, reaching zero bait-take on day 23 after the original baiting (check 17) (Fig. 3).

Throughout the poisoning phase, 62% of bait stations were visited by rats, with 42.7% active within the first three days of the original baiting. This level of activity was similar to the Lundy and Isle of Canna eradications which had 42.5% and 62% of bait stations visited by rats, respectively (Bell, 2004; Bell, et al., 2011). The high number of active bait stations during the first two bait checks shows that the rats quickly accepted the bait across St Agnes and Gugh. It is likely that the small grid size and intensive baiting regime targeted the rats effectively within a short timeframe.

The average number of blocks taken by rats was 4.3 (± 0.1) blocks per active station (range 0–41 blocks). Again, this level of activity was similar to the Lundy and Isle of Canna eradications which had 3.2 and 8 blocks taken by rats by per active station, respectively (Bell, et al., 2004; Bell, et al., 2011). This also indicates that rats were quickly removed from most sites across St Agnes and Gugh. As shown by Fig. 4, bait-take was not evenly distributed over both islands, with the greatest level of bait-take on the coastal areas of both islands and each of the offshore

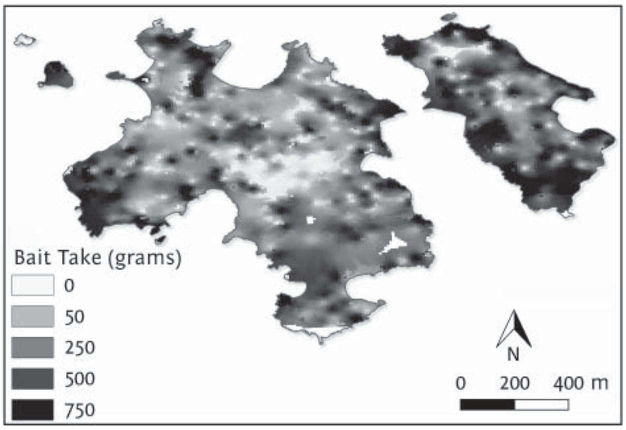

Fig. 4 Distribution of total bait-take (g) by rats consumed per station during the brown rat (*Rattus norvegicus*) eradication on St Agnes and Gugh, Isles of Scilly.

rock stacks connected to the main islands at low tide. The distribution of rats and density on Gugh was likely to be having an impact on Manx shearwaters and other seabirds and land bird and invertebrate populations present on St Agnes and Gugh.

There were 19 rat carcasses collected on the surface during the operation. These were collected and incinerated to prevent availability to non-target species.

There were low levels of interference by non-target species with nearly 54 kg of bait being consumed; cattle kicked up stations and ate a small amount of bait (1.4 kg), slugs and other insects consumed 51.9 kg and shrews consumed 0.4 kg. The weather conditions also complicated the operation and accounted for 3.4 kg of bait that had to be replaced due to the loss of 54 bait stations in storms. Carcasses of a water rail (*Rallus aquaticus*), a song thrush (*Turdus philomelos*), a blackbird (*T. merula*) and nine Scilly shrews were found. There was no evidence that any of these non-target species was affected by the rodenticide.

Monitoring

Monitoring for rat presence continued island-wide for two years after the end of the poisoning operation. The last rat was detected on chocolate flavoured wax on 29 November 2013 during the overlap between the poisoning and intensive monitoring phases and this rat was successfully targeted using the main bait, Contrac™, by 2 December 2013. No rats or sign were detected during any phase of the long-term or final check monitoring. St Agnes and Gugh were declared rat-free in February 2016.

Cattle, shrews and birds interfered with 899 monitoring stations (by eating the flavoured wax or soap, marking tracking plates or, in the case of cattle, by removing the monitoring wires) a total of 12,156 times between 21 November 2013 and 26 February 2014. There were 127 stations affected 1,384 times by cattle, 60 (82 times) by birds, 5 (8 times) by insects, 9 (9 times) by rabbits and 454 (2084 times) by shrews. Interference by birds, shrews and rabbits was limited to teeth or beak marks on the soap or flavoured wax or footprints on tracking plates. Cattle removed wires and ate flavoured wax and soap, so monitoring points had to be moved or hidden in those areas with cattle.

DISCUSSION

The success of the St Agnes and Gugh brown rat eradication shows that a well-planned, adequately resourced, well-executed programme, with the complete support of the community, local agencies and government and directed by an experienced operator with dedicated workers, can eradicate rats from inhabited islands using a ground-based bait station operation. The project on St Agnes and Gugh is the largest community-led (with 85 residents) brown rat eradication anywhere in the world. Most other eradications on inhabited islands either have smaller communities (e.g. Isle of Canna, 12 residents; Bell, et al., 2011; Rakino in New Zealand, 16 residents; Bassett, et al., 2016) or have staff or a military population (e.g. Bird, Denis, Curieuse and Fregate Islands in the Seychelles, Merton, et al., 2002; Lundy Island, Bell, 2004; Wake Island, Brown, et al., 2013) and have not had direct involvement of the community during and after the eradication or leaving the community responsible for all biosecurity measures (Pearson, et al., this issue).

However, the success of the eradication was dependent on the participation and support of the entire local community. The community maintained an integral role and was consulted extensively in the planning, preparation and implementation of the eradication programme. As such, it is vital that techniques and protocols developed during eradications on islands with even small communities should be assessed, utilised or adapted for islands with larger communities. The opinions and safety of local communities need to be a priority in any eradication planned for inhabited islands.

Stock and chicken feed provided a possible alternative food source for rats, but all the farmers were fully supportive of the project and stored all the unopened feed on pallets (with bait stations and/or traps underneath) or in rodent-proof containers and any opened feed was stored in large plastic, metal or wooden sealed bins. Where possible, farm buildings were kept clean to ensure fresh sign was quickly noted. All these methods meant that the sheds were cleared of rats and any roaming rats which re-invaded the area could be noted quickly. The presence of a large chicken farm could have been a major problem as their runs provide excellent rat habitat and alternative food. The owner of the chicken farm strictly managed his chickens and feeding regime throughout the rat eradication operation which made targeting rats and monitoring for any survivors on this farm easier.

Rubbish can be the most serious issue on an inhabited island wanting to eradicate rats. This was discussed comprehensively with the community before the project commenced. As a result, rat-proof wheelie bins and Green Johanna compost bins were provided to the residents and all rubbish was stored in these prior to removal to St Mary's. Rubbish was removed regularly (generally weekly) from St Agnes to St Mary's by the Isles of Scilly Council. In October and early November 2013, with the permission and assistance of residents, a number of sheds, farm buildings and outhouses were cleared and tidied by the IOSSRP team to ensure bait stations could be placed along all the walls.

St Agnes and Gugh were cleared of rats within three weeks (23 days from original baiting). Bait-take showed that the rat population appeared to be low (approximately 2,000 rats) and was not evenly distributed across the islands. There were high concentrations of rats on Gugh and around the coastal areas on St Agnes where the burrow-nesting seabird colonies are present, meaning rats were likely to have been having an effect on these breeding seabirds (Moors & Atkinson, 1984; Atkinson, 1985; Jones, et al., 2008).

The interference by cattle was another major factor affecting the operation, with cattle kicking up or crushing stations, but cooperation by the farmers to move stock around different paddocks, as well as altering the bait station positions, wiring the bait or lids into position in addition to the crow clip or weighting the stations down with rocks, meant this problem was quickly dealt with. Many of the monitoring stations were removed from, and then replaced back into, certain areas (such as Covean and Wingletang) as the cattle were rotated between paddocks.

Importantly, there were no known non-target species affected by this operation. Although a small number of Scilly shrews (n = 9) were found dead and necropsied during the eradication, proof of poisoning could not be confirmed (i.e. no symptoms of anticoagulant poisoning such as blood in body cavity, bruising or discolouration of organs). However, no liver or tissue samples were taken from non-target species for further analysis. It should be noted that, in certain cases, bait-take by shrews subsequently stopped in nearby stations suggesting these animals had died due to primary poisoning. Although there is no information on the LD50 for shrews, using LD50 data from other small mammals (voles and mice), it is likely that shrews would have to eat between 0.2–1.25 mg/kg to be affected by bromadiolone. This amounts to 0.001 blocks of bait and this level of bait take by shrews occurred at 83 different stations between 22 November 2013 and 5 March 2014 suggesting that approximately 83 shrews may have been affected by the baiting phase (totalling to 0.4 kg of bait). However, it is thought that as Scilly shrews have small home ranges (< 50 m^2; Spencer-Booth, 1963; Rood, 1965), excluding those with a bait station in their immediate home range, most shrews would not encounter bait stations or poisoned invertebrates using the 40 m × 50 m grid. This means that even if a small number of individuals was killed, the overall population would survive. The risk to the shrew population was considered minimal, but the potential for a small number of individuals to be affected was acknowledged (Bell, 2011). Calculations of bait-take indicate that more shrews than anticipated may have been at risk, but extensive searches for carcasses and the necropsies performed do not support this; there was no definitive evidence of any shrew death being attributable to the rodenticide. Scilly shrew numbers have increased to population levels higher than those before the eradication (IOSSRP, unpublished data).

A large quantity of bait was consumed or damaged by slugs and other insects. Bait was changed often to ensure there was always the most attractive and palatable bait available to rats. Contrac™ was more durable than expected, compared to earlier experience on Lundy Island where it deteriorated within one to two days (Bell, 2004), meaning it lasted better in the St Agnes and Gugh environment. Occasionally it was difficult to interpret sign on the blocks during the important monitoring phase of the operation, owing to the nature of the block and ridges, but the Contrac™ bait successfully targeted all rats on St Agnes and Gugh within three weeks.

There was no evidence that any other non-target species were affected by the rodenticide, traps or monitoring tools used in the operation. Following necropsy of shrews and other non-target species carcasses (water rail, thrush and blackbird), there was no bait found in the stomach or symptoms of anticoagulant poisoning (i.e. blood in the body cavity, bruising or haemorrhaging or discoloured organs). Although 19 dead rats were found on the surface (1.1% of estimated rat population on St Agnes and Gugh), there was no evidence of any other animal scavenging these carcasses. There were no observations of pet cats, crows, gulls or raptors eating dead or dying rats on St Agnes and Gugh.

Weather also affected the eradication when storms removed or dislodged stations, but this generally was limited to coastal areas.

The eradication of invasive species such as rats from islands has become one of the most important tools in avian conservation worldwide. It was recognised that for the restoration and protection of seabird colonies on St Agnes and Gugh, the eradication of rats was required. This operation has already benefited key seabird species on the islands as well as the Scilly shrew as shown by comparisons between the pre- and post-eradication biodiversity monitoring. Manx shearwaters were recorded successfully breeding within one year of the eradication and 73 pairs were recorded in 2016 compared to 22 pairs and no fledged chicks in 2013 (Pearson, 2016). European storm petrels were first recorded on St Agnes in 2015, with 9 pairs in 2016, and the Scilly shrew population has increased to levels higher than the pre-eradication levels since rats have been eradicated (IOSSRP, unpublished data; Pearson, 2016; Thomas, et al., 2017).

Although eradicating rats from St Agnes and Gugh is a considerable and significant achievement, it is important to stress that keeping these islands rat-free will require constant vigilance and commitment from the whole community, partner agencies and visitors in order to prevent, detect and respond to any incursions. Prevention of an accidental rat re-introduction should be the primary aim. The greatest risk is via service and private vessels traveling between all of the inhabited islands in the Isles of Scilly, especially if delivering farming equipment, hay, stock feed, equipment or food to St Agnes. There is also a small risk from visiting yachts and general tourism. Permanent biosecurity stations have been established on St Agnes and Gugh; these will be maintained indefinitely by trained community members and IOSSRP personnel. A detailed biosecurity plan has been developed to prevent, detect and respond to possible incursions. Residents have been trained in these biosecurity measures, identification of rodents and rodent sign, and methods to reduce the risk of accidentally introducing rodents, demonstrating the commitment of the St Agnes and Gugh community to the restoration of their islands.

It is important to stress that the eradication of brown rats from St Agnes and Gugh is a valuable education tool to show other island communities that it is possible to safely eradicate rats without unduly impacting on the lives and habits of the local residents. The successful eradication of brown rats from St Agnes and Gugh demonstrates how the techniques of ground-based bait station operations can be utilised on inhabited islands throughout the UK and the world where this technique is feasible and where the community is involved and supportive.

ACKNOWLEDGEMENTS

This project was carried out with funding from EU LIFE (Scilly Isles LIFE Project 11 UK NAT 387), UK's Heritage Lottery Fund (HG-11-06880) and the Defra-funded Isles of Scilly Area of Outstanding Natural Beauty (AONB) Partnership Sustainable Development Fund. The Contrac™ bait, T-Rex™ and Protecta™ bait stations were generously donated by Bell Laboratories. The Roban Excel™ and Vertox Oktablok II™ bait were donated by PelGar International Ltd. Our heartfelt thanks go to the entire St Agnes and Gugh community for their support and enthusiasm throughout the project, supplying goods and services to the team, providing rat sightings, and for their willingness to implement new waste management and ongoing biosecurity procedures. We would also like to thank Sophie Thomas (RSPB), David Appleton (Natural England), Michelle Hawkins (Natural England), Peter Exley (RSPB), Tony Whitehead (RSPB), Trevor Kirk (AONB), Rebecca Steggles (AONB), Dave Mawer (IOSWT), Darren Hart (IOSWT), Dr. Alan Buckle (Reading University), Dr. Colin Prescott (Reading University) and David Rymer (Reading University). St Agnes Boating, The Isles of Scilly Steamship Company, St Mary's Boating Association, Bryher Boats and St Martin's Boating Association all provided boat transport. Samantha Sadighi, Great Green Systems Limited, supplied the compost bins for the St Agnes & Gugh community at a discounted rate. Special thanks to all the IOSSRP Seabird Taskforce Volunteers – Helen Brandes, Haydn Brooks, Alex Cropper, Bob Dawson, Lindsey Death, Neil Duffield, Paul Garner-Richards, Richard Halstead, Sarah Havery, Vickie Heaney, Jack Ibbotson, Cal James, Helene Jessop, Darren Mason, Tegan Newman, Will (Billy) Renny, Jack Roper, Rebecca Steggles, Colin Taylor, Toby, Rachel and Otto Taylor, Karen Varnham, Alastair Wilson, Will Whittington and Lewis Yates for their hard work, enthusiasm and support throughout the project. Extra thanks to Jenny Parker (RSPB) and David Flumm (RSPB) and their team of mainland-based volunteers who made the 1,500 bait stations.

Rat eradication in the Pitcairn Islands, South Pacific: a 25-year perspective

M.de L. Brooke

Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, UK. <m.brooke@zoo.cam.ac.uk>.

Abstract This essay offers a 25-year overview of efforts to remove Pacific rats (*Rattus exulans*) from the four islands of the Pitcairn group. Following the 1991–1992 discovery that rats were severely reducing breeding success of gadfly petrels (*Pterodroma* spp.), Wildlife Management International proposed eradication. Eradication success was achieved using ground-based baiting on the small atolls of Ducie and Oeno in 1997, and there is now evidence of petrel recovery on Oeno, but two eradication attempts on inhabited Pitcairn (1997 and 1998) failed. By the early 2000s, the development of aerial baiting through the 1990s placed an eradication operation on the fourth island, Henderson, within reach. Preparatory fieldwork in 2009 allayed doubts in two key areas: the feasibility of maintaining a captive "back-stop" Henderson rail (*Porzana atra*) population, and bait uptake by crabs (*Coenobita* spp.). Royal Society for the Protection of Birds (RSPB) expertise secured the necessary funding of £1.5 million, and 75 tonnes of brodifacoum-containing bait were dropped in August 2011. Despite extensive mortality of free-living rails, the population, supplemented by released captive birds, returned to pre-operational levels in 2–3 years. Meanwhile those tending captive rails saw no rat sign before leaving Henderson in November 2011. Unfortunately, a rat was sighted in March 2012, and continuing rat presence confirmed in May 2012. Subsequently rat numbers have returned to pre-operational levels without any sign of population 'overshoot' as observed on Pitcairn. Genetic analysis suggests around 80 rats, roughly 1 in 1,000, survived the bait drop. With no evidence of imperfect bait coverage or deficiencies in bait quality or brodifacoum resistance, it seems some animals chose not to eat bait. Choice tests on Henderson Island rats suggest some rats prefer natural foods over bait. This adverse situation may have been exacerbated because, in August 2011, natural fruits were more abundant than anticipated due to drought earlier in the year. To overcome rat preference for natural food, any second Henderson attempt might benefit from more attractive bait. Without such developments, a second attempt risks another failure. Henderson's biota will survive the delay.

Keywords: brodifacoum, Ducie, Henderson, Henderson rail, Oeno, *Pterodroma*

INTRODUCTION

The Sir Peter Scott Commemorative Expedition to the Pitcairn Islands of 1991–1992 involved 35 personnel in the field over a span of 15 months. While short periods were spent on the sole inhabited island of Pitcairn (500 ha) and the low atolls of Oeno (c. 60 ha) and Ducie (c. 75 ha), Henderson Island (4300 ha) was the principal study site. Since Henderson had been designated a World Heritage Site in 1988 "as one of the last near-pristine limestone islands of significant size in the world" (<http://whc.unesco.org/en/list/487>), it had been appreciated that the natural history of the island was incompletely documented. The expedition aimed to rectify this omission, bringing together expertise in archaeology, geology and many branches of natural history.

One of the Expedition's unexpected findings was the very low breeding success of gadfly petrels (*Pterodroma* spp.) on Henderson: ca. 5% among Murphy's petrels (*P. ultima*), 10% in Kermadec petrels (*P. neglecta*), and 15–20% in Herald (*P. heraldica*) and Henderson petrels (*P. atrata*) (Brooke, 1995). This was especially concerning in the case of Henderson Petrels, split from Herald Petrels as a result of expedition work (Brooke & Rowe, 1996), endemic to Henderson and therefore without any source of immigrants to rescue the situation, and potentially on a downward trajectory to extinction within a few centuries (Brooke, et al., 2010a).

Field observations showed that the cause of this low breeding success was predation by Pacific rats (*Rattus exulans*), introduced to the island by Polynesians settlers about 700–800 years ago (Weisler, 1994). Hatching success was apparently not substantially reduced by rats. Rather, the problem arose in the first week after hatching, especially when the chick moved from under to beside the parent. Then the rats approached, pulled the chick away from the nest site, even in the presence of a brooding parent, and ate it (Brooke, 1995).

Observations on the atolls of Oeno and Ducie were too intermittent to establish whether rats there had a similar impact on the breeding success of petrels. However, the fact that petrel densities were 1–2 orders of magnitude higher on Oeno and Ducie than on Henderson prior to the eradications on the atolls suggested that rat impact was less, if not negligible. Probably because of the presence of rats and feral cats (*Felis catus)*, petrels do not breed on Pitcairn.

After these findings had entered the public domain via the expedition report (Pitcairn Islands Scientific Expedition, 1992) and a special volume of the Biological Journal of the Linnean Society (Benton & Spencer, 1995), the late Brian Bell of Wildlife Management International contacted the author to propose rat eradication in the Pitcairn Islands (Bell & Bell, 1998). At this time, the mid-1990s, an eradication on Henderson was not feasible using ground-based methods. Therefore, the proposal was for eradications on Oeno and Ducie using tested ground-based methods to benefit three gadfly petrel species but, crucially, not the Henderson Petrel which was not confirmed as a nesting species on either atoll.

ACTIONS

Oeno and Ducie

The modest extent and flat accessible topography of the atolls meant that the proposed eradication campaigns were likely to be successful, given prior achievements elsewhere (Towns & Broome, 2003). The eventual source of funding was the UK's Department for International Development (DfID) whose interest lay principally in Pitcairn Island and its people. For this reason, the programme linked eradications on Oeno and Ducie, offering clear biodiversity gains with limited risk of failure, to an eradication attempt on Pitcairn where the risks of failure were higher

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 95–99. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

because of the rugged and heavily vegetated topography and the complications associated with human presence. Nonetheless the project proceeded in late 1997 with approximately £100,000 of funding for Pitcairn and Oeno from DfID and a further £20,000 for Ducie from the World Wide Fund for Nature (Bell & Bell, 1998).

Success was duly achieved on Oeno and Ducie by hand-laying of bait (baiting rate unspecified) on a 25 m grid (Bell & Bell, 1998). The Oeno eradication has been followed by growth of the population of the seabird species most easily censused, Murphy's petrel, at an annual rate of 6% (Brooke, et al., 2017). There are no post-eradication census data from Ducie.

Pitcairn

Eradication was not achieved on Pitcairn in 1997. There, preceding bait laying, the endeavour of cutting a 25 m grid of paths through the dense scrub cloaking the island's extremely severe terrain taxed the endurance of the WMIL team, especially since, in the absence of prior reconnaissance, the severity of the task ahead had not been appreciated. Coverage of the cliffs was probably incomplete. A lesson was learnt: future operations of this magnitude must involve prior on-site reconnaissance by key personnel.

The WMIL team departed shortly after the completion of bait laying (overall baiting rate not specified), entrusting the task of follow-up monitoring to the Pitcairn Islanders (Bell & Bell, 1998). Given the many calls on the islanders' time, and their lack of appropriate expertise, this strategy was probably a mistake. With the benefit of hindsight, it would have been better if extra costs had been incurred and logistical difficulties overcome to allow some dedicated team members to remain on Pitcairn to detect any residual rat presence. While this change in protocol would not have guaranteed a successful outcome, it could only have increased the probability of success.

WMIL returned in 1998 to attempt to rectify the 1997 eradication failure. Unfortunately, the outcome reprised that of 1997 despite more intensive monitoring after the initial baiting, coupled with spot-laying of bait wherever rat sign was detected (Bell, 1998).

A striking feature of these failures was not simply the rapidity with which rats recovered to their pre-bait levels which, the reports of Pitcairners suggested, happened within 18–24 months. There was also a universal impression among the islanders and indeed myself on a visit in 2000 that numbers overshot the status quo ante, to a startling extent. For example, rats were frequently encountered in homes, even in cooking ovens left ajar. A possible explanation of this 'overshoot', that cannot be confirmed by any formal existing trapping or density data, is that, after the reduction in rat numbers due to baiting, a large amount of food accumulated, for example on or below Pitcairn's abundant fruit trees. This surfeit possibly nourished the extreme increase in rat numbers.

Henderson

Following the successful eradication of rats from several large New Zealand islands using aerial baiting techniques during the 1990s (Towns & Broome, 2003) and from 113 km^2 Campbell Island in 2001 (McClelland & Tyree, 2002), the possibility of an eradication project on Henderson Island using aerial baiting moved up the agenda. A feasibility report delivered a favourable verdict, subject to two caveats (Brooke & Towns, 2008). The first was that, in the areas of high land crab (*Coenobita* spp.) density behind Henderson's beaches, it should be demonstrated that sufficient bait could be scattered so that, even after substantial bait removal by crabs, enough bait remained to permit all rats to consume a fatal quantity. The second concerned the endemic flightless Henderson rail (*Porzana atra*). Given the recorded susceptibility of rails to brodifacoum in cereal bait (Eason, et al., 2002) – as would be used in a Henderson operation – there was a need to demonstrate that Henderson rails could be caught and then kept healthy in captivity. In the worst-case scenario, the elimination of the wild population during the eradication operation, the captives, once released after the disappearance of bait, would become the founders of the new wild population.

Both these issues were successfully addressed by a field expedition in August/September 2009 (Brooke, et al., 2010b; Cuthbert, et al., 2012), paving the way for an eradication operation in 2011. The feasibility report (Brooke & Towns 2008) suggested the late winter months of September/October as the period of lowest food availability and therefore the most suitable for bait-laying. This suggestion was based on a 1-year study of plant phenology (Brooke, et al., 1996), and drew on the fact that *Rattus exulans* includes a proportion of vegetable material in its diet. In the absence of any data whatsoever on the intra-annual variation in the availability of invertebrates and their contribution to the rats' diet, this potential factor

Table 1 Summary table of rat eradication operations on the four Pitcairn Islands. Details from Bell & Bell (1998), Bell (1998), Torr & Brown (2012) and E. Bell (pers. comm.).

Island	Type	Method	Year baited	Month(s) baited	Bait type	No. baitings	Successful?
Pitcairn	Volcanic	Hand broadcast	1997	June – August	Pestoff 20R; wax-covered chocolate bait for 3rd baiting	3	No
Pitcairn	Volcanic	First two: hand broadcast. Then bait stations and spot-laying	1998	April – July	Pestoff 20R. Later baitings supplemented by wax-covered chocolate bait	3+	No
Oeno	Atoll	Hand broadcast	1997	July – August	Pestoff 20R	2	Yes
Ducie	Atoll	Hand broadcast	1997	November	Pestoff 20R	2	Yes
Henderson	Makatea	Aerial	2011	August	Pestoff 20R	2	No

could not be addressed in project planning. In the event, late August 2011 became the provisional project date. Fund-raising for the £1.5 million budget proceeded apace under the aegis of the Royal Society for the Protection of Birds (RSPB).

The operation was logistically complex involving the 298-tonne Alaskan crab-fishing vessel, the *Aquila*, sailing from the United States. Carrying two helicopters, the *Aquila* undertook other rat eradications in the central Pacific (Palmyra Atoll followed by Enderbury and Birnie in the Phoenix Islands) before loading the 76 tonnes of bait required for Henderson in Samoa. She then sailed east to Henderson.

Meanwhile the rail-catching team were landed on the island on 8 July 2011. The team immediately noticed that fruit was more abundant than expected – of which more anon. Catching of rails proceeded satisfactorily but adapting birds to captivity proved more problematical than in 2009, and 22 died before the solution was found, enticing the birds to the food bowls with live bait such as immobilised moths (Oppel, et al., 2016). In retrospect, it appears that, by chance, the smaller 2009 batch of rails (26 caught: two died) simply included few birds reluctant to adapt to captivity (Brooke, et al., 2010b; Brooke, et al., 2012).

The losses meant that the number of captive rails, 75, at the time of the *Aquila*'s arrival on 14 August, was lower than the target of 100 birds, but not so much lower as to cause a postponement or cancellation of baiting. The details of bait spreading are covered in the report of the project leaders (Torr & Brown, 2012). Overall the process went remarkably smoothly, with bait buckets filled on board the *Aquila*, obviating the need for any onshore storage of bait. GPS mapping of the island, prior to the first bait drop, revealed the area to be 43 km^2, an enlargement over the 37 km^2 that had been the basis for planning. Fortunately there was sufficient contingency bait that this unexpected expansion necessitated no adjustment of planned bait densities.

Excluding enhanced bait application in the areas of high crab density (Cuthbert, et al., 2012) and in the coconut groves, the application rate was 10 kg/ha of pellets (brodifacoum concentration of 20 ppm) over the majority of the island for the first drop carried out between 15 and 17 August, and 6 kg/ha during the second bait drop on 21 and 22 August. The 5-day interval between drops was slightly less than originally planned because settled weather prompted a decision to proceed immediately, rather than delay until the planned interval of seven days (Torr & Brown, 2012).

The immediate impact of the bait drop on the wild free-living rails was dramatic – as it was on rats. Sixteen of 16 rails that were radio-tagged, and whose fate could therefore be determined with certainty, died. However, mortality island-wide was not total. The best estimate is that 93 percent of free-living rails died, leaving c. 500 survivors (Oppel, et al., 2016). A few weeks after the drop, these birds began breeding. Their numbers were supplemented in October and November by the release of the captive birds, and the population has since completely recovered (Oppel, et al., 2016). Although, in the event, the captive birds were not essential for the species' persistence, the outcome was in doubt in the anxious days after the bait drops, and there is no question that a similar captive rail population must be established, should there be another eradication attempt in the future. This recommendation only gains force if, for example, the bait drops occur over a longer time period, or there are three drops instead of two. No other bird species is known to have been adversely affected by the bait drops on Henderson.

At the time the team caring for the captive rails left Henderson in November, three months after the bait drop, no signs of surviving rats had been noticed. Disastrously, a surviving rat was seen and captured on video by a visitor in March 2012. A follow-up visit, in May, confirmed continuing rat presence and, as expected, rat numbers had returned to 'normal' about two years later with no sign of the overshoot noted on Pitcairn (Bond, et al., 2019).

The eradication failure immediately prompted a review of the operation and a search for possible operational errors. None has been discovered (Internal RSPB documents). There were no apparent gaps in bait coverage, and none of the batches of bait, deliberately retained for post-operational testing, was shown to have incorrect toxin loading. Such post-hoc testing cannot absolutely exclude the remote possibility that some bags of bait did not have toxic baits, a factory error. Finally, fieldwork on Henderson in 2013 tested the rats, presumably animals descended by several generations from the actual survivors, for resistance to brodifacoum. No such resistance was found (Churchyard, et al., 2015).

Genetic studies after failure excluded the possibility that Pitcairn or other islands elsewhere in the Pacific had been a source of rats that had somehow reached Henderson and re-populated the island. In any case, knowledge of boat traffic made this scenario extremely unlikely. Thus, there had been a failure of eradication and not a re-introduction. Because rat samples had been secured before the operation, and were then obtained afterwards, it was possible to use the change in microsatellite allele frequency to estimate how many rats survived (Amos, et al., 2016). The answer was about 80 individuals, very roughly one in a thousand of the rats present on Henderson before the operation (Brooke, et al., 2010b). It is a total compatible with the absence of observations of living rats for around seven months after the bait drops.

Can this total, neither indicating a tiny number of survivors that might be ascribed to chance nor several hundreds, even thousands, indicating serious deficiencies in operational protocol, suggest improvements that might be made for a second attempt?

Mention has already been made of the fact that the rail team encountered more fruit than expected on Henderson in July 2011. This was probably a delayed consequence of a drought that afflicted Pitcairn, and presumably also Henderson, from November 2010 to March 2011. When this drought broke, it is likely that the trees became greener, flowered and then fruited, at a time that was inopportune for the rat eradication, especially if flowering and fruiting were accompanied by increased numbers of invertebrates. Although there has been one year-long study of the leafing, flowering and fruiting phenology of Henderson's plants (Brooke, et al., 1996), this is clearly inadequate to understand how plant phenological schedules may change from year to year, and how they are altered by annual variations in weather. That would require around 20 years of study, an impossible task on isolated Henderson. Thus, tailoring a rat eradication to a particular window of plant food scarcity will always be difficult, if not impossible. And no subsequent findings have altered the cautious recommendations of the feasibility study (Brooke & Towns, 2008), derived from the Brooke, et al. (1996) plant phenology study, that September or a month either side is the most suitable period.

Compounding this problem is that the operation must be set in train – boats chartered, bait ordered and so forth – at least six months before baiting (Parkes & Fisher, 2017). It would, in theory, be possible to cancel an operation at a late stage, for instance if there were reports of a surge in fruit abundance, but the penalties for such a late cancellation could well approach £500,000.

Following their helicopter flights across the island in 2011, the pilots reported, to universal surprise, a few tens of coconut trees (*Cocos nucifera*) emerging from the canopy growing on the raised atoll lagoon. Since the ground is about 30 m above sea level, these trees must have involved human intervention. They were certainly not planted by members of the Sir Peter Scott Commemorative Expedition of 1991–1992. There are two other known possibilities. The first is that the Pitcairners who, during World War II, cut a network of paths across the island, some several kilometres from the coast, were responsible. Another possibility is that the helicopter presence associated with the visit of the USS Sunnyvale in 1966 provided an opportunity for coconuts to be 'bombed' from overhead.

However the coconuts arrived, it is not surprising that they have been growing unknown for decades since most parts of this impenetrable island have remained unvisited for centuries. The relevance of these observations is that the research visit of 2013 (Churchyard, et al., 2015) conducted captive trials to test which natural foods, if any, were preferred by rats to bait pellets. Given a four-way choice between coconut (removed from its shell), *Myrsine* fruits, *Pandanus* nuts and Pestoff bait pellets, coconut was preferred, with pellets second. Moreover 11 of 30 rats ate no pellets whatsoever in a 3-day trial (details in Churchyard, et al., 2015). These findings were confirmed by further similar research in 2015 that also indicated the preference for natural food could not be overcome by increasing the relative abundance of bait pellets, an experimental adjustment equivalent to increasing the bait application rate during helicopter operations (Lavers, et al., 2016).

Although the coconut groves behind the North and North-West Beaches received deliberately high applications of bait pellets (Torr & Brown, 2012), this was not the case for the unknown isolated trees in mid-island. However, there are no data bearing on where on the island the 80 surviving rats lived and whether their home ranges were in the vicinity of coconuts.

It is evident that an absence of coconuts is not a sine qua non of a successful rat eradication. Success was achieved on Oeno (coconuts present) and Ducie (no coconuts). Projects failed on Henderson and Pitcairn, both with coconuts. More generally, numerous islands with coconuts have been cleared of rats, including the island of Palmyra (</www.fws.gov/refuges/news/PalmyraAtollRatFree.html>) visited by the *Aquila* two months before it reached Henderson.

Although Henderson's coconuts could have contributed to the project's failure (Holmes, et al., 2015), removing this possible cause would not be easy. Reaching every mid-island coconut would require a helicopter to insert a small group of "coconut destroyers" close to each tree, perhaps via a winch. Their task would be to destroy all the nuts and possibly the tree as well. That would still leave the coastal coconuts. It is unlikely that their total destruction would be countenanced by the Pitcairn Islanders and, in any case, their flowers are a significant food of the endemic Stephen's lorikeet (*Vini stepheni*) (Trevelyan, 1995). Even destroying or removing off-island all the fallen nuts, weighing several tens of tonnes, would not be easy. But the practicalities should be explored.

The discussion has reached the stage where the 2011 eradication appears to have failed, not because of any operational blemishes and not because of any brodifacoum-resistance but because a small number of rats failed to consume a fatal dose, approximately one pellet, of bait. Instead they chose to eat natural food in preference to bait (Keitt, et al., 2015). This picture is entirely compatible with the more general observation that tropical rodent eradications are less likely to be successful than those on temperate islands (Russell & Holmes, 2015)

If a second eradication attempt is to have an improved chance of success, some aspects of the protocol may have to change. The impracticalities of guaranteeing that a bait drop occurs at a time of minimal food abundance have already been discussed. The challenge of reducing the availability of coconuts needs further thought. Finally, I strongly advocate consideration of a further option, the development of a more attractive bait formulation that will entice even those rats that might have shunned the pellets used in 2011 to eat bait. It will probably never be known whether these crucial rats did not eat bait pellets because a more palatable natural food was available, and/or whether illness or pregnancy affected their appetite for novel foods (neophobia). Altering the formulation of bait pellets by the addition of such flavours as chocolate or peanut has already been trialled by Orillion, the manufacturers of PestOff pellets (Bill Simmons, pers. comm.). However, it remains uncertain whether these changes would demonstrably reduce the risk to an operation of such rat behaviours as neophobia.

Although modest alteration of pellets may not engender regulatory problems in UK Overseas Territories (Bill Simmons, pers. comm.), the development of pellets of enhanced attractiveness could pose technical problems. For example, any additives must not make the pellets more 'sticky' and liable to clog the hoppers underslung from bait-distributing helicopters. But, optimistically, such developments will occur as New Zealand develops the expertise to rid itself of alien predators by 2050, as other countries follow New Zealand's lead, and as the relative intractability of tropical islands is addressed.

Meanwhile, from my 25-year perspective, Henderson will probably not change greatly in the next decade. A patient approach will hugely increase the likelihood that any second rat eradication attempt on Henderson is made when the chances of success are demonstrably higher. It will also avoid the mistake made on Pitcairn, of undertaking an eradication project because money was available rather than because a rational, even hard-nosed, assessment confirmed that the chances of success and the biodiversity gains of success outweighed the costs and risks of failure.

ACKNOWLEDGEMENTS

This personal account arises from eight separate visits to the Pitcairn Islands, hugely facilitated by the Sir Peter Scott Commemorative Expedition, the Foreign & Commonwealth Office, the Royal Society for the Protection of Birds, and the Pitcairn Islanders. Thanks to referees for many helpful comments. Opinions expressed are my own.

House mice on islands: management and lessons from New Zealand

K. Broome[1], D. Brown[2], K. Brown[1], E. Murphy[1], C. Birmingham[1], C. Golding[1], P. Corson[1], A. Cox[3] and R. Griffiths[4]

[1]Department of Conservation, P.O. Box 10-420 Wellington New Zealand. <kbroome@doc.govt.nz>. [2]Picton, New Zealand. [3]Ashburton, New Zealand. [4]Island Conservation, Auckland, New Zealand.

Abstract The impacts of house mice (*Mus musculus*), one of four invasive rodent species in New Zealand, are only clearly revealed on islands and fenced sanctuaries without rats and other invasive predators which suppress mouse populations, influence their behaviour, and confound their impacts. When the sole invasive mammal on islands, mice can reach high densities and influence ecosystems in similar ways to rats. Eradicating mice from islands is not as difficult as previously thought, if best practice techniques developed and refined in New Zealand are applied in association with diligent planning and implementation. Adopting this best practice approach has resulted in successful eradication of mice from several islands in New Zealand and elsewhere including some of the largest ever targeted for mice; in multi-species eradications; and where mouse populations were still expanding after recent invasion. Prevention of mice reaching rodent-free islands remains an ongoing challenge as they are inveterate stowaways, potentially better swimmers than currently thought, and prolific breeders in predator-free habitat. However, emergent mouse populations can be detected with conventional surveillance tools and eradicated before becoming fully established if decisive action is taken early enough. The invasion and eventual eradication of mice on Maud Island provides a case study to illustrate New Zealand-based lessons around mouse biosecurity and eradication.

Keywords: biosecurity, eradication, impacts, invasive rodents, Maud Island

INTRODUCTION

The house mouse (*Mus musculus*) established in New Zealand (NZ) around 1830, about 550 years after the first rodent to arrive, the Pacific rat or 'kiore' (*Rattus exulans*), 60 years after Norway rats (*R. norvegicus*) and 30 years before ship rats (*R. rattus*) (Atkinson, 1973). Mice in New Zealand have traces of ancestry from three subspecies – *Mus musculus domesticus*, *M. m. castaneus* and *M. m. musculus* – however *M. m. domesticus* is the dominant subspecies (King, et al., 2016; Veale, et al., 2018). The hybridisation of subspecies could have occurred before or after the mice arrived in NZ (Veale, et al., 2018).

Today mice are widespread and common throughout NZ but not as common as ship rats. Mice increase in numbers quickly in response to pulses of food and reductions in ship rat abundance (Elliott & Kemp, 2016).

Rodent colonisations of smaller islands in the NZ archipelago have different histories influenced by past human visitation and proximity to the largest islands 'North' and 'South' considered 'mainland' by New Zealanders. Of the 1065 islands >1 ha (excluding the mainland), mice established on about 42 of them (Ruscoe & Murphy 2005; Department of Conservation (DOC), unpublished data).

Action against mice for biodiversity protection goals began with efforts by NZ Wildlife Service with rodent-proof packaging of stores destined for rodent-free islands. The first eradication of mice in NZ occurred in 1984 on 2 ha Whenuakura Island, although the project targeted Norway rats, not mice (Veitch & Bell 1990).

In 1989 the first deliberate attempts to eradicate mice from islands occurred on Mana 217 ha (Hook & Todd, 1992), Rimariki 22 ha (Veitch & Bell, 1990), and Allports 16 ha, (Brown, 1993). We can identify 36 attempts to remove mice from NZ islands larger than 1 ha, 28 of them succeeded and eight failed (Appendix 1). Mice have reinvaded seven of the 28 from which they were eradicated. Some of the eradication failures could possibly be attributed to reinvasion. These figures update NZ data presented by MacKay, et al., (2007) and Howald, et al. (2007) who included eradication attempts worldwide where the eradication of mice was not always a stated goal and where the presence of mice on the island prior to eradication remained unproven.

In this paper, we explore three questions related to the management of mice on islands for biodiversity protection:

1. What do we know about the impacts of mice on NZ island ecosystems?
2. What have we learnt about eradicating mice from islands and what do we now consider best practice in NZ?
3. What have we learnt about preventing mice from establishing new populations on NZ islands?

We use the invasion of Maud Island by mice in 2013 and their successful eradication in 2014 as a case study to illustrate our lessons.

IMPACTS OF MICE

Mice often inhabit islands with other invasive species which can confound efforts to quantify mice impacts. Predators, particularly rats, can have a marked influence on the behaviour and densities of mice while simultaneously reducing and masking mice impacts (Bridgman, 2012). Removal of mice in these situations often requires simultaneous removal of other invasive mammals, thereby continuing the confusion over how to attribute recovery to the absence of mice and not the other species involved.

On islands where mice are the only invasive mammal present they usually attain higher densities, exhibit different behaviours and therefore have more conspicuous impacts on native biodiversity (Angel, et al., 2009).

Mice as bird predators

Mice eat small bird's eggs. Frogley (2013) filmed them eating quail (*Coturnix japonica*) (30 × 24 mm), zebra finch (*Taeniopygia guttata*) (14 × 9 mm) and canary (*Serinus canaria*) eggs (16 × 11 mm) from unattended used nests placed on the forest floor. Fewer of the quail eggs tested were eaten, suggesting they are near the size limit for mice to break into. Over 400 hours of filming six natural forest bird nests in podocarp-broadleaved forest at Maungatautari resulted in observation of only a single mouse visit (Watts, et al., 2017).

Smaller seabirds such as some storm petrel species appear more vulnerable to egg and sometimes chick predation by mice although some studies suggest this has little effect on productivity (Campos & Granadeiro, 1999). Shore plover (*Thinornis novaeseelandia*) breed very successfully on Waikawa Island with mice at high densities. There is no evidence of egg predation on shore plover (egg size 37 × 26 mm) or white-faced storm petrels (*Pelagodroma marina*) (egg size 36 × 26 mm) on Waikawa Island in the presence of high mouse numbers (H. Jonas & J. Dowding pers. comm.).

The evidence for other impacts on birds in NZ is more circumstantial, for example differences in abundance of snipe (*Coenocorypha aucklandica*) and black-bellied storm petrels (*Fregetta tropica*) on Antipodes Island with mice and rodent-free islands such as Adams and Bollons (Miskelly, et al., 2006; Imber, et al., 2005).

Mice as reptile predators

On Mana Island removal of grazing livestock led to an increased mouse population due to improved habitat from rank grass. The McGregor's skink (*Oligosoma macgregori*) population declined and mice were seen eating skinks in pitfall monitoring traps. Following the eradication of mice in 1989 McGregor's skink numbers increased and they became more conspicuous (Newman, 1994).

Norbury, et al. (2014) followed the fate of translocated Otago skinks (*Oligosoma otagense*) in a fenced site which contained mice as the only mammalian predator. They observed mice attacking 25 cm adult skinks but noted skink survival rates were adequate for population persistence.

Romijn (2013) compared the capture rates of ornate skinks (*Oligosoma ornata*) between sites with and without mice present (without other predators). The site with mice had periodic control of mice to maintain densities below 21 per100 trap-nights. He found population increases at both sites but significantly higher rates in the site with no mice.

Mice were implicated in the suppression of recruitment in a shore skink (*O. smithi*) population at Tawharanui fenced sanctuary (Wedding, 2007).

Mice as invertebrate predators

Invertebrates are an important part of the broad diet of mice (Ruscoe & Murphy, 2005). St Clair (2011) compiled the known impacts of invasive rodents on island invertebrates including a range of NZ species influenced by mice.

Watts, et al. (2017) conducted a large-scale treatment switch experiment at Maungatautari in 2011–2016. Two fenced enclosures in forest had all mammalian pests removed except mice. At one site they eradicated mice and at the other allowed mice to increase. Results suggested mice suppressed beetles, spiders, earthworms and weta in both abundance and size.

Mice impacts on vegetation

Williams, et al. (2000) found mice destroy all seed they eat, rather than acting as seed dispersers. On the New Zealand mainland, seed predation by mice may affect regeneration of kauri (*Agathis australis*) (Badan, 1986), pingao (*Desmoschoenus spiralis*) and sand tussock (*Poa triodioides*) (Miller & Webb, 2001). Mouse predation on mountain beech (*Fuscospora cliffortioides*) and rimu (*Dacrydium cupressinum*) seeds not only reduces rates of seedling establishment, but may also alter the composition of forests over time (Wilson, et al., 2007). Seed predation by mice may also impede ecological restoration efforts, for example inhibiting a tree planting programme on Mana Island (Hook & Todd, 1992).

Watts, et al. (2017) found no significant impact of mice on forest seedling establishment over their five-year study. However, they noted their (predator fenced) mainland study site has been subject to modification by a range of introduced mammals for hundreds of years prior to the beginning of the study.

Other biodiversity impacts by mice

Two studies reported observations of mice eating the eggs of a NZ native fish, inanga (*Galaxias maculatus*) (Baker, 2006; Hickford, et al., 2010).

Besides the direct impacts discussed above, mice also influence other predators who use them as a food source. For example, stoats (*Mustela erminea*) will include mice in their diet. In beech (*Fuscospora* spp.) dominated forest, mast seeding events lead to high populations of mice followed by increased stoat populations with consequent impacts on native species (King & Murphy, 2005).

Mice may also provide an important year-round food resource for larger predators on islands with strongly seasonal primary food resources such as colonial nesting seabirds. They may therefore 'artificially' sustain higher predator populations through the non-seabird nesting periods.

MOUSE ERADICATION

Since 1989 developments in mouse eradication methodologies in New Zealand mirrored those of rat eradications (Towns & Broome, 2003; Broome, 2009; Russell & Broome, 2016). Aerial broadcast baiting was consistently chosen for eradications targeting mice on islands larger than 40ha (Appendix 1).

Mouse susceptibility to brodifacoum is highly variable. For example, Cuthbert, et al. (2011) had two Gough Island mice survive doses of 2.44 and 5.41 mg/kg, respectively. These individuals were subsequently offered more bait in no-choice tests and died after ingesting 12.2 and 7.14 mg/kg. Three (of 10) mice from Lord Howe Island survived doses of 5.2 mg/kg in a no-choice bait test (D. Priddel pers. comm.). A subsequent trial using 30 wild-caught Lord Howe mice allowed to feed *ad libitum* for three days resulted in 100% mortality (A. Walsh pers. comm.).

Mice usually die from about five days following the first application. For example, MacKay, et al. (2007) found no sign of surviving mice on Adele Island eight days after bait application. However, they can survive much longer (see case study) and in one laboratory trial, a warfarin-resistant mouse survived a total of 65 days after first feeding on brodifacoum laced bait (Rowe & Bradfield, 1976).

Bridgman (2012) studied the behaviour of mice in the presence of ship rats. She found ship rats strongly influenced the movements of mice, reducing home ranges and nutrition levels. This has implications for eradication projects targeting both rats and mice, reinforcing the need for comprehensive bait coverage and well-spaced multiple bait applications to allow for the dominant rats to die off and theoretically 'free up' the movement of any mice remaining.

Some projects failed to eradicate mice because they did not explicitly target them. For example, on Mokoia Island in 1989 an eradication project targeting Norway rats using bait stations spaced at 50 × 50 m subsequently found mice on the island (P. Jansen, pers. comm.). Because the eradication was designed around the home range of Norway rats, mice survived and became detectable after the rat population had crashed.

Eradications of mice on islands in NZ progressed through the 1990s with mixed success (MacKay, et al., 2007). The review of mouse eradication projects by MacKay, et al., in 2007 could not find a consistent operational factor contributing to eradication failure but recommended robust planning of future projects to rule out operational errors, thereby providing better insight into the cause of failures.

Following this recommendation, a project to eradicate mice from three islands (Adele, Tonga, Fisherman) in Tasman Bay in 2007 strictly adhered to the current agreed best practice methodology for mouse eradications (Golding, 2010). The Island Eradication Advisory Group (IEAG), a technical advisory group of the NZ Department of Conservation, updates and maintains a document providing technical advice to project managers in the planning, implementation and monitoring of rat eradications on islands (Broome, et al., 2017a).

The IEAG consider best practice for mouse eradications to be similar to that used for rats with the following changes:

Bait applications use 50% overlap on both the first and second application (cf. for rats where 50% overlap is recommended for the first application and 25% for the second) (Fig. 1).

Bucket flow rates remain at or above 4 kg/ha (cf. for rats where bucket flow rates of 3 kg/ha are permissible). With 50% overlaps as in 1 above, this means applying a minimum of 8 kg/ha on the ground in each application.

The interval between applications is extended to a minimum of 14 days (cf. for rats where more flexibility in timing of the second application is permissible).

The IEAG has recently developed a best practice document incorporating these elements with other advice borrowed from the rat best practice (Broome, et al., 2017b). Since the Tasman Bay project, all subsequent mouse eradications following this advice have succeeded. including one of the largest (Macquarie 12,800 ha); multi-species eradications (Macquarie, and Rangitoto/Motutapu 3,809 ha) and a still-establishing mouse population (Maud 309 ha – see case study).

Changes 1 and 2 recognise the smaller territories of mice than rats and strive to ensure all mice encounter bait. Relatively few mouse home range studies have occurred on NZ islands (Ruscoe & Murphy, 2005). MacKay, et al. (2011) measured home ranges varying from 0.15–0.48 ha on Saddle Island. Radio-tracking found animals living in areas with dense shrub and grass cover had smaller ranges and mean nightly movements than those living in areas with tall canopy and minimal ground cover. Elsewhere on the NZ mainland in the absence of other mammalian predators and competitors, Goldwater, et al. (2012) estimated densities of 160 mice/ha in rank kikuyu grass (*Pennisetum clandestinum*) immediately after other mammals were eradicated, but density has since greatly declined.

Eradication designs must cater for not only the smallest home range (rather than the mean) but also the smallest foraging movements by mice over the limited period that bait is available in palatable condition. At 8 kg/ha the 2 g baits used in NZ would in theory be on the ground at 0.4 baits/m^2 providing ample opportunity for mice to encounter baits, especially after a second application.

Keeping bucket flow rates relatively high (possum control operations using the same equipment routinely use rates around 1 kg/ha), reduces the risk of interruptions in bait flow out of the bucket. Such interruptions in flow are potentially fatal to eradication success as they would not be mapped by the helicopter's GPS navigation recording system, and therefore could go unnoticed.

Change 3 acknowledges mice as light and erratic feeders compared to rats (Clapperton, 2006). Extending the period of bait availability, compared to a rat eradication, is desirable to ensure all mice have access to lethal doses before bait is consumed by other fauna or environmentally degraded. Brown (1993) found mice initially reluctant to take bait presented in bait stations on Allports and Motutapu Islands. They often 'sampled' small portions of baits over several nights before full-scale consumption ensued. He described a gradual spread of consumption from a focal point, speculating that social interactions between mice encouraged more to try the new food resource presented.

To counter the risk of mice being present but undetected in the presence of rats, some projects have deliberately designed their baiting strategy to mice eradication standard. For example, the rodent eradication (ship rats and kiore) on Great Mercury Island was designed to mouse eradication best practice standards despite no confirmed evidence of mice. The island operated as a pastoral farm with minimal biosecurity precautions for over 50 years so it was difficult to believe mice had not arrived during this time. The project sponsors found it cost effective risk management to assume mice were present and design the project accordingly (Corson & Hawkins, 2016).

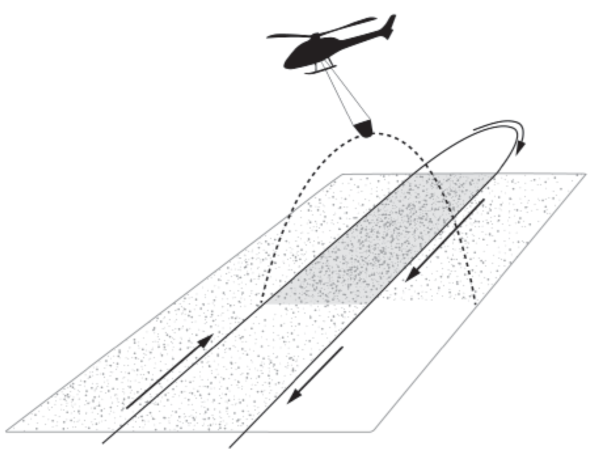

Fig. 1 50% overlap when aerially sowing bait. Arrows indicate centres and direction of two consecutive sowing lines. The dark shaded area shows the area of overlap between the first and the (half-completed) second line.

MOUSE BIOSECURITY

Keeping islands free of mice presents ongoing challenges in quarantine, surveillance and responding to arrivals. Pathways for invasion include cargo and personal luggage landed on the island, vessels and aircraft of all sizes, and swimming or rafting to islands.

Vulnerabilities to these pathways differ between islands but some islands may also be less susceptible to establishment of a mouse population following incursion. For example, Secretary, Kapiti, Stewart, Raoul and Campbell Islands have records of mice arriving, without evidence of meaningful action to respond, and yet failing to subsequently establish populations (DOC unpublished data). At the time all of these large islands had rats or stoats present, potentially providing a form of biological defence against mouse establishment. Weka (*Gallirallus australis*) may also play a role where they occur on islands. For example, on rat-free Tarakaipa Island mice were barely detectable in the presence of weka (DB pers. obs.). Weka held in captivity eagerly attacked mice entering their pen (CG pers. obs.). Conversely, the subsequent eradication of such predators could, in theory, increase the vulnerability of the island to invasion by mice. Further research into this phenomenon is warranted.

The probability of establishment can relate to propagule pressure (Lockwood, et al., 2005). Because rodent populations fluctuate seasonally in NZ with peaks in late summer, the risk of invasion could increase at this time of year. Additionally, mast seeding events in some forests can produce superabundant populations of mice which increase propagule pressure on nearby islands. For example, mice were successfully eradicated from Adele Island in 2007 and a biosecurity system installed. In the 2014/15 summer a significant mast seeding event occurred in the adjacent Abel Tasman National Park where mice became abundant. In February 2015 they were discovered on Adele. Attempts to eliminate them by localised trapping around points of detection failed and a population re-established (CG pers. obs.).

Mice as stowaways

Mice are inveterate stowaways with numerous records of their discovery in cargo destined for islands. The DOC invasion incidents database has 24 records of mice reaching islands amongst cargo between January 2010 and June 2017. Two more were intercepted on vessels en route to pest-free islands. Mice have been discovered in visitor day packs, in kayaks and nesting in under-seat dingy flotation. Container, building and vessel openings must be <6 mm to restrict mouse access. Of equal importance is the vigilance required to ensure doors, lids and hatches remain closed when not in use.

Quarantine measures to prevent mice reaching islands require constant vigilance by people involved. Careful checking of cargo, using rodent-proof containers for transport and control measures on board vessels are key components. These precautions can be enhanced by good rodent management and habitat control at ports and minimising the quantity of equipment transferred to islands (e.g. by having field equipment remain on-island).

Mice swimming to islands

Mice are often thought of as poor swimmers relative to rats (Russell & Clout, 2005). However, Evans, et al. (1978) found mice would readily enter water and swim. A fisherman saw a number of mice 600 m from shore in Lake Monowai while night fishing during the 2009 mouse plague (CG pers. comm..). Fishermen anecdotally report them in trout guts (James & Fox, 2017) and they have been found live in coastal flood debris (DB pers. obs.). The maximum distance over water that mice can cross unassisted remains unknown and therefore the pathway should not be assumed unimportant when considering biosecurity risks for an island.

Pomona and Rona Islands in Lake Manapouri were both assumed a 'safe' distance offshore (500 m and 600 m respectively) but both were reinvaded by mice within a decade of successful eradication, probably by swimming or rafting on flood debris. These re-invasions coincided with beech masting events when mice reached high abundance on the mainland.

Detection methods

We can readily detect mice at low densities, in the absence of other rodent species, using a range of tools including footprint tracking tunnels, chew cards and other bait interference methods, snap traps and trained detection dogs. Nathan, et al. (2013) studied mouse detection on Saddle Island (6 ha) during an experimental invasion event in which a male and a female mouse were released on the rodent-free island. They readily detected mice by both tracking tunnels and wax tags, even during the initial phases of the invasion.

Invading mice can move large distances. For example, pairs of mice sequentially released at opposite ends of Saddle Island (approximately 400 m apart), increased their nightly movements two-fold, and range sizes ten-fold, relative to movements on this island prior to the mouse eradication. This allowed them to rapidly and reliably encounter each member of the opposite sex (MacKay, 2011).

A mouse invading pest-free Moturua Island initially tracked inked footprint tracking cards in October 2011 and was finally trapped in late 2011. On one occasion this animal travelled at least 750 m between tracking tunnels over a 36-hour period (KB unpublished data).

Mice established on islands in relatively high numbers can hinder the detection of newly invading rats by 'swamping' detection tools. For example, they cover ink tracking cards on Waikawa Island within a few nights which can obscure the footprints of an invading rat. Mice usually do not trigger DOC200 stoat and rat traps but steal the bait, rendering the trap less attractive. These mouse-induced limitations delayed the detection of a Norway rat incursion on Waikawa Island in 2012, indicated by a dramatic decline in the critically endangered NZ shore plover. The rat was never caught and only retrospectively identified with the help of a rodent detection dog by the discovery of a nest containing bird remains and Norway rat fur and droppings (EM unpublished data).

Incursion response

Responding to the discovery of invading mice on a pest free island is challenging due to the potential delay between incursion and discovery through periodic surveillance checks. Nathan, et al. (2015) demonstrated the urgency of responding to a mouse invasion by experimentally releasing one male and one female mouse on Saddle Island. They subsequently bred and the mouse population reached the island's carrying capacity within five months. Routine surveillance discovered invading mice on Adele Island in February 2015, potentially months after arrival. Despite intensive trapping around points of detection the incipient population could not be eliminated.

CASE STUDY MAUD ISLAND

Biosecurity

Before 2013 rodents had never established on Maud Island (309 ha) in the Marlborough Sounds. Consequently, it has some highly rodent-vulnerable native species including some not found elsewhere, such as the Maud Island frog (*Leiopelma pakeka*), and others restricted to a handful of nearby pest-free islands.

Keeping pests from reaching Maud has long been a priority. Landing is restricted and DOC staff are present year-round. Stoats are considered the biggest invasive threat because they can swim the 900 m from the mainland and have done so on at least three occasions. Traps targeting stoats and rats are throughout the island and checked regularly. A quarantine store at the mainland DOC ranger station is used to check cargo destined for Maud or other pest free islands. Extra precautions are taken to prevent chytrid fungus – a pathogen implicated in the worldwide decline of frog populations (Berger, et al., 1999) – from reaching Maud.

In 2006, a mouse was killed by the Maud Island resident ranger when turning garden compost. An incursion response using mouse traps and a trained rodent detection dog failed to find further sign of mice after several weeks.

In October 2013, a mouse was captured in visitor accommodation on the island. An incursion response immediately deployed traps, detection devices and a rodent detection dog. Several mice were trapped around the buildings. The dog handler reported mice in several places across the island. Breeding was confirmed from necropsied animals. The youngest mice were in age class 1 (0–1 months in age) and the eldest in age class 6 (8–10 months) suggesting the first invaders arrived about a year previously and they had bred through the winter, which is uncommon in NZ.

DNA analyses found the Maud Island population highly inbred, suggesting the population arose from a single incursion. Although the mice were a genetic subset of the mainland population, their point of origin could not be established (E.M. & R. Fewster, unpublished data).

With an emerging picture of an established mouse population across the island, the incursion response team were forced to admit their efforts had begun too late and a whole island eradication was required.

To understand how mice had reached the island and remained undiscovered for long enough to establish, an independent review of biosecurity procedures was undertaken (Kennedy & Chappell, 2013). This found several weaknesses, including a lack of devices capable of killing or detecting mice on the island or on the ranger's boat, that was pulled onto a slipway on the island when not in use. The focus on stoats and rats allowed mice to go unnoticed. Some staff regularly visiting the island bypassed quarantine standards.

The review could not identify the pathway for the mouse incursion but made many recommendations for improvement which were actioned prior to the eradication. The island's biosecurity plan has recently been re-written to capture these new practices and give more authority to biosecurity rangers to enforce standards.

Eradication

In 2014, mouse eradication best practice was successfully applied to eradicating the newly established population of mice on Maud Island. Challenges included the abundance of natural food available to the expanding mouse population, and the presence of residential buildings requiring careful management of domestic foodstuffs and waste to minimise access to alternative food after toxic baiting.

A helicopter applied 8 kg/ha on 23 July 2014 followed by 8 kg/ha 23 days later (15 August) with strict adherence to the current agreed best practice described above. Two mice were trapped on Maud on 19 August, 27 days after the first bait application. Both had bait in their stomachs. A badly decayed male mouse was taken from a snap trap on 22 September and a female trapped the next day. This sexually mature female showed no signs of past or present breeding and appears to have survived about 60 and 37 days after the first and second bait applications, respectively. An intensive trapping grid (10 m × 10 m) was installed around each capture site covering about one hectare. No further mice were caught.

We estimated the age (from tooth eruption and wear) of the last mouse caught to be five months, meaning it could have lived through all bait applications. Bait was freely available from July to October, so these individuals must have encountered it. Although a range of trap baits were used, the snap traps which caught each mouse were baited with a Pestoff 20R pellet as used for the aerial baiting, indicating no aversion to the bait.

Testing of all four trapped mice revealed brodifacoum liver residues in three of them of 4.65–8.82 mg/kg. Considering liver values probably resulted from higher doses due to losses through excretion and metabolism (Eason & Wickstrom, 2001), these mice probably received many times the published LD50 for mice of 0.52 mg/kg (O'Connor & Booth, 2001). Maggots from the more decomposed male caught 22 September contained 2.35 mg/kg. DNA testing found these mice to be clearly from the original Maud invasion, not a new independent invasion.

Extensive monitoring over the subsequent two years no further survivors but a further incursion in 2018 has once again established a mouse population on the island. Mouse trapping on the island after bait application was intended as indicative monitoring only and had limited coverage of the island. We assume other mice survived in un-trapped areas long after bait application. These animals presumably acquired a lethal dose of brodifacoum and died without reproducing.

The successful eradication of an expanding population of mice from Maud is an indication of high bait acceptance despite other natural food being available in relative abundance. Camera footage from some of the buildings on Maud showed mice taking large quantities of bait placed in trays during the eradication and presumably caching it (CB pers. obs.).

CONCLUSION

Mice remain on many large islands in New Zealand and around the world. The techniques used in NZ to eradicate mice have been successful and could readily be applied to other temperate islands of similar size with a good chance of success. Biosecurity measures to protect islands from mouse invasion are challenging and mice must be considered a real threat to all rodent free islands, regardless of previous invasion history.

Biosecurity lessons:

Quarantine standards must apply to everyone to be effective. The pre-eminence of biosecurity over other duties of island staff and managers needs regular reinforcement to create an organisational culture which can sustain high biosecurity standards over time.

All potential threats and all potential pathways need to be assessed and multiple layers of protection established: i.e. quarantine checking, pest proof containerisation, hygiene of transportation, targeted surveillance, capability and readiness for incursion response.

Independent review of procedures can give valuable insights into opportunities for improvements and should be done proactively and routinely.

The risk of successful mouse invasions may be influenced by island predators (or lack thereof) and mouse abundance at potential source populations.

Eradication lessons:

The current agreed best practice used in NZ has a very good track record of success (>90% in known outcomes) against mice on temperate islands. This is far better than previously published review figures which did not present data on the quality of planning and delivery or discriminate between operations deliberately targeting mice and those targeting other species where mice also occur.

Mice can take a long time to succumb to the cumulative effects of small doses of brodifacoum and some individuals may require significantly higher doses than others. A baiting strategy which prolongs the availability of toxicant to mice has a better chance of success. In NZ this is usually achieved with two well-spaced bait applications but a third application is also an option.

Bait application rates need to allow for other bait consumers when multiple target species are involved and must not fall below the ability of sowing equipment to spread bait 100% reliably.

Where the presence of mice is likely but unproven due to suppression by other species, it is prudent to design the eradication assuming their presence, rather than discover that they have survived a rat eradication and thrived in the absence of rats or other predators.

Eradication is feasible against newly established and expanding populations of invading mice, especially if current agreed best practice is followed.

Simultaneous rat, mouse and rabbit eradication on Bense and Little Bense Islands, Falkland Islands

P.W. Carey

SubAntarctic Foundation for Ecosystems Research, 8 Estuary Road, Christchurch, New Zealand. <peter@subantarctic.com>.

Abstract Bense and Little Bense Islands (144 ha total area) have, for over a century, supported populations of three introduced pest mammals: Norway rat (*Rattus norvegicus*), house mouse (*Mus musculus*), and European rabbit (*Oryctolagus cuniculus*). An operation to eradicate these mammals simultaneously was undertaken in winter 2016. Cereal pellets laced with brodifacoum (25 ppm) were hand-broadcast on both islands in two applications with 3,900 kg of bait applied in total. Baiting transects were spaced at 20 m intervals and bait-throwing positions located every 20 m along each transect. The coastline was also baited at 20 m intervals. Precision bait coverage was aided by programming GPS units to give off an audible alarm when staff reached each correct bait-throwing position. Application 1 resulted in an average bait density of 15.3 kg/ha. Application 2 commenced 10 days later and resulted in an average baiting density of 11.7 kg/ha. Reduced availability of field staff resulted in coverage in Application 2 being less complete than in Application 1 and only the most important mammal habitats were baited a second time. These were: all tussock areas, all coastlines, and some inland heath areas. Areas with no vegetation (e.g. burned zone on Bense) and some inland heath communities were not treated, although all of these retained unconsumed bait from Application 1. Some non-target mortality was recorded, with dolphin gulls (*Larus scoresbii*) being the most common victims. This was also the only species observed to consume bait pellets. Consumption of poisoned mammals or gulls may have killed three turkey vultures (*Cathartes aura jota*), one striated caracara (*Phalcoboenus australis*), and one short-eared owl (*Asio flammeus*). The removal of invasive species is part of a broader ecological restoration plan for these islands and will hopefully lead to an increase in native biodiversity, including the re-establishment of the endemic passerines Cobb's wren (*Troglodytes cobbi*) and blackish cinclodes (*Cinclodes antarcticus*).

Keywords: ecological restoration, invasive species

INTRODUCTION

Like the natural biodiversity on most islands, the native plants and animals of the Falkland Islands are vulnerable to catastrophic impacts when non-native mammals are introduced (Tabak, et al., 2014; Carey, 2015). Prior to the arrival of humans, the Falklands had only one species of terrestrial mammal – the Falklands fox, or warrah (*Dusicyon antarcticus*). While people quickly hunted this sole native mammal to extinction by 1876, they also introduced a further nine alien species which have since established feral populations. These are: Norway rat (*Rattus norvegicus*), black rat (*R. rattus*), house mouse (*Mus musculus*), European rabbit (*Oryctolagus cuniculus*), eastern cottontail rabbit (*Sylvilagus* sp.), brown hare (*Lepus capensis*), Patagonian grey fox (*Dusicyon griseus*), domestic cat (*Felis catus*), and guanaco (*Lama guanicoe*), as well as domestic dogs (*Canis lupus*), poultry, and livestock (Strange, 1992; Woods & Woods, 2006). These invasive species have had negative impacts on the native birds (Tabak, et al., 2015) and invertebrates (St Clair, 2011) through direct predation and competition for food.

The Falkland Islands are located in the south-west Atlantic Ocean, approximately 500 km east of Argentina. Spanning 51°–53° S and 57°–62° W, there are 778 islands in the archipelago (FITB, 2016). Eleven islands are permanently inhabited, although only the two largest of these are home to more than one family. The Falklands are unique among subantarctic islands in that much of the land is privately owned, and conservation-minded landowners have been at the forefront of environmental work in the islands (for example Strange, 2007; Poncet, et al., 2011). Invasive species eradications began in 2001 with the removal of Norway rats from two small islands (Brown, et al., 2001). Rats have since been successfully cleared from a further 66 islands, while the Patagonian grey fox was eradicated from one island in 2008 (Poncet, et al., 2011; FIG, 2015). The project covered here is the first Falklands attempt to eradicate mice and rabbits, and the first to attempt the simultaneous removal of three species: *R. norvegicus, M. musculus,* and *O. cuniculus*. These were the only introduced mammal species on the Bense islands.

Although conservation gains can be made by eradicating a single mammal species where more than one invasive species is present (Helmstedt, et al., 2016), eradication attempts that simultaneously target all invasive species are desirable when logistically and financially feasible. Simultaneous multi-species eradications can avoid magnifying the problems caused by one pest species when another is removed. On subantarctic Macquarie Island, the removal of cats prior to the eradication of rabbits may have contributed to a population increase of the latter species, which in turn exacerbated grazing pressure on plants and soil erosion (Bergstrom, et al., 2009; but see Springer (2016) for a discussion of the role of rabbit population fluctuations).

METHODS

Site description

Bense (c. 107 ha) and Little Bense (c. 37 ha) Islands are found in Port North, in the north-west Falkland Islands at 51°29'S 61° 31'W. These two islands have been home to Norway rats, house mice, and European rabbits for more than 100 years. Rabbits were deliberately introduced by whalers whereas rats and mice arrived as stowaways on vessels anchored in the nearby harbour or used to move livestock (R. Napier pers. comm.). The islands are joined by a rocky reef, exposed at low tide, and therefore were treated as a single island for eradication purposes (Fig. 1).

The vegetation is broadly similar across the two islands, with at least 20 species of vascular plants recorded (Table 1). The coastal zone is maritime tussock formation, with lush stands of tussock grass (*Poa flabellata*) growing to 3 m in height. The interior is low-growing oceanic heath

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 108–113. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Fig. 1 Bense Island (bottom left), Little Bense Island (top) and West Falkland Island (bottom right). Note the dark, burned area along much of the east coast of Bense. At low tide, Bense and Little Bense Islands are connected by a rocky reef. Bense is 750 m away from West Falkland at its closest point.

formation, dominated by diddle-dee (*Empetrum rubrum*) (Moore, 1968). Bense Island has had greater grazing pressure with horses, cattle, and sheep wintering on the island at various times during the 20th century. These same species were also placed on Little Bense but would quickly migrate to Bense Island as Little Bense has no water on it. (W. Goodwin, pers. comm.) This may explain why palatable species such as boxwood (*Hebe elliptica*) are more prevalent on Little Bense, and why there are also greater expanses of dense tussock on the smaller island. Both islands have been free of livestock since 1985. Also in 1985, a fire burned about 20% of Bense Island. The scorched area remains an unvegetated barren zone of peat and ash, with loose peat creeping downwind and smothering some areas of unburned vegetation.

The western coast of Bense Island has vertical cliffs up to c. 25 m in height. The terrain gradually tilts lower as one moves east, with gentle cobble or sand beaches found on the east coast. Little Bense is lower (c. 18 m maximum height) with a coastline of sloping rocks in the west and north, and sand beaches in the east and south. At its closest point, the mainland of West Falkland Island is 750 m away from Bense Island.

Despite the presence of invasive mammals, the avifauna of these islands is not completely extirpated (Table 1)

Table 1 Plants and birds commonly found on Bense and Little Bense Islands.

Birds		**Plants**	
Magellanic penguin	*Spheniscus magellanicus*	Tussock grass	*Poa flabellata*
Rock shag	*Plalacrocorax magellanicus*	Couch grass	*Agropyron pubiflorum* (*magellanicum*)
Imperial shag	*Phalacrocorax atriceps albiventer*	Common bent grass	*Agrostis tenuis*
Black-crowned night heron	*Nycticorax nycticorax falklandicus*	Hair grass	*Aira* sp.
Upland goose	*Chloephaga picta*	Small fern	*Blechnum penna-marina*
Kelp goose	*Chloephaga hybrida*	Chickweed	*Cerastium arvense*
Ruddy-headed goose	*Chloephaga rubidiceps*	Wavy hair grass	*Deschampsia flexuosa*
Falklands steamer duck	*Tachyeres brachypterus*	Diddle-dee	*Empetrem rubrum*
Crested duck	*Lophonetta specularioides*	Tufted fescue grass	*Festuca cirrosa (erecta)*
Turkey vulture	*Cathartes aura jota*	Cudweed	*Gamochaeta nivalis*
Variable hawk	*Geranoaetus polyosoma*	Pig vine	*Gunnera magellanica*
Striated caracara	*Phalcoboenus australis*	Native boxwood	*Hebe elliptica*
Magellanic oystercatcher	*Haematopus leucopodus*	Mountain berry	*Pernettya pumila*
Blackish oystercatcher	*Haematopus ater*	Meadow grass	*Poa* sp.
Two-banded plover	*Charadrius falklandicus*	Sheep's sorrel	*Rumex acetosella*
Magellanic snipe	*Gallinago paraguaiae magellanica*	Sea cabbage	*Senecio candicans*
Brown skua	*Catharacta antarctica*	Procumbent pearlwort	*Sagina procumbens*
Dolphin gull	*Larus scoresbii*	Groundsel	*Senecio vulgaris*
Kelp gull	*Larus dominicanus*	Christmas bush	*Baccharis magellanica*
South American tern	*Sterna hirundinacea*	Wood rush	*Luzula alopecurus*
Dark-faced ground tyrant	*Muscisaxicola maclovianus*		
Grass wren	*Cistothorus platensis*		
Falklands thrush	*Turdus falcklandii*		
White-bridled finch	*Melanodera melanodera*		
Long-tailed meadowlark	*Leistes loyca*		
Black-chinned siskin	*Spinus barbatus*		

and the islands were listed within the Falklands as a top priority for mammal eradication (Miller, 2008). While 26 land and sea bird species were commonly found on the islands, conspicuously absent were the only Falklands endemic passerines: Cobb's wren (*Troglodytes cobbi*) and blackish cinclodes (*Cinclodes antarcticus*). Neither of these species breeds on islands with rats (Tabak, et al., 2016). The islands are also bereft of burrowing seabirds such as sooty shearwater (*Puffinus griseus*) and thin-billed prion (*Pachyptila belcheri*), both of which breed on nearby rat-free islands (Woods & Woods, 1997).

Bense and Little Bense have never had a resident human population, but because they were a desirable site for wintering livestock, for much of the 20th century they were occasionally home to shepherds and farmhands for a few days at a time. A small shanty, built on Bense in 1926, was the only building found on either island until 2002, when a second shanty was built next to the original structure. All farming ceased in 1996, when Bense and Little Bense Islands (along with neighbouring Cliff Island and Bradley Islet) were purchased by the SubAntarctic Foundation for Ecosystems Research (SAFER) with a goal to restore the islands' ecology and improve them as wildlife habitat.

Index trapping

Index trapping to ascertain habitat preferences and relative abundance of rodents was conducted on Bense Island over eight visits, spanning 10 years and most seasons (i.e. November 2004, October 2006, July 2007, August 2007, September 2008, March 2010, January 2013, January 2014). Trap lines followed the methods described in Cunningham and Moors (1996), using Victor Easy Set wooden snap-traps (Woodstream Corp., Lititz, Pennsylvania, USA), with an interval of 25 m between trapping stations. A trap which caught an animal or which was sprung with no catch, was deemed to have been effective for half the night, and was therefore counted as 0.5 of an effective trap-night. Trap lines were placed in two different habitats: coastal tussock formation (1,612.5 effective trap-nights), or inland heath communities (1,077 effective trap-nights).

Eradication operation

Following basic ecological studies, including surveys of birds and invertebrates, an operation to eradicate rats, mice, and rabbits was undertaken in winter 2016. For bait distribution, local field staff were hired in Stanley, the Falklands capital. None had previous experience with hand-baiting so training was provided the day prior to the beginning of operations. The operation ran from 8 August to 3 September and was timed to coincide with the period when natural food on the islands is most scarce. Cereal pellets laced with brodifacoum at 25 ppm (25-W Conservation Pellets, manufactured by Bell Laboratories) were hand-broadcast along parallel transects in two applications, with an interval of 10 days between them.

A baiting map of the islands, comprising a series of parallel transects spaced at 20 m intervals laid over a high-resolution satellite photo, was created using QGIS software. Along each of these transects, baiting points were located every 20 m (Fig. 2). This resulted in an imaginary grid with 20m squares across both islands. Baiting points were also created at 20 m intervals along the coastlines of both islands, following the natural contours of the shoreline. Map data were loaded onto handheld GPS units (Garmin GPSMAP64) with an audible alarm set to sound whenever the unit reached a baiting point. Field personnel could then navigate to a desired transect line and follow it exactly, with the alarm telling them when they had reached a baiting point. GPS units were accurate to around 2 m.

Fig. 2 Detail of the baiting map of Bense Island. Each white or purple dot represents a baiting point. Baiting points are 20 m apart.

The walking tracks of field staff were monitored using GPS tracking and were checked each night against a base map. Any areas not covered properly were thus identified, and targeted for remedial attention the following day.

At each baiting point, five full scoops of bait were flung in five different directions as per hand broadcast best-practice (Broome, et al., 2011). Thus, coverage at each baiting point overlapped with bait thrown from neighbouring baiting points. Bait pellets were thrown with plastic scoops cut to hold 100 g when full. Staff carried the pellets in 20-litre plastic buckets, which could hold about 15 kg of bait. Rubber gloves, Tyvek coveralls, and dust masks were available to all field personnel.

Bait was transported to the islands from Stanley. It first went by barge to a protected bay on West Falkland Island, and from there it was moved to Bense and Little Bense in loads slung under a Chinook helicopter. The helicopter deposited the bait in six depots across the approximate midline of Bense Island, and at one location in the centre of Little Bense Island. A total of 4,400 kg of bait was delivered to the islands for this operation.

At the end of the operation, seven bait stations were established along the north-eastern coast of Bense Island, in areas thought to be the most likely zone of landfall for any rats that might swim from West Falkland Island. Bait was placed inside lengths of polyethylene pipe, 15 cm in diameter. Wax baits (containing 0.0005% w/w difenacoum and 0.001% w/w denatonium benzoate) were wired to the inside of the pipe and a handful of brodifacoum cereal pellets were also added. Bait stations were secured to the ground with wire staples and rocks.

Post-eradication monitoring

The islands were re-visited briefly in December 2016 (three months post-baiting) and in November 2017 (14 months post-baiting) to search for survivors of the baiting operation. During the latter visit, two hundred chewsticks (PCR Wax Tag, Pest Control Research) with peanut butter-flavoured wax attractants were installed in all coastal areas and in vegetated interior zones, with preference given to those areas known to be good rodent habitat. Chewsticks were checked for bite marks from rabbits and rodents before departure (up to 14 days after installation) and were left in place to be checked on subsequent visits to the islands. Staff actively searched for tracks, fresh droppings, and other signs of mammals throughout the visit. Daytime searches for rabbits were made by a dedicated hunter, including extensive observations by binoculars from a camouflaged position on high ground and by careful downwind stalking through areas known to be favoured by rabbits. A thermal camera (Thermapp) was used to replicate these searches at night without the use of lights that could frighten rabbits.

Weather during eradication operation

Temperatures ranged from -3° C to +7° C, with moderate to strong winds on all days. Snow and sleet showers frequently swept the islands but accumulation was slight and short-lived. No precipitation fell as rain. Weather did not prevent baiting except for one half-day during Application 1 and one full-day during Application 2, when wind speeds were too high to cast bait effectively.

RESULTS

Index trapping

Index trapping showed rats were much more prevalent in coastal tussock areas, with 82 rats caught there from 1,612.5 effective trap nights, whereas on inland heath areas, only three rats were recorded from 1,077 effective trap nights. Mice were more evenly distributed between the two habitats sampled, with 50 caught in coastal tussock, and 32 caught in inland heath.

Rabbits were not targeted with snap traps but individuals were observed on most parts of Bense, except the denuded burn-zone. Rabbits were not thought to be present on Little Bense until a single animal was observed there in February 2015. This was the only time in 18 visits that a rabbit was seen on Little Bense, suggesting that if there was a resident population on the island, it was likely much smaller than that on Bense.

Effectiveness and coverage of Application 1

For the first application (8–16 August), a team of five field staff covered Bense and Little Bense with bait, resulting in a mean density of 15.3 kg/ha. However, bait was more densely applied along the shoreline and in dense tussock, while it was applied less densely in the burn zone, which is devoid of vegetation. All cliffs were baited along their top edges and on all lower ledges that were safely accessible. Where safe access was not possible, pellets were thrown from above. Along accessible shorelines, particular attention was paid to the beach margin where vegetation began and to areas just above the high tide line where debris had accumulated.

Although Little Bense is only a third the size of Bense, baiting there proved to be much more challenging due to the extremely dense tussock grass and the fragmented, convoluted northern coast. Overland access to the many coastal chasms and rock slabs was particularly difficult since it required climbing through or over the worst of the tussock (over 2 m high). To apply bait to this northern coast more efficiently, a small boat was used. In some chasms the boat could be used as a mobile baiting platform, with pellets broadcast into the tussock from the deck. In other areas, personnel were landed to climb to the vegetated margin, then re-boarded and moved to the next position.

Effectiveness and coverage of Application 2

For the second application (26 August–3 September), a team of three field staff attempted to duplicate the coverage achieved in Application 1. However, due to the smaller team and staff injuries, this was not possible. Instead, Application 2 made selective coverage, with priority given to areas known from index trapping to be the best rodent and rabbit habitat. On Bense Island, Application 2 covered all tussock areas, all shorelines, and all areas north of the island's midline, regardless of vegetation type. Not covered were some areas of inland heath south of the midline, and the denuded burn zone. These latter areas still had intact bait remaining from Application 1.

On Little Bense Island, Application 2 covered all tussock areas and all shorelines, but did not cover inland heath areas. As on Bense, the inland heath here still had intact, uneaten bait remaining from the first application. On Little Bense, staff injuries also curtailed coverage in the tussock area: bait was applied on every second transect, meaning there was a gap of 40 m (instead of the normal 20 m) between each baiting line. To help reduce the size of the potentially un-baited space between transects, bait was thrown wider on lateral throws, and a greater quantity was thrown. The coastline was baited as in the first application, including the use of the boat to access the north coast. Mean baiting density on Application 2 was 11.7 kg/ha. Over the whole operation, c. 3,900 kg of bait were applied to the islands.

Daily reviews of the GPS tracks of workers revealed that some areas were missed in the earliest days of baiting but these were easily remedied the following day. After the first two days, all workers had mastered navigation and no further areas needed remediation.

Mammal and non-target mortality

Staff stayed on the islands from the start of Application 1 until seven days after the completion of Application 2 and during this time staff searched for animals killed in the operation. In total, 64 dead rabbits were found on Bense Island but none was found on Little Bense. All intact carcasses found were placed under heavy tussock grass or in burrows to hide them from scavenging birds. However, many carcasses were discovered after they had been scavenged, so some secondary poisoning is likely to have occurred. Three dead mice were found on Bense Island and one was found on Little Bense. No dead rats were found on either island, presumably because they died in their burrows.

Dolphin gulls (*Larus scoresbii*) were the most common non-target casualty with a total of 23 carcasses discovered. This species was observed to eat bait pellets directly, often fighting conspecifics for them. Dolphin gulls were the only species seen to eat the pellets. Three dead adult turkey vultures *(Cathartes aura jota)* were found, as was one adult striated caracara (*Phalcoboenus australis*) and one short-eared owl (*Asio flammeus*). The owl had been scavenged before discovery. Dissection of the striated caracara showed no visual evidence that it had directly ingested bait pellets, so perhaps it died from eating parts of a poisoned animal, most likely a rabbit or dolphin gull. Striated caracaras were observed playing with pellets but were never observed to ingest them. Two dead flightless steamer ducks (*Tachyeres brachypterus*) were found (one on each island). Direct consumption of bait may explain these deaths, but this species is known to eat offal occasionally (Woods, 1975) so it is also possible they were victims of secondary poisoning from eating a dead dolphin gull. Kelp gulls (*Larus dominicanus*) and snowy sheathbills (*Chionis alba*), two birds known for their curiosity and scavenging habits, were both present but were not seen to touch the pellets and no dead kelp gulls or sheathbills were recorded during the operation.

Post-operation follow-up

During the December 2016 follow-up visit, informal observations did not detect any live mammals, and no footprints were found despite careful examination of areas with soft soil or wet sand, where rabbit or rat tracks had been commonly seen in the past. The bait stations on Bense were also completely undisturbed with no evidence of gnawing on the wax baits. Three freshly-dead kelp gulls were found and evidence of pellet consumption was discovered upon dissection: the crops of two of the birds were discoloured with the bright green biomarker found in the pellets. It is thought these birds consumed bait that was inadvertently exposed during this visit when stored bait was moved near the campsite.

The more thorough post-operation visit in November 2017 did not discover any evidence of rodents or mammals on the islands. No live rodents or rabbits were seen, nor were any fresh droppings or tracks discovered. No chewsticks had been sampled by rodents, although the bite marks of striated caracaras and other birds were found on 10 sticks. Nocturnal observations with the thermal camera also found no mammals. However, bait blocks inside bait stations were found to be heavily sand-blasted and in need of replacement.

DISCUSSION

The first application of bait achieved 100% coverage as per the project design. However, Application 2 was less complete and several compromises were made, with priority given to bait the areas shown by index trapping to be the most important as habitat for invasive mammals. However, one area of concern was the dense tussock on Little Bense where the second application of baiting could have left gaps between baiting lines.

Rats have proved easier to eradicate from islands than mice, with rats successfully removed from islands in 92% of the operations attempted (Howald, et al., 2007), whereas early reports found success was achieved in only 62% of mouse operations (MacKay, et al., 2007). However, recent findings show a more optimistic picture, with mice successfully eradicated in 77% of operations in New Zealand, and this figure rises to 100% when considering only operations that followed current best-practice techniques (Broome, et al., 2019). Mice may be harder to eradicate because of behavioural traits such as aversion to cereal (Humphries, et al., 2000) or smaller home range (Clapperton, 2006; MacKay, et al., 2011). This necessitates a denser and more meticulous application of bait to ensure that all mice encounter pellets. The possible gaps in bait availability in dense tussock areas on Little Bense are thus a cause for concern.

Eradication operations carry a risk of killing non-target species through direct ingestion of poison pellets or by eating an animal that was poisoned. At South Georgia, brodifacoum pellets were consumed directly by skuas, sheathbills, and pintails, while other scavengers such as kelp gulls and giant petrels were less likely to eat baits (Lee, et al., 2013). In contrast, at Campbell (McClelland, 2011) and Macquarie Islands (Springer & Carmichael, 2012) kelp gulls were found to be extremely vulnerable to primary poisoning. In the Falklands, the death of non-target species is not well known since most islands have been without observers immediately after the completion of baiting operations. However, on Great Island, the bodies of many kelp and dolphin gulls were found following a rat eradication operation in July 2016 (T. Poole, pers. comm.). Dolphin gulls were the most common bird species poisoned on Bense and Little Bense Islands and their corpses were possibly a source of secondary poisoning of turkey vultures and striated caracara. It is suggested that future eradication operations in the Falklands plan for some personnel to remain on the island after the completion of baiting in order to improve understanding of non-target mortality.

That no evidence of mammals could be found on the island 14 months post-baiting is cause for optimism. However, the overall success of this operation will not be known until late 2018 (26 months post-baiting) after further monitoring has taken place. Elsewhere, rabbits have proven particularly difficult to eradicate using poison alone (Torr, 2002) and monitoring may reveal the need to use additional techniques on Bense and Little Bense Islands. There are no trained detection dogs in the Falklands and snares and fumigants are not advised as they could have an impact on burrowing penguins. In addition, biosecurity concerns prevent the import of rabbit-specific pathogens, thus leaving spotlight shooting as the most effective tool available for eliminating any remaining rabbits.

This Bense and Little Bense islands operation was intended to help restore native biodiversity with the potential to re-establish populations of the endemic Cobb's wren and blackish cinclodes. However, it will also contribute to future operations on other Falkland islands by allowing landowners to understand which eradication techniques do, or do not, work. As the first attempt to eradicate mice in the Falklands, the results will be especially helpful in planning for eradications on mouse-infested islands such as Steeple Jason Island, which is home to many seabird species and has been identified as an Important Bird Area. (Falklands Conservation, 2006). In the Falkland Islands, private landowners have been a driving force in many ecological restoration projects, so the training and experience gained by local residents in the course of the Bense operation also serves to increase the pool of skilled staff who can participate in future eradications on other islands.

ACKNOWLEDGEMENTS

Bait for this operation was generously donated by the Falkland Islands Government. The SAFER foundation is also grateful for support from N. Beazley, Encounter Foundation NZ, the Environmental Planning Department of the Falkland Islands Government, Falklands Conservation, J. & S. Holman, The Baroness Hooper CMG and G. Roldan. We thank P. Goodhue for creating the operational maps, and A. Cox, E. Murphy, S. Poncet, and K. Springer for advice on operational design. Key logistical support was provided by Hurtigruten Cruises, Lindblad Expeditions, K. McCallum, Ministry of Defence / British Forces South Atlantic Islands, One Ocean Expeditions, and B. & S. Pole-Evans. For baiting, we thank A. Cleminson, L. Hartnoll, S. Henry, J. Henry, D. Hewitt, and T. Poole, and for post-baiting monitoring, we thank J. Davis, R. Moore, and K. Olds. Thanks to J. Fenton for the plant list. Critical comments from P. Broady and two anonymous reviewers improved this manuscript.

The history of the aerial application of rodenticide in New Zealand

P. Garden[1], P. McClelland[2] and K. Broome[3]

[1] 5 Ruby Ridge, Wanaka 9803, New Zealand. <pghltd@xtra.co.nz>. [2] 237 Kennington Roslyn Bush Road, Invercargill 9876, New Zealand. [3] Department of Conservation, P.O. Box 10-420, Wellington 6143, New Zealand.

Abstract Following the incursion of rats (*Rattus rattus*) on Taukihepa (Big South Cape Island; 93.9 km²) off southern New Zealand in 1963, and the subsequent extirpation of several endemic species, the New Zealand Wildlife Service realised that, contrary to general belief at the time, introduced predators do not reach a natural balance with native species and that a safe breeding habitat for an increasing number of 'at risk' species was urgently needed. Offshore islands offered the best option for providing predator free habitat but there was a limited number of predator-free islands available and most were very small. Eradicating rodents on larger islands to provide a wider range and greater area of habitats was required and hand treating these larger areas using trapping and hand application of toxicants, the only methods available at the time, proved problematic and often impossible. Helicopters had been used to distribute bait for the control of rabbits and brushtail possums in the past but eradication of any particular predator species was considered 'not feasible'. The development of a GPS-based aircraft guidance system, a suitable bait product, specialised bait delivery systems and second-generation anti-coagulant toxicants changed that. Now islands as large as South Georgia (3,900 km²) have been treated using this method.

Keywords: aerial application, brodifacoum, eradication, helicopter, *Mus musculus* – house mouse, *Rattus exulans* – Pacific rat, *Rattus norvegicus* – Norway rat, *Rattus rattus* – ship rat

INTRODUCTION

New Zealand's terrestrial flora and fauna evolved in isolation from mammalian predators leading to many species being highly susceptible to any ground-based predators that hunt by smell and sight (e.g. Tennyson & Martinson, 2006). Since the arrival of humans, this unique environment has suffered from the deliberate or accidental introduction of a range of species that have decimated native biodiversity. This includes four species of rodent, Norway rat (*Rattus norvegicus),* ship rat *(R. rattus),* Pacific rat or kiore *(R. exulans*) and house mouse (*Mus musculus*), which continue to have a devastating impact on New Zealand's native flora and fauna (King, 2005).

Polynesians arrived in New Zealand bringing with them the Pacific rat or kiore. The rats, along with kuri or native dog (*Canis familiaris*), were brought for food and clothing and led to the first wave of extinctions in New Zealand (Tennyson & Martinson, 2006). In 1770, James Cook mentions vermin in his journals and this may refer to Norway rat (Innes, 2005). House mice had arrived in New Zealand by 1830 (Ruscoe & Murphy, 2005). Ship rats were introduced with early European settlers between 1860 and 1890 and had both cumulative and additional impacts to the rodent species that were already present (King, 2005; Tennyson & Martinson, 2006).

Invasive species have caused ecological problems around the world since humans started exploring but it was in New Zealand, where biodiversity loss was obviously due to introduced predators (Tennyson & Martinson, 2006), that organisations began to consider ways to minimise these impacts. It was not until the mid-1990s that technology advanced to a stage where this human induced disaster could be offset on any significant scale (Towns, et al., 2013).

This paper outlines the key events that led to the development of a rodent eradication tool used around the world today and discusses the role played in this process by the New Zealand agricultural aviation industry.

RECOGNITION OF THE DAMAGE RODENTS COULD DO TO NEW ZEALAND WILDLIFE

The ship rat invasion of Taukihepa (Big South Cape Island; 93.9 km²) in the early 1960s and the extinction of three species of endemic vertebrates sent shock waves through conservation circles (Bell, et al., 2016). A fourth species was saved only by transferring to it a nearby predator-free island. This disaster led to an increased interest in the ecology of rodents and their impact on native species as well as ways to control or eradicate them along with other introduced predators (Towns & Broome, 2003).

ERADICATION TOOLS AND ADVANCES

Early application of aircraft in New Zealand agriculture

Demobilised World War II pilots in New Zealand began an industry applying fertiliser and grass seed to hill country and established the skills to fly accurate parallel swath patterns. The spread of fertiliser and seed initially used fixed wing aircraft as outlined by Alexander & Tullett (1967), but the skills were later transferred to the use of helicopters.

The skill and experience of the pilots is a crucial component of any aerial baiting operation. In addition to having experience with all the systems that are to be used

Fig. 1 Auster aircraft loading rabbit bait, MacKenzie Basin 1951.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 114–119. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

in the operation (e.g. helicopter, bucket, GPS etc.), they are often required to fly under adverse conditions such as during poor weather, across islands with challenging topography and frequently a high risk of bird strikes. Pilots are expected to fly accurate lines in spite of these challenges whilst also monitoring the bait flow out of the bucket. It is highly desirable that the pilots are involved in the planning for an eradication as they can identify both risks and opportunities associated with the bait application.

The establishment of the Department of Conservation

The establishment of the New Zealand Government's Department of Conservation (DOC) out of the Wildlife Service, Forest Service and Department of Lands and Survey brought the various government agencies charged with protecting biodiversity under one management regime and allowed better focus on prioritising 'endangered species' programmes, including predator removal. The Department of Conservation was able to provide the financial and political support necessary to carry out this work. This was especially so with the larger projects such as Campbell Island (113.3 km²) in the New Zealand sub-Antarctic. Current operations now follow the international trend of joint venture or partnership operations with Non-Government Organisations (NGOs) and private conservation trusts.

Fig. 3 Purpose built eradication bucket 2001.

IMPROVEMENTS IN TECHNOLOGY

Development of toxins

On the mainland, compressed grain bait (pellets) suitable for dispersal through a mechanised spreader bucket (Fig. 2) were also laced with 1080 and phosphorus to target brushtailed possums (*Trichosurus vulpecula*) (Bill Simmons pers. comm.). Prior to this, aerial bait application had been predominantly diced carrot or grain.

The development of the second-generation blood anticoagulant toxicant brodifacoum in England in the mid-1970s provided a toxicant suitable for large-scale rodent eradication (Dubock & Kaudeinen, 1978). The delayed action of the anticoagulant toxicants meant that rodents would consume a lethal dose of toxicant before showing any symptoms, thus eliminating the risk of bait avoidance. Brodifacoum also has the ability to kill a rodent with a single feed, compared to the first-generation anti coagulants that required multiple feeds over several days. Brodifacoum is currently registered in over 40 countries in the form of over 100 separate registrations covering different formulations or product forms (Kaudeinen & Rampaud, 1986).

Fig. 2 Compressed cereal bait impregnated with brodifacoum.

Development of bait spreading equipment

Various New Zealand agricultural helicopter companies had been developing underslung cargo hook-mounted spreader buckets for the application of fertiliser and seed. By 1980, these spreader buckets had been modified to spread toxin-laced chopped carrot and cereal-based pellets for the control of rabbits and possums (Peter Garden, unpublished data).

Purpose-built bait-spreading buckets have continued to be developed (Fig. 3), and these now allow for a consistent swath width and density of bait application on a large scale. Buckets have been repeatedly refined to provide a wider bait swath and, most importantly, the addition of an internal deflector to direct bait just out one side minimising any bait that may go into the marine environment as well as being able to treat cliffs. Additional improvements including linking the bait flow to the flight track recording system are currently being developed.

Development of guidance and data recording equipment

Various methods to assist pilots in following straight lines have been tried. One of these, the Decca Navigation System, was used on forestry spraying operations as early as 1980 and used in a possum control operation on Rangitoto Island in 1990. Another method trialled was using reciprocal compass headings at the end of each run. This required the pilot to make calculations using compass variation, deviation and cross wind headings.

The United States military developed a constellation of global orbiting satellites in the late 1970s to provide very accurate navigation information. The Global Positioning System (GPS) relies on highly accurate time and position information transmitted by these satellites to receivers on the ground or in aircraft. The receivers use triangulation to compute three-dimensional position, direction and speed of travel information. To preserve security of this information, deliberate errors were factored in and the corrections for these errors were only available to those with security clearance to use them. This error factor was known as 'selective availability'. The civilian world was keen to access this information and several companies developed simple navigation devices that could be used for guidance within the expected error range. The error range was not consistent but was never much more than a few hundred meters, which was acceptable to support other navigational equipment. However, to be an effective guidance tool for aerial application this error could be no more than one or two metres. In 1993, attempts were made to use GPS for guiding bait spread onto Cuvier Island, but a suitable satellite triangulation system at that time was not available (D.R. Towns, pers. comm.).

In 1995, an American avionics manufacturer, Trimble Navigation, set up a facility in Christchurch New Zealand with the specific purpose of developing systems for use in aerial agricultural application that could meet the very stringent accuracy requirements of that industry. The system required the use of a 'base station' that recorded satellite signals transmitted over time and calculated the errors. The corrected information was then transmitted to the aircraft by radio telemetry.

By 2000, the US military had switched off the 'selective availability' function so the use of base stations was no longer necessary. More recently, a New Zealand based company, TracMap Ltd™, has developed a system designed specifically for aerial application – for the distribution of both agricultural products and bait (Fig. 4).

The first island eradication where GPS guidance equipment was successfully used was on Tiritiri Matangi (1.7 km²) in 1993 (Veitch, 2002d).

ERADICATION HISTORY

Early aerial application of toxicants

Rabbits (*Oryctolagus cuniculus*) were introduced for sport and as supplementary food for settlers in the 1830s (King 2005). However, the animals soon developed into plague proportions, particularly in the drier inland areas where they contributed to significant land erosion (King, 2005). Systems were developed for the aerial application of toxicants to control rabbits using fixed wing aircraft (Fig. 1). This was predominantly using either carrot pieces or grain laced with the toxin 1080 (sodium monofluoroacetate).

The first recorded island rat eradication in New Zealand was the removal of Norway rats by hand baiting from Maria Island (1 ha), Noises Islands, in 1960 (Towns & Broome, 2003). as the first in a series of unintended rodent eradications when control had been the expected outcome.

Fig. 4 TracMap™ GPS guidance equipment fitted to South Georgia Heritage Trust aircraft,2015.

The first use of bait stations was by Ian McFadden on Rurima Island (0.045 km²) in 1983, using maize laced with the anticoagulant bromadialone and the same product was used successfully on Korapuki Island (0.18 km²) in 1986. Both campaigns were against Pacific rats (and rabbits on Korapuki, McFadden & Towns, 1991). Between 1986 and 1988, commercially available Talon™ (brodifacoum) wax blocks in bait stations were used to eradicate Norway rats from Hawea (9 ha) and Breaksea (1.70 km²) islands in Fiordland (Thomas & Taylor, 2002). While this type of technique has been used on islands as large as 31 km² Langara Island, Canada (Taylor, et al., 2000), the usefulness of this method is limited by topography of the target island and logistical difficulties associated with ensuring complete coverage of the island.

Early use of aircraft targeting rodents on islands

In 1986, Moutohora Island (1.43 km²) in the Bay of Plenty was the first island in New Zealand to be treated using aerially distributed toxic bait (Talon™ 20P, active ingredient brodifacoum) to target rabbits using a fertiliser spreading bucket. As an unplanned side effect, Norway rats were also removed as part of this operation (Jansen, 1993).

The first attempt at aerially distributing rodenticide targeting rats in New Zealand occurred on the Mokohinau Islands (0.73 km²) in the Hauraki Gulf in 1990 (Towns & Broome, 2003). This operation was carried out using a 'monsoon' firefighting bucket to spread Talon™ 20P and resulted in the removal of Pacific rats. However, it was identified that the bait spread was concentrated along a narrow swath, due to the bucket not having a spinner to spread the bait out, and hand spreading was required to fill in the gaps (McFadden & Greene, 1994).

Between 1991 and 1993 a partnership was developed between DOC and ICI Crop Care, to improve the durability of Talon™ 20P (brodifacoum) and to license the product for aerial spread against rodents. An efficient means of spreading the baits also needed to be developed. By 1993, Ian McFadden of DOC and Tony Monk of Heletranz had developed a bait bucket with spinner, for use against rodents on offshore islands. The bucket was used to spread Talon™ 20P to target Pacific rats on Cuvier Island (1.81 km²) in 1993 (Towns & Stephens, 1997).

Increasing the scale

The first large scale aerial application operation specifically targeting rodents (Norway and Pacific rats) was carried out on 19.65 km² Kapiti Island (Fig. 5) off the south-west side of the North Island, New Zealand (Miskelly & Empson, 1999). The operation succeeded in removing both species. This island was four times larger than any previously attempted (Broome, 2009).

Fig. 5 Mechanical loading of bait for Kapiti Island, 1996.

Fig. 6 Hand loading bait on Codfish/Whenua Hou, 1997.

Fig. 8 Bait spreading on Mokonui Island, off Stewart Island, 2006.

Pacific rats were eradicated from Putauhina Island (1.41 km²) and Raratoka Island (0.88 km²) off southern Stewart Island in 1997 in the lead-up to rodent eradication on Whenua Hou (Codfish Is; 13.96 km²). (McClelland, 2002) Although these islands had significant conservation values in their own right, the removal of rats was largely to establish procedures and issues for the treatment of Whenua Hou in order to provide a predator free environment to establish a kakapo breeding base (Merton, et al 2006)

In August 1998, two applications of brodifacoum-laced compressed cereal bait were aerially applied to 13.96 km² Whenua Hou (Fig. 6) to remove Pacific rats (McClelland, 2011). The Kapiti project used two applications and this has become the standard methodology for aerial bait applications for eradicating rats on islands worldwide, with modifications as required for each island.

Tuhua/Mayor Island (12.83 km²) in the Bay of Plenty, New Zealand was successfully treated for the removal of Norway rats and Pacific rats in 2000, largely to test the methods required against rats and cats on the much larger and more remote Raoul Island in the Kermadecs (Williams & Jones, 2003).

Campbell Island followed on from the success of the Kapiti and Codfish/Whena Hou eradication programmes. DOC embarked on a very ambitious plan to eradicate Norway rats from this 113.31 km² island, 700 kilometres south of mainland New Zealand. The logistics of this project far exceeded anything that had been contemplated previously and required a rethink on how such operations could be streamlined to make them logistically and financially feasible. The resulting operational plan called for a single application of just 50% of the standard bait rate. This was a substantial risk but the GPS navigation and spreader bucket technology and experienced pilots gave planners confidence in being able to achieve complete coverage. A 600 ha trial involving the aerial application of non-toxic bait with a biomarker was carried out to test the proposed methodology before the full operation (Fig. 7) was started. (McClelland, 2011). Over the period 2000 to 2008, more than a dozen islands around the New Zealand coastline were treated including: Raoul (29.38 km²) in the Kermadecs (Ambrose, 2006; Little Barrier (30.83 km²) in the Hauraki Gulf (Griffiths, et al., 2019); Bench (1.21 km²) and Pearl (5.12 km²) off Stewart Island (Brent Beaven pers. comm.); Coal (11 km²) Preservation Inlet, (Brown, 2013); Pomona (2.62 km²) and Rona Islands (0.6 km²) (Shaw & Torr, 2011). Notable during this period was the Rakiura Titi Islands restoration project (McClelland, et al., 2011) which included Mokonui (0.86 km²) (Fig. 8) and Taukihepa/ Big South Cape (9.39 km²) islands. Managing non-target risks, multi-species eradications and reinvasion issues are all now part of the planning process and this culminated in the Rangitoto/Motutapu project 34.81 km² in 2009 that targeted seven species of introduced mammals including the four species of rodent (*M. musculus, R. rattus, R. norvegicus, R. exulans*). (Griffiths, et al., 2015).

Mice removal from 20.02 km² Antipodes Island 850 km south-east of Bluff (New Zealand) occurred in winter, 2016 (Horn & Hawkins, 2017) (Fig. 9). Success has been confirmed.

INTERNATIONAL PROJECTS

Exporting the technology

Because of the concern for the critically endangered Seychelles magpie robin *(Copsychus sechellarum),* an operation to carry out the eradication of Norway rats from Denis (1.43 km²), Frigate (2.19 km²) and Curieuse (2.86 km²) Islands in the Seychelles was completed in June and July 2000 (Merton, et al., 2002).

The same basic technique, usually using New Zealand-made spreader buckets and often with experienced New Zealand pilots, has been and is used to eradicate rodents on islands worldwide. Methods are modified for each island with alterations made to sowing density, number of drops, timing between drops etc., To date rodents have been eradicated from more than 300 islands using this technique, making it the most widely used and most successful technique for rodent eradications compared to bait stations, hand broadcast or traps. (Howald, et al., 2007). Whereas there are still some situations where the other techniques are the most suitable option, e.g. on islands where it is not practical to use aerial eradication methods it has allowed islands that could never previously have been considered for eradication programmes to be treated successfully. The largest island worked on to date is 3900 km² (1070 km² treated) South Georgia Island in the sub-Antarctic (Black, et al., 2013), which had Norway rats and an isolated population of mice treated in three phases over a five-year period from 2011 to 2015. Other successful international eradications using this methodology include Macquarie (128 km²) where rabbits, ship rats and mice were eradicated in 2012 (Parks and Wildlife Service, 2014) and Rat Island/Hawadax (10 km²) in the Aleutians where Norway rats were eradicated in 2008 (Buckelew, et al., 2011).

Aerial distribution of bait has now been successfully used for the eradication of rodents in more than ten countries including Australia, USA, Canada, Mexico, Japan, Italy and several smaller Pacific Island nations.

CONCLUSION

The aerial dispersal of rodenticide has been a 'game changer' allowing large and geographically challenging islands and tracts of land to be treated quickly and efficiently. The advent of GPS guidance and recording equipment and purpose-built distribution systems (spreader buckets) has given project managers confidence that a lethal dose of toxic bait can be delivered into each home range of the target species, maximising the chances of eradication.

Many organisations and islands around the world have benefited from the developments carried out in New Zealand since the availability of second-generation anticoagulant toxicants. Now NGOs and Government departments in all corners of the globe are using this information to carry out their own projects. These in turn are now providing feedback to advance the knowledge base needed to carry out ever more complex and challenging projects.

While aerial application of toxic bait has been a major advancement in habitat restoration, ground based techniques – bait stations and hand broadcast – are still used where relevant. These methods tend to be used on smaller, more accessible islands as well as around dwellings on inhabited islands during aerial operations. However, the ability to treat large areas in a short space of time and the lower overall cost per hectare of treatment make aerial application a valuable tool in the continuing fight against invasive predators. The scale of islands that may be treated in the future is limited only by the supporting logistics, funding and political support.

The fact that much of the aerial application expertise resides in New Zealand has more to do with the incremental development of systems, procedures and technology that has occurred here over the past 30 years. As the baiting pilot has the final control over the success of any project, it is vital that they have complete commitment to that end. Project managers should involve the likely application pilot(s) at an early stage to ensure this commitment.

Many challenges still exist, especially in tropical and subtropical regions where success rates have been lower, and there is room for continued development of equipment and systems, but the use of this method of distribution of rodenticide will continue into the foreseeable future. An increasing number of inhabited islands is now being treated and this brings a new series of challenges for project managers. Numerous issues that do not need to be considered on uninhabited islands come into play, making these operations considerably more complex.

Abstract Rat eradication is a highly effective tool for conserving biodiversity, but one that requires considerable planning effort, a high level of precision during implementation and carries no guarantee of success. Overall, rates of success are generally high but lower for tropical islands where most biodiversity is at risk. We completed a qualitative comparative review on four successful and four unsuccessful tropical rat eradication projects to better understand the factors influencing the success of tropical rat eradications and shed light on how the risk of future failures can be minimised. Observations of juvenile rats surviving more than four weeks after bait application on two islands validate the previously considered theoretical risk that unweaned rats can remain isolated from exposure to rodent bait for a period. Juvenile rats emerging after bait was no longer readily available may have been the cause of some or all the project failures. The elevated availability of natural resources (primarily fruiting or seeding plants) generated by rainfall prior to project implementation (documented for three of the unsuccessful projects) may also have contributed to project failure by reducing the likelihood that all rats would consume sufficient rodent bait or compounding other factors such as rodent breeding. Our analysis highlights that rat eradication can be achieved on tropical islands but suggests that events that cannot be predicted with certainty in some tropical regions can act individually or in concert to reduce the likelihood of project success. We recommend research to determine the relative importance of these factors in the fate of future tropical projects and suggest that existing practices be re-evaluated for tropical island rodent eradications.

Keywords: best practice, conservation, invasive, restoration, rodent

INTRODUCTION

Marine islands house an estimated 15–20% of terrestrial biodiversity and are home to 61% of IUCN Extinct species and 37% of IUCN Critically Endangered species (B. Tershey unpubl. data). Invasive species have been the most frequent cause of extinctions on islands and the second leading cause of Critical Endangerment (B. Tershey unpubl. data). Commensal rats (*Rattus* spp.) are considered the most damaging group of invasive species on islands because of their near global distribution and the frequency with which they cause extinctions, extirpations and ecosystem-level impacts (Towns, et al., 2006; Howald, et al., 2007; Kurle, et al., 2008). Rats can be eradicated from islands (Keitt, et al., 2011) resulting in significant species and ecosystem recovery (Bellingham, et al., 2010). Thus, rat eradication is a powerful tool with which to prevent extinctions.

Although this tool has been widely deployed, with more than 500 successful rat eradications to date (DIISE, 2017), most rat eradications have been on small, mid to high latitude islands (Howald, et al., 2007) where endemic species diversity is lower. If rat eradication is to realise its full potential to prevent extinctions, then future eradications need to be more frequently conducted where endemic species diversity is high: on larger tropical islands (Kier, et al., 2009). However, while rat eradication is being successfully conducted on increasingly large, high latitude islands, with a failure rate of less than 3% (Russell & Holmes, 2015), success on both large and small tropical islands has been more elusive, with a failure rate of 10% and very little understanding as to the underlying causes of failure (Holmes, et al., 2015; Keitt, et al., 2015).

In an attempt to better understand the mechanisms responsible for eradication failure on tropical islands and improve the rate of success of future projects, a global review of rodent eradication practice on tropical islands was instigated (Russell & Holmes, 2015). In support of the review, Holmes, et al. (2015) performed a statistical analysis on as many rat eradication attempts as possible to determine correlative factors that might pinpoint important influences on tropical rat eradication success. However, rat eradication projects are complex and multifaceted (Cromarty, et al., 2002) and, like complex projects within other disciplines, it can be challenging to determine the reason(s) for project failure. To reduce the risk that the broad-brush approach utilised by Holmes, et al. (2015) overlooked important and influential factors, we completed a second review, this time using a qualitative framework on a subset of the projects assessed by Holmes, et al. (2015).

Qualitative comparative reviews are used extensively in the social and behavioural sciences (e.g. Ragin, 1989; George & Bennett, 2005; Bennett & Elman, 2006), but also in other fields such as software engineering (Abrahamsson, et al., 2003), human resource management (e.g. Allen, et al., 1997), and political science (e.g. Bennett & Elman, 2006). A qualitative comparative review offers the opportunity to compare projects and their nuances in detail, which superficially, statistical analyses cannot do, but also allows for the possibility for making generalisations if they exist (Ragin, 1989). This approach, which we believe has greater utility in conservation biology, offered a complementary mechanism for verifying or dispelling the importance of factors identified as significant or insignificant in Holmes, et al. (2015).

We examined in depth, reported data from eight well-planned and sufficiently resourced tropical rat eradication attempts, balanced among four successful and four unsuccessful projects, to better understand: 1) the variability in factors influencing tropical rat eradication projects irrespective of outcome, 2) the factors that consistently differentiate successful from failed tropical rat eradication attempts for projects where full reported data are available, 3) what steps can be taken to improve eradication reporting and minimise the risk of failure for future tropical rat eradications.

METHODS

Island eradication study sites

For the purposes of this study we focused on rat eradication projects that used the method shown to have the greatest chance of success, but which faced all of the challenges associated with tropical islands and described by Keitt, et al. (2015). We did not consider geographical location to be important if these conditions were met. Projects that met the following criteria were selected for our analysis:

- Rodent bait was applied by helicopter, guided by GPS. Projects that used the aerial application of bait were the focus for our study because this method has the best record of success in both temperate and tropical climates (Howald, et al., 2007).
- The project was undertaken on a tropical island or islands. Although Henderson lies just south of the tropic of Capricorn at a latitude of 24°21'S, we considered this island to be tropical in the context of rodent eradication due to the island's temperature range, vegetation and absence of pronounced seasonality (Spencer, 1995; Brooke, et al., 1996).
- The project was undertaken on an island or islands with a Precipitation Coefficient of Variance (CV) of mean monthly rainfall of less than 50% (Fig. 1). We focused our analysis not on particularly wet or dry islands, but on islands where rainfall and ecosystem productivity were more difficult to predict. We excluded projects completed on arid or semi-arid islands such as along the Pacific Coast of Mexico or North-western Australia because, for rodent eradication, these islands share the seasonality associated with temperate islands i.e. an eradication operation can be undertaken when natural food resources are scarce and breeding, within the rat population, is less likely. The island of Banco Chinchorro, Mexico was excluded from our analysis because it had a rainfall CV greater than 50%. Nevertheless, Banco Chinchorro is another well documented project and could have been a useful addition to our comparative review.
- The project was undertaken on an island or islands with land crabs. The presence of land crabs was identified as a significant influence on project success in Holmes, et al. (2015).
- Projects where reinvasion could be dismissed as an unlikely cause of failure. Projects were only included if reinvasion had been ruled out through comparative DNA analysis or were undertaken on uninhabited islands that were rarely visited and extremely remote. This excluded islands such as Denis and Curieuse in the Seychelles (Merton, et al., 2002) and the Aleipata Islands in Samoa (Butler, et al., 2011).
- Sufficiently detailed information was available to allow the project to be reviewed within the framework recommended by Keitt, et al. (2015).

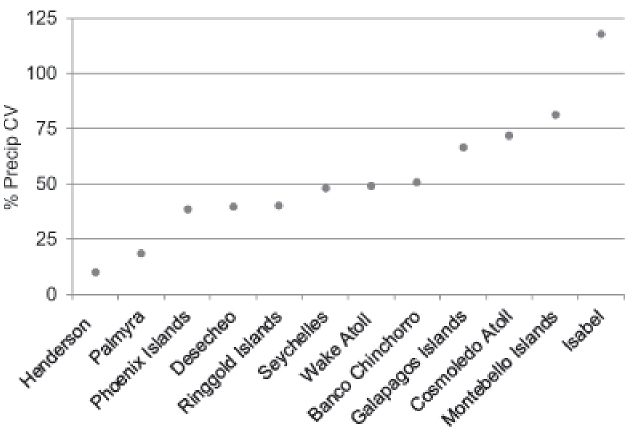

Fig. 1 Monthly Precipitation Coefficient of Variance (CV) for tropical islands where rodent eradications have been attempted using rodent bait containing a 2nd generation anticoagulant applied by helicopter.

Of the 17 discrete projects completed on tropical islands that applied rodent bait containing a second generation anticoagulant by helicopter, eight were selected for analysis. Six were completed on islands located in the tropical Pacific; Henderson (part of the United Kingdom Overseas Territory of Pitcairn), Wake (an unincorporated territory of the United States north of the Marshall Islands), Palmyra (an unincorporated territory of the United States in the Northern Line Islands), Enderbury and Birnie (part of the Phoenix Islands Group of the Republic of Kiribati) and the Ringgolds (part of Fiji). Two projects were located outside of the Pacific Region; Desecheo (Puerto Rico Archipelago) located in the Caribbean and Frégate (Seychelles) in the Indian Ocean.

Island size varied from 49 to 4,310 ha (Table 1) and all islands experienced relatively similar temperature ranges and annual rainfall (Table 1). Except for the Wake project that targeted Pacific rat (*R. exulans*) and Asian house rat (*R. tanezumi*), the eradication operations targeted the removal of just one species. *R. exulans* was targeted in four operations, ship rat (*R. rattus*) in two and Norway rat (*R. norvegicus*) in one (Table 1). Holmes, et al. (Holmes, et al., 2015) found no significant difference in eradication success between rat species for projects that applied bait aerially. Four of the islands were inhabited; Wake, Frégate, Palmyra and the Ringgolds (Table 1).

Determining success and failure

In line with best practice guidelines produced by the New Zealand Department of Conservation (Broome, et al., 2011), we considered an eradication project to be successful where the absence of rats was determined after a minimum of two breeding seasons (at least one year) after the completion of the operation, as rat populations may remain low and undetected for shorter periods. Rats were first reported as being present five months after the operation on Wake Island; eight months after on Henderson Island; 13 months after on Desecheo; and two years after on Enderbury. At the time of writing 14, six, four and three years have passed for the Frégate, Ringgolds, Birnie and Palmyra projects, respectively, and all four islands remain rat free. A failed attempt to eradicate rats from Palmyra Atoll in 2001 was hampered by both technical and implementation constraints and was not evaluated (USFWS, 2011).

Identifying potential factors that influenced success and failure.

While there are other alternate or contributing hypotheses (Table 2; Holmes, et al., 2015), the most proximate reason for the reduced rate of success for tropical rodent eradications is likely to be that not all rats consumed a lethal dose of brodifacoum, the rodenticide used in most rat eradications (Howald, et al., 2007) either because they did not have access to sufficient bait or because they did not consume bait that was available (Holmes, et al., 2015). We used the framework outlined in Keitt, et al. (2015) to review the four unsuccessful projects. To determine if some individuals within the rat population *could not* eat a lethal dose of bait, we reviewed operational design, operational procedures, GIS maps of bait coverage, baiting density,

Table 1 Characteristics of the islands where the eight projects were undertaken.

Permanent human population	0	100–200	0	0	0	12	2	20–30

[a]The Wake project successfully removed *Rattus tanezumi* but not *R. exulans* from Wake Atoll and successfully removed both species from part of the atoll, Peale Island (95 ha).

Table 2 Hypotheses to explain increased failure of rat eradications on tropical islands.

Proximate cause	Underlying cause	Possible response to increase success rates
Some individuals within the island's rat population could not eat a lethal dose of bait		
	Land crabs or other species consume bait	Higher bait application rates Additional bait applications Bait at a time when competitors are at lower density or less active
	Rats have small home ranges	Higher bait application rates Flexible scheduling to apply bait when food supply low
	Bait decomposes rapidly	More preservatives in bait Additional bait applications
	Lactating females or young in nest when bait available	Bait available longer (more bait, additional applications) Flexible scheduling to drop bait when breeding is reduced or non-existent.
	Rats don't leave human dwellings	Comprehensively bait entire island including within commensal areas
Some individuals within the island's rat population would not consume a lethal dose of bait		
	Bait biodegrades rapidly	More wax or preservatives in bait Additional bait applications
	Abundant natural food	Multiple bait formulations Bait available longer (more bait, additional applications) Flexible scheduling to drop bait when food supply low
	Individual foraging preferences	Multiple bait formulations Bait available longer (more bait, additional applications)
	Lactating females very neophobic	Bait available longer (more bait, additional applications)
	Different dietary preferences of lactating females	Multiple bait formulations Bait available longer (more bait, additional applications) Flexible scheduling to drop bait when food supply low
Poor quality planning and implementation		
	Lack of capability	More training & collaboration Appointment of experienced staff Adequate resourcing Peer review during the planning process
	Lax regulatory requirements	Plan & implement using internationally recognised standards
	Insufficient resourcing	Source more funding Increase collaboration
Higher rate of reinvasion		
	Warm water allows increased swimming distances	Select more isolated islands
	Human use characteristics	Better biosecurity Incorporate human use into island selection criteria

bait availability over time, timing between applications, and any operational difficulties noted. The statistical approach of Holmes, et al. (2015) could not address all of these issues because of the scarcity of well documented projects such as those we investigated. We also assessed bait toxicity and the chance that rats were resistant or tolerant to anticoagulants. Insufficient information was available to evaluate the impact of any spatial variation in land crab density across each of the islands.

To evaluate if some individuals within the rat population *would not* eat a lethal dose of bait, we looked at the operational design, the bait type, data from trials completed, the environmental conditions present at the time of the eradication and any observations made during implementation. Evidence for and against each factor was evaluated and used to form an opinion on its relative importance to the project's outcome. Evidence for the existence of a similar or different set of conditions for the successful projects was used to inform this analysis.

Not all projects monitored bait availability over time and for those projects that did, different methods were used, making it difficult to compare how long bait remained available to rats after its application. To compare between projects we used both the minimum period of time that bait was available in all plots or transects sampled and, where data were available, the lower limit of 99% CI of the T-Statistic for bait availability four days after its application as recommended by Pott, et al. (2015). For those islands where no monitoring was undertaken we used anecdotal reports to provide an estimate of the minimum period of bait availability.

Comparison among projects

We undertook a qualitative comparative review because the number of projects that formed the basis of our assessment was small, there was inconsistency between projects in the data collected and the methods by which data were obtained. A qualitative comparative review allows for generalisations to be made among cases and we considered it the best option for this study. Akin to Abrahamsson, et al. (2003), we cross-examined all projects to identify factors common to successful or unsuccessful projects. To inform this cross examination we drew from Holmes, et al. (2015) and our cumulative experience to identify a set of environmental variables and components of operational design we considered to be important to the success of rat eradication operations. These variables are listed in Tables 1–3. Information on each project was obtained from documentation prepared prior to and after project implementation and from personal communications with project team members.

RESULTS

Identifying causes of operational failure

Some individuals within the island's rat population could not eat a lethal dose of bait

The design of each of the four unsuccessful eradications, encompassing aerial application, overlapping aerial bait swaths, application rates comparatively higher than those applied in temperate regions and a minimum of two applications (Table 4), should have ensured comprehensive coverage of the islands with rodent bait. During the first bait application on Desecheo, some technical difficulties resulted in several small areas of the island (the largest being ~0.8 ha in size) receiving bait at less than the planned application rate. These issues were remedied for the second application when a more even spread of bait was achieved and, between both applications, comprehensive coverage of the island was achieved. Similarly, with the exception of areas deliberately excluded from bait application such as the sealed runway on Wake, we could not discern any biologically significant gaps in bait distribution from a review of the GIS data accumulated for any of the four unsuccessful projects. A biological gap was defined for our analysis as a gap greater than 0.015 ha in area. This was the smallest home range size reported in the literature for any of the four rat species targeted (Wirtz, 1972; King, 1990; Shiels, 2010; Low, et al. 2013).

On this basis we conclude that the operational strategy employed on Henderson, Desecheo and Enderbury likely ensured that all foraging rats encountered rodent bait. Although not identified from GIS maps of bait spread, it was more difficult to reach the same conclusion for Wake because of the more complex operational strategy (multiple methods of bait application) employed there (Griffiths, et al., 2014). The existence of interspecific competition, not a factor for the other islands, also likely limited access to bait for some individual rats. However, the successful eradication of *R. tanezumi,* formerly widespread across the atoll (Griffiths, et al., 2014), demonstrated that broad coverage across all habitats was achieved.

All four projects had factored bait consumption by non-target species such as land crabs into operational decisions on application rates (Table 4). However, bait disappeared more rapidly than anticipated from some transects monitored on Wake and Desecheo (Brown, et al., 2013; Brown & Tershy, 2013) (Table 4). Bait persisted in all transects monitored on Henderson until close to the end of the 30-day monitoring period (Brooke, et al., 2011). However, as described by Pott, et al. (2015), a different monitoring method was used and, because of the inaccessible nature of the island, monitoring was confined to a small part of the island. No monitoring of bait availability was undertaken on Enderbury but ad hoc observations suggest that rodent bait was broadly available for at least the first five days after its initial application (Pierce & Kerr, 2013).

Rat pups yet to emerge from the nest may not have had immediate access to bait. Evidence of rat breeding activity was documented on all four islands at the time of implementation (Brooke, et al., 2011; Brown, et al., 2013; Brown & Tershy, 2013; Pierce & Kerr, 2013). A rat of indeterminate age was sighted and captured on Desecheo, 23 days after the first bait application. On Wake, a juvenile *R. exulans* was found inside a bait station 18 days after bait was first applied and a second juvenile *R. exulans* was caught alive at the base of a coconut (*Cocos nucifera*) palm after 47 days. A low body weight and large head relative to body size indicated the latter individual had suffered from malnutrition likely because of having been weaned prematurely. As evidenced by liver assay, it had been exposed to brodifacoum (Griffiths, et al., 2014). No live rats were seen by project team members monitoring Henderson rails (*Porzana atra*) at the north-east end of Henderson beyond five days after the initial bait application, despite being on the island for more than three months after the operation. However, two very small, freshly dead, likely juvenile, rats were discovered 11 and 14 days after bait was applied suggesting these animals had survived for 10–13 days after the initial bait application.

Operational procedures were in some instances modified during project implementation due to environmental and physical factors encountered during the operation and/or the detection of a small number of rats after bait application. Lack of accurate geographical data led to an underestimate of island size for Henderson during project planning. As a consequence, the application rate for the second application across the island's plateau had to be reduced from 7 kg/ha to 6 kg/ha (Torr & Brown, 2012). Methods for applying bait to vegetated intertidal habitats were modified during implementation on Wake (Griffiths, et al., 2014). Bait stations were also deployed and bait was hand spread at several sites on Wake to target rats detected within five months of bait application, although such efforts were eventually abandoned after increasing numbers of rats sighted confirmed the eradication had been unsuccessful for *R. exulans* (Griffiths, et al., 2014). We do not consider the operational changes made for these three projects to have reduced the availability of bait to rats. No significant changes to the operational strategy were reported for the Enderbury project and bait application, as described by team members, followed the prescription outlined within the project's operational plan.

Based on the evidence available, we conclude that some individuals within the island's rat populations could not eat a lethal dose of bait. Unweaned rats present at the time of bait application did not have immediate access to bait and, as evidenced by individuals surviving for so long after bait application on Wake, this is also likely for some breeding female rats. However, we cannot conclude that this factor was the only cause of failure for the four failed projects.

Bait toxicity

Assays of samples of the rodent bait applied on Henderson (mean brodifacoum concentrations of 16.4 ppm), Wake (28.3 ppm) and Desecheo (29.3 ppm) confirmed that bait toxicity was within normal tolerances (Brown, et al., 2013; Brown & Tershy, 2013; RSPB, unpublished data). Inadequate bait toxicity is unlikely to have been a factor on Enderbury because the bait used there was produced at the same time as the bait used for the successful Birnie operation. Mortality associated with the operation and a rapid decline in rat numbers was also observed at all sites. All three bait types used are produced via an industrial production process with quality assurance checks in place to ensure appropriate rodenticide concentrations prior to shipping and all have been used successfully on both temperate and tropical islands. Based on the evidence available we conclude that inadequate bait toxicity was not a factor in the failure of the four unsuccessful projects reviewed.

Resistance

There were no indications to suggest rats on Henderson, Wake, Enderbury and Desecheo were resistant or tolerant to anticoagulants. Rats on Henderson, Enderbury and Desecheo had no prior exposure to anticoagulants so there was no selection pressure for pharmacodynamic resistance involving mutations in the Vkorc1 gene. For Henderson, subsequent testing of rats from the surviving population confirmed the lack of any genetic basis for resistance to brodifacoum (RSPB, unpubl. data). Although anticoagulants were used on Wake prior to the eradication (Mosher, et al., 2008) available evidence, as discussed in Griffiths, et al. (2014), did not support resistance as a factor in the project's outcome. Most importantly, although increased tolerance to brodifacoum has been documented for some rat populations, 'practical' resistance, as defined by Buckle & Prescott (2012), that might have caused the Wake project to fail, has never been encountered, even at sites where anticoagulants have been used repeatedly for long periods of time (Lund, 1984; Bailey, et al., 2005). It is unknown if any plant species present on Henderson, Wake, Desecheo and Enderbury contained elevated levels of vitamin K, but dietary-based resistance is not considered a major mechanism of resistance elsewhere (Buckle & Prescott, 2012). Based on the lack of evidence for resistance or increased tolerance to anticoagulants we conclude that this mechanism was not a factor in the recorded failures.

Some individuals within the island's rat population would not consume a lethal dose of bait

All four of the unsuccessful projects used proven bait types (Table 4) that have achieved rat eradication on other tropical islands. In addition, palatability of two of the bait types was proven by bait exposure trials undertaken on Henderson and Desecheo that showed, through use of a biomarker, 100% acceptance by trapped rats (Swinnerton & McKown, 2009; Brooke, et al., 2010). On Wake, concerns about behavioural resistance were generated after some rats in a two-choice laboratory trial undertaken on the island (Mosher, et al., 2008) were documented not eating rodent bait. Three *R. exulans* also avoided exposure during an *in situ* biomarker trial (Wegmann, et al., 2009). However, as outlined by Griffiths et al. (2014), the successful elimination of *R. tanezumi* from the atoll, the complete removal of *R. exulans* from a discrete part of the atoll (Peale Island), and the marked reduction of *R. exulans* for a period of time, are not consistent with a bait shy rat population. No pre-eradication trials to assess bait palatability were undertaken on Enderbury.

Some evidence for neophobia or rats preferring alternative foods over rodent bait was seen at the time of bait application for Enderbury and Wake. On the first night after the initial application of bait on Enderbury, rats were observed walking past rodent bait, despite it being readily available, to forage on the flowers and fruits of *Tribulus cistoides* on the island (Pierce & Kerr, 2013). Observations of rats foraging on natural foods in the presence of bait were also made on Wake (Griffiths, et al., 2014). However, it is unknown if such observations are unusual or should be considered the norm for rodent eradications, because of a lack of information.

Relative to previous site visits, signs of elevated resource availability were observed on Henderson and Enderbury islands (Cuthbert, 2012; Pierce & Kerr, 2013) at the time of project implementation. Rainfall leading up to the operations is presumed to have led to this increase (Cuthbert, 2012; Pierce & Kerr, 2013). On Henderson, three plant species, *Cyclophyllum barbatum, Myrsine hosakae* and *Eugenia reinwardtiana* were observed with more fruit than seen in previous years and the presence of a large number of recently fledged fruit doves (*Ptilinopus insularis*) indicated that a large fruiting event had occurred shortly prior to the operation (Cuthbert, 2012). On Enderbury, 10 of the 11 common plant species present were recorded as either flowering or fruiting at the time of the operation including the four dominant plants *T. cistoides, Portulaca lutea, Boerhavia albiflora* and *Sida fallax*. Higher than average rainfall prior to the unsuccessful Desecheo eradication (as evidenced by mainland weather records) may have also generated increased food availability there (Brown & Tershy, 2013). It is unknown if resources on Wake were elevated at the time of the operation, but abundant seed observed on *Casuarina* trees growing across the island at the time of the operation and high numbers of rats observed at the time of the operation correspond with this possibility.

Based on available evidence we cannot reach a definite conclusion on the role of this factor in the outcome observed in the four unsuccessful projects. However, the elevated availability of alternative resources may have compounded other factors such as rat breeding to influence project outcome.

Comparison among all eight projects

We could not separate unsuccessful projects from successful projects based on geographic location, habitat or standard climatic variables (Table 1). However, three of the unsuccessful projects were undertaken on islands significantly larger than those that were successful. Rats were also successfully removed from the smaller of the two disconnected land masses that comprise the Wake Atoll complex (Griffiths, et al., 2014). Commensal issues associated with the presence of a resident human population, a known risk factor for rodent eradications (Oppel, et al., 2011), were a significant component of the Wake project but were also present, albeit on a smaller scale, on three of the islands where rats were successfully removed suggesting these issues were not insurmountable.

Similarly, more parallels than differences were evident between successful and unsuccessful projects for the environmental variables identified by Holmes, et al. (2015) and ourselves as important to eradication success (Table 3). Elevated rainfall preceding the eradication operation differentiated three of the unsuccessful projects, Desecheo, Henderson and Enderbury. However, abundant natural food resources, as observed on Henderson, Enderbury, Desecheo and Wake at the time of project implementation, were also observed on Palmyra, the Ringgolds and Frégate where rats were successfully removed. Fruiting *Pandanus tectorius*, coconut and nesting sooty terns (*Onychoprion fuscatus*) on Palmyra, *Terminalia littoralis* fruit and coconut on the Ringgolds and coconut, multiple fruiting tree species, breeding seabirds, kitchen refuse, cultivated crops and food for livestock on Frégate all offered plentiful resources to rats. However, the level of natural food availability during project implementation relative to other times of the year for these islands is unknown. An abundance of natural resources was not documented on Birnie, where rats were successfully removed. Little flowering or fruiting by the four common plant species that are present was noted on this island at the time of the implementation (Pierce & Kerr, 2013).

Land crabs were an influential factor on all eight islands. Bait availability data provided some indication of their relative impact on each of the operations but, in the absence of crab survey data for each island, an independent assessment of relative crab population density among islands was not possible. Such data would have provided a clearer picture of the relative impact of land crabs on project success. Anecdotal observations suggest that rat numbers were high on all eight islands at the time of project implementation, but relative population densities were once again unknown. Reproduction was not investigated on the Ringgolds, but evidence indicates that rats were breeding at the time of the eradication at the other sites. On Palmyra, where rats were successfully removed, a juvenile rat was sighted and captured 28 days after the initial bait application within the island's commensal area where bait stations were being maintained. This individual was near death and an assay of its liver confirmed exposure to brodifacoum. Like the second of the two juveniles discovered on Wake after bait application, this rat also appeared malnourished. It is possible, based on observations of elevated rainfall and increased resource availability, that the intensity of rat breeding was higher on Henderson, Enderbury and possibly Desecheo than on the islands where rats were successfully removed but in the absence of data this cannot be confirmed. Two of the successful projects targeted rat populations that had previously been exposed to anticoagulants (Table 3). Rats on Palmyra, where anticoagulants had been used previously, were thought to be tolerant to brodifacoum because some individuals survived for longer than anticipated during a toxicity trial (Howald, et al., 2004), yet this project was successful.

Details for each of the eight eradication operations are presented in Table 4. All projects used a helicopter and bait spreading bucket as the principal method for bait application, utilised proven rodent bait types and applied bait with a similar swath overlap. The main difference between operations was in the amount of bait applied, which ranged between 10 and 84 kg/ha for the first application and between 6 and 79 kg/ha for the second. Difference in application rate was largely a function of decisions made by respective project teams based on an assessment of relative bait competition by land crabs for each island. While this difference was evident, there was no clear relationship between application rate and success or failure for the eight projects (Table 4). Relative to the three unsuccessful projects where monitoring of bait availability was undertaken, bait on Palmyra also disappeared rapidly but remained at higher densities beyond the seven-day observation period in coconut canopy (Berentsen, et al., 2013), a preferred habitat for rats (Wegmann, 2008). Bait persisted in all plots monitored on Frégate for 10 days after its application and bait availability would have been extended by the third application (Merton, et al., 2002) but this was not monitored. No monitoring of bait was undertaken on Birnie or the Ringgolds, but bait was reported to be widely available on both islands for the six days between the first and second applications of bait.

As with two of the failed projects, operational procedures were also modified during project implementation for two successful projects. For instance, an unplanned third application of bait was completed following the sighting of

Table 3 Environmental variables present at the time of project implementation that could have influenced the project's outcome.

	Henderson	Wake	Desecheo	Enderbury	Birnie	Palmyra	Ringgolds	Frégate
Project outcome	Failed	Failed	Failed	Failed	Succeeded	Succeeded	Succeeded	Succeeded
Hermit crabs present	Yes	Yes	Yes	Yes	Yes	Yes	Yes	Yes
Other land crab species present	No	No	Yes	No	No	Yes	Yes	Yes
Ant species present	Yes	Yes	Yes	No	No	Yes	Yes	Yes
Permanent human population present	No	Yes	No	No	No	Yes	Yes	Yes

Rat population breeding at time of project implementation	Yes	Yes	Yes	Yes	Yes	Yes	Unknown	Yes

[a]Inferred from observations of flowering and fruiting during project implementation.

a surviving rat on Frégate Island (P. Garden, pers. comm.). On Palmyra, bait was hand broadcast across a 10 ha area on Cooper Island following the discovery of the juvenile rat mentioned above (Wegmann, et al., 2012). No changes to the operational strategy were reported for the Ringgolds and Birnie projects and, as with the Enderbury project, bait application proceeded according to plan.

From our qualitative comparative analysis, we could not reach a conclusion on the role of geographic, habitat, climatic and environmental variables or operational parameters on the relative outcome of the eight projects reviewed. The two variables that best differentiated unsuccessful from successful projects were elevated rainfall preceding the operation and island size.

DISCUSSION

Reasons for project failure

Based on the robust design of the eradication operations reviewed and GIS maps of bait coverage, we conclude that bait was made available to all rats actively foraging at the time of the operation for the Henderson, Enderbury and Desecheo projects. We cannot be as confident of this for Wake, despite one rat species being successfully eradicated, because the more complex operational strategy employed there coupled with competitive exclusion may have led to functional gaps in bait availability (Griffiths, et al., 2014). Notwithstanding the greater risk on Wake, some individuals within the rat population were not actively foraging at the time of bait application on all four islands

Table 4 Key elements of operational design for the eight projects.

	Henderson	Wake	Desecheo	Enderbury	Birnie	Palmyra	Ringgolds	Frégate
Project outcome	Failed	Failed	Failed	Failed	Succeeded	Succeeded	Succeeded	Succeeded
Bait type[a]	20R	25W	25D	20R	20R	25W	20R	20R
Application rate 1st/2nd/3rd bait applications (kg/ha)[b]	10/6[c]	18/9	19/10	22/17	25/25	84/79	16/11	14/9/12
Mean total bait application rate (kg/ha)	17.4	27.7	29	38.4	50	165	27	35
Percentage swath overlap per application	50/25	50/50	50/50	50/25	50/25	50/50	50/50	50/50/50
Area of plot/transect used to sample bait availability	~270 m^2	25 m^2	25 m^2	NA	NA	2.49 m^2	NA	10 m^2
Number of days that bait remained available in all sampled plots/transects after 1st application	25+	3	2	6[d]	6[d]	1[e]	10[d]	10[f]
Number of days that bait remained available in all sampled plots/transects after 2nd application	20+	5	1	Unknown	Unknown	1[d]	Unknown	5[e]
Number of days between applications	5	9	10	5	6	6	10	5/24
Lower 99% CI of the T-statistic for bait available four days after the 1st application (kg/ha)	1.93	6.33	0.25	Unknown	Unknown	19.16	Unknown	-3.32
Areas excluded from aerial bait application	No	Yes	No	No	No	Yes	No	Yes

[a] Bait pellet types listed are 20R – Pestoff 20R rodent bait produced by Animal Control Products, Wanganui, New Zealand; 25W – Brodifacoum-25W Conservation manufactured by Bell Laboratories, Wisconsin, USA; 25D – Brodifacoum-25D Conservation manufactured by Bell Laboratories, Wisconsin, USA.
[b] Areas subject to hand broadcast were applied at the same rates as for aerial application.
[c] Rates listed here were used across the island's plateau which amounted to 95% of the island's area. Higher bait application rates were applied in the vicinity of the island's beaches where hermit crabs were most numerous.
[d] No monitoring of bait availability was undertaken and figures are inferred from ad hoc observations. The project team left the islands after the number of days listed.
[e] The figure reported is for terrestrial plots: bait persisted longer in coconut palm canopy.
[f] No monitoring was undertaken after the 3rd application which would have extended the number of days that bait was available.

where rats survived. Rats were breeding on Henderson, Wake, Desecheo and Enderbury at the time of project implementation and evidence suggests that brodifacoum is not passed on in sufficient amounts via lactation to cause mortality (Milne, et al., 2001; Gabriel, et al., 2012). Pups in the nest at the time of bait application were therefore effectively isolated for the period they were dependent on the lactating female.

Such a scenario has been previously considered by eradication practitioners as a theoretical possibility (e.g. Broome, et al., 2011), but the discovery of juvenile rats on both Palmyra and Wake after bait application validates it as a very real concern for tropical island rodent eradications, where breeding cycles cannot be predicted with certainty. Weaning times reported for *R. exulans* (Wirtz, 1972; Tobin, 1994), *R. rattus* (Cowan, 1981; Yom-Tov, 1985) and *R. norvegicus* (King, 1990) range from 21 to 28 days, much longer than the period over which bait is typically available for tropical rat eradication projects including a number of the projects reviewed here.

It has generally been accepted that breeding females, like other individuals within a rat population, would access and ingest a lethal dose of bait and die within a few days of bait application. However, there are reasons to be sceptical that this will always occur. Home ranges for female rats (e.g. *R. rattus*) can be significantly smaller than those of males (Pryde, et al., 2005) and, as has been documented for house mice (*Mus musculus*) (Krebs, et al., 1995), lactating female rats may have constricted foraging ranges. Changes in dietary requirements by rats can also occur during lactation (Leshner, et al., 1972) potentially affecting bait palatability. The maximum period of time documented for mortality following the ingestion of a lethal dose of brodifacoum is 21 days, from a trial conducted with captive *R. rattus* on Palmyra (Howald, et al., 2004). Any of these traits could increase the chance of juveniles emerging after bait is no longer readily available on an island and, with natural food abundant on many tropical islands, these individuals have an enhanced probability of survival.

The fact that bait remained available in all transects monitored on Henderson for more than 25 days challenges the premise of juvenile survival as a potential cause of failure for this project. However, as described by Pott, et al. (2015), a different method of monitoring bait availability was used for this project and monitoring was confined to one small corner of the island (Brooke, et al., 2011) so comparison with other projects is difficult. It is also possible that bait disappeared more rapidly in unmonitored parts of the island. Bait was applied at a lower rate on Henderson than in the other projects reviewed and this, coupled with the island's complicated 'makatea' or uplifted coral substrate, may have reduced the rate at which breeding female rats encountered bait.

Rats were confirmed as breeding during project implementation on Birnie, Palmyra and Frégate where rats were successfully removed. Why did these projects succeed? Some explanations can be tendered but, without additional evidence, cannot be verified. For example, the high bait application rate used on Palmyra likely ensured that breeding female rats rapidly encountered bait plus bait in the coconut palm canopy, a known nesting habitat for female rats, was accessible for a longer period. On Frégate, a third bait application extended the period of bait availability out beyond 24 days and less competition by hermit crabs and lower rat densities on Birnie may have increased bait availability there. It is also plausible that in the absence of the supplementary interventions made on Palmyra and Frégate, these projects could also have failed. Insufficient information is available to form similar conclusions for the Ringgolds project.

We were able to rule out inadequate bait toxicity and resistance as factors for the survival of rats on Henderson, Enderbury and Desecheo and the persistence of *R. exulans* on Wake. Neither has been documented for any of the 490 attempted higher latitude rat eradications and we know of no viable hypothesis that would predict a greater incidence of resistance in rats or insufficient bait toxicity for tropical rat eradication projects. For the unsuccessful projects we reviewed we reject bait toxicity as a factor based on: factory test results demonstrating that the bait used on Henderson, Wake and Desecheo contained a sufficient concentration of brodifacoum; the marked reduction in rat numbers on all three islands; and the fact that *R. tanezumi* was successfully removed from Wake. The bait applied on Enderbury was produced as part of the same consignment as that was used successfully to remove rats from Birnie.

Similarly, we found no evidence to support anticoagulant resistance as a factor in the unsuccessful outcome seen on Henderson, Wake, Desecheo and Enderbury. Rat populations on Henderson, Enderbury and Desecheo had no prior exposure to anticoagulants and the successful eradication of *R. tanezumi* from Wake, the removal of *R. exulans* from part of the atoll, and the reduction of *R. exulans* to undetectable levels elsewhere is at odds with the levels of survivorship reported for rodent populations in which practical resistance has been documented (e.g. Drummond & Rennison, 1973; Greaves, et al., 1982). Most importantly, 'practical' resistance to brodifacoum that might have caused the failure of these projects, has never been encountered, even at sites where anticoagulants have been used repeatedly for long periods of time (Buckle & Prescott, 2012). Increased tolerance to brodifacoum has been detected in some locations (Buckle & Prescott, 2012) and may have been present on the three islands where anticoagulants had been used previously. However, rats were successfully removed from two of these islands including Palmyra where a bait toxicity trial had suggested the possibility of anticoagulant tolerance.

Conflicting evidence meant we could not rule out the possibility that some rats avoided rodent bait in preference for natural foods. Certainly, for all four unsuccessful projects, natural food was readily available to rats at the time of project implementation. Observations of rats foraging on natural foods after bait application on Enderbury and Wake lend weight to this hypothesis. However, this may simply have been a function of neophobia, as described by Barnett (1956), and not necessarily active bait avoidance. We are unaware of similar observations from other projects, but this is likely a result of insufficient observational effort. The discovery of recently weaned juvenile rats on Palmyra and Wake, more than four weeks after bait application, suggests that some individuals, in this case lactating female rats, may have avoided bait for a period. Rats detected on Desecheo and Fregate after bait application also point to this possibility. Set against this evidence is the fact that natural food was also available on the islands where rats were successfully removed, and signs of malnutrition and early weaning of the juveniles found on Palmyra and Wake suggest that the females producing these pups died because they consumed bait. A necropsy verified bait consumption for the Desecheo rat and the Frégate project was ultimately successful, confirming all individuals there were eventually exposed. The successful removal of the more dominant rat species on Wake also perhaps points to bait availability rather than bait palatability as the more important influence.

In summary, it is unknown if the elevated availability of natural resources on Henderson, Enderbury, Wake and Desecheo led to bait avoidance, but the possibility cannot be discounted. Increased natural food availability may have also compounded other factors influencing project success such as the intensity of rat breeding. Given the unpredictability of resource availability within many tropical island ecosystems this will need to be an important consideration for future rat eradication projects.

Comparative analysis

We could not separate unsuccessful projects from successful projects based on habitat or standard climatic variables. However, three of the unsuccessful projects were undertaken on islands significantly larger than those that were successful and both rat species present on Wake were removed from Peale Island, one of the two land units that make up the Wake Atoll complex. This is consistent with the trend identified by Holmes, et al. (2015) of an increasing failure rate for larger islands. It is therefore possible that the outcomes observed on Henderson, Wake and Enderbury were simply a consequence of biogeographic theory. Larger populations on the bigger islands increased the chance that some individuals would avoid bait or that some breeding females would survive for long enough to wean juveniles when bait was no longer readily available. No threshold for island size has yet been identified for rodent eradications undertaken using the methodology reviewed in this paper. However, the threshold may be smaller for tropical islands because of increased availability of natural resources, higher rat population densities and the likelihood that a proportion of the population will be breeding during project implementation.

Rainfall is closely linked to ecosystem productivity on tropical islands (Murphy & Lugo, 1986) and elevated rainfall levels preceding the eradication were associated with three of the unsuccessful projects reviewed. Variability in rainfall was also found by Holmes, et al. (2015) to be correlated with failure for tropical rat eradications. However, as discussed above, we could not fully resolve whether rainfall contributed to an increased risk of failure for these projects because palatability of rodent bait was reduced in the presence of increased natural food availability or greater reproductive activity within the targeted rat populations led to juveniles surviving the eradication attempt.

In summary, although our review of eight tropical rodent eradications could not discern the relative importance of bait availability or bait palatability in the outcome of the four unsuccessful projects, it suggests that both are important to consider in the planning of future rodent eradications on tropical islands. In the absence of a more palatable bait type, we recommend greater emphasis is placed on operational design for future tropical island rodent eradications. As recommended by Keitt, et al. (2015), projects should aim to ensure that bait is readily available within all rat territories for a period of time that allows all individuals within the population to encounter bait. Even though the projects we reviewed were well documented, our analysis was limited by a lack of consistency in data collection. Until more is known about the mechanisms that promote survival during a rat eradication attempt, future monitoring of eradication projects undertaken on tropical islands should aim to document as many of the variables discussed in this paper as possible to determine the relative importance of these factors in the project's fate. Standardisation of monitoring protocols, as promoted by Keitt, et al. (2015) and Pott, et al. (2015), should also be instigated.

ACKNOWLEDGEMENTS

We would like to thank the organisations who supported, advised or implemented the projects we reviewed and who were willing to share the information on which this publication was based. The organisations and individuals on whom we relied upon for information include the Royal Society for the Protection of Birds, U.S. Air Force, U.S. Fish and Wildlife Service, The Nature Conservancy, EcoOceania Pty Ltd, Island Conservation, the New Zealand Department of Conservation and Peter Garden.

We are also extremely grateful to the organisations and individuals who supported the tropical island rodent eradication workshop held in Auckland, New Zealand in 2013. The views expressed in this paper reflect the wider experience and knowledge of workshop attendees. The workshop was funded in part by the National Fish and Wildlife Foundation and the David and Lucile Packard Foundation. We are indebted to James Russell and Nick Holmes for constructive criticism on the structure and content of the manuscript.

All authors were involved in drafting the manuscript or revising it critically for important intellectual content, and all authors approved the final version to be published. RG had full access to all the data used in the study and takes responsibility for the accuracy of its tabulation. RG, AW, WP, RC, DB, SC supplied information on which the paper is based.

Eradication of mice from Antipodes Island, New Zealand

S. Horn, T. Greene and G. Elliott

Department of Conservation, P.O. Box 743, Invercargill, New Zealand. <*shorn@doc.govt.nz*>

Abstract In winter 2016, the New Zealand Department of Conservation (DOC) eradicated mice (*Mus musculus*) from the Antipodes Islands located at 49°S 178°E, 760 km south-east of New Zealand's South Island. Mice were the only mammalian pest species present. They have extensively impacted the abundance and survival of invertebrates, with likely secondary impacts on endemic terrestrial birds and nesting seabird fauna. Public-private partnerships with DOC instigated the project and provided essential financial support. Baseline scientific data for operational planning and outcome monitoring were collected by a research expedition in July 2013 and project planning began in 2014. At the time of writing, this is the largest eradication of mice undertaken where mice are the sole mammalian pest species. Logistical challenges were complicated by a broad range of regulatory obligations. The expedition-style project used a ship to deliver a team and equipment to Antipodes Island where they established camp and remained until the completion of baiting. Bait spread was completed incrementally as weather allowed, comprehensively covering the islands in two separate treatments between 18 June 2016 and 12 July 2016. The last sign of mice was detected 20 days after the first application of bait and the eradication of mice was confirmed by monitoring in late summer 2018. Public engagement was achieved with regular operational updates across multiple platforms and positive media coverage. Non-toxic bait trials accurately predicted some by-kill of pipit (*Anthus novaeseelandiae steindachneri*) but did not anticipate poisoning of some Antipodes parakeet (*Cyanoramphus unicolor*) and Reischek's parakeet (*Cyanoramphus hochstetteri*). Known pest-free islands were not baited, providing refuge for land birds to mitigate the risk. Fledging success of Antipodean albatross *(Diomedea antipodensis antipodensis)* chicks was not impacted by the operation and those species that were affected had recovered by summer 2018.

Keywords: brodifacoum, house mouse, Million Dollar Mouse, *Mus musculus*, non-target impacts, subantarctic

INTRODUCTION

The Antipodes Islands group (2,100 ha) is in New Zealand's Subantarctic Islands region and was gazetted as a Nature Reserve in 1978 and a World Heritage site in 1998. The group comprises six islands and one islet located in the Southern Ocean, at 49°41'S, 178°48'E, 760 km from New Zealand's South Island (Fig. 1). The islands are uninhabited and administered by New Zealand's Department of Conservation (DOC). House mouse (*Mus musculus*) was the only mammalian pest species present and known only on the main island, Antipodes Island (2,012 ha).

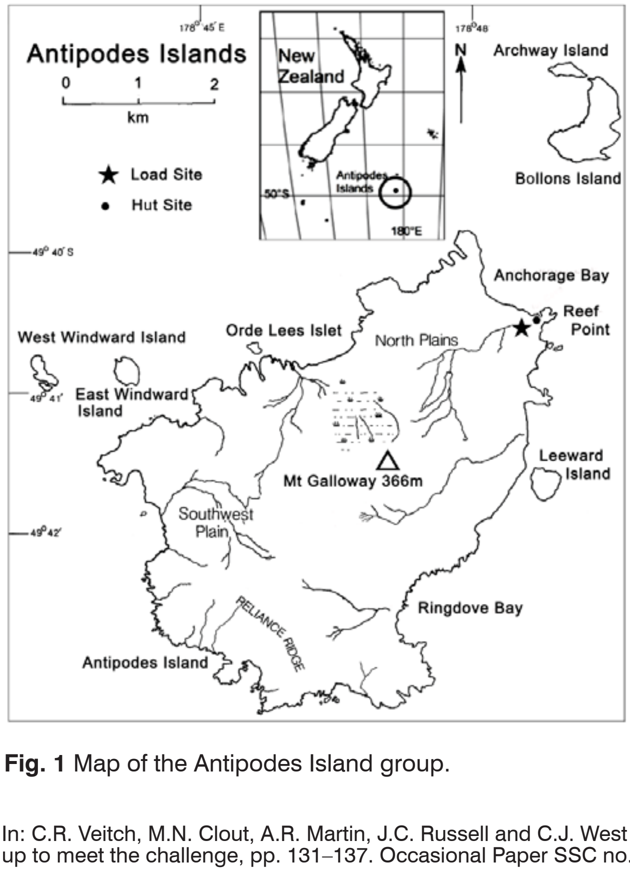

Fig. 1 Map of the Antipodes Island group.

The Antipodes were discovered in 1800 and sealers arrived by 1804 (Taylor, 2006). A small shelter (castaway depot) was built in 1886 to support shipwreck survivors. It was resupplied periodically until 1927 (Taylor, 2006). Mice were first recorded on Antipodes Island in 1907 but probably arrived earlier (McIntosh, 2001) with sealers or as the result of a foreign shipwreck (*Spirit of the Dawn*) in 1896 (Taylor, 2006). DNA studies of the mouse population identified a mtDNA haplotype also found in Spain but not elsewhere in New Zealand (Searle, et al., 2009.).

Mice were abundant; their density has been recorded as high as 147/ha in the coastal zone (Russell, 2012). They have had a significant detrimental impact on the endemic, rare and threatened animal species. Invertebrates have been severely depleted. Mice are responsible for the general absence of large beetles and the extirpation of at least two taxa: *Loxomerus* n.sp. and *Tormissus guanicola* (Marris, 2000); and several large ground dwelling species are severely restricted in distribution (Marris, 2000; Russell, 2012). Mice also compete with the four endemic land birds and have suppressed at least two species of burrowing seabirds: black-bellied storm petrels (*Fregetta tropica*) and subantarctic little shearwater (*Puffinus elegans)* (Imber, et al., 2005).

The aim of the project was to eradicate mice from the archipelago to halt the degradation of biodiversity and allow native species to recover and flourish. Eradicating mice would also protect potentially vulnerable species, for example the nationally critical Antipodean albatross *(Diomedea antipodensis antipodensis)*, from potential attacks as recorded on Gough Island and Marion Island (Davies, et al., 2015; Dilley, et al., 2016).

The site has good ongoing biosecurity integrity. The islands are remote and isolated, landing requires a permit and the coastline is generally inaccessible, with no harbour. In 2012, DOC partnered with the Morgan Foundation to initiate the project. The Morgan Foundation fronted a highly publicised fundraising campaign "Million Dollar Mouse" (MDM), and matched public donations dollar for dollar. Additional funding came from DOC and other partners, WWF New Zealand and Island Conservation.

MATERIALS AND METHODS

Planning

DOC planned and managed the operation from its Murihiku Office in Invercargill. Planning started in February 2014, with the employment of a full-time project manager, and took two and half years with a core team of two increasing to four in the last six months. A much larger DOC team supported pre-departure preparations. The Department's Island Eradication Advisory Group (IEAG) was engaged from the start, providing technical oversight. Eradication design was based on agreed best practice (Broome, et al., 2019). DOC's Animal Pest Framework and elements of DOC's Project Management Framework (PMF) provided the tools to manage the project.

Procurement

Helicopter and shipping services were sourced using government processes. In early 2016, DOC contracted the services of the M.V. *Norfolk Guardian*, a coastal freighter flagged in Kingdom of Tonga and a yacht, S.V. *Evohe*, to supplement passenger transport.

An experienced eradication pilot was engaged as a consultant to progress planning while a helicopter supplier was being sought. Following consultation with potential suppliers, a temporary hangar (16 m × 12 m × 5. 6 m high) and a large wooden platform (29 m × 13.8 m) incorporating a helipad were added to the planned infrastructure to help protect helicopters and other sensitive equipment from the elements. The hangar was fastened to the wooden platform and the whole structure anchored with 38 t of water ballast positioned around the base of the hangar frames in palletised 1,000 l cage tanks (Intermediate Bulk Containers). The anchoring system was designed for easy installation and extraction and to withstand winds of up to 190 km/hr.

A specialist company "Island Aerial Solutions Ltd" (IASL) was contracted to supply helicopter services and a helicopter engineer. Three helicopters were taken to the island, two AS350 Squirrels (1 × B2 and 1 × FX2) and one Robinson R44. The R44 provided contingency for marine search and rescue, enabling baiting to continue using one AS350 if the other became inoperative.

Preparations

The hangar construction was trialled in a large warehouse prior to departure. The International Chamber of Shipping Guide to Helicopter/Ship Operations (2008) was used in the development of protocols for managing shipborne helicopter operations. Ship preparations included establishing a helipad and upgrading emergency response capabilities onboard. Two months before departure, interaction trials allowed pilots to practice shipborne helicopter operations and familiarise the ship's crew. Two methods were also trialled for loading helicopters onto the ship and baiting systems were tested during the same period. Bucket calibration was done by sowing non-toxic bait across a line of marked quadrants (5 m × 10 m) extending 65 m perpendicularly from each side of a flight line over tarmac. Baits were counted in every quadrat to determine "usable swath width" – the distance to which bait is reliably spread at or above the desired rate.

An experienced operational team was selected, with additional skills and experience including engineering and mechanical repairs, a recovery doctor with extensive patient extraction and remote emergency medicine experience, biodiversity monitoring, bait bucket mechanics, technical eradication knowledge, remote construction, digger driving and rigging and receiving external helicopter loads.

Biosecurity was a significant part of preparations, and actions were coordinated with a biosecurity plan. A dedicated DOC team quarantined equipment and supplies arriving from all around New Zealand. Quarantined items were generally wrapped in plastic or sealed in plywood boxes (pods). Pest detection and prevention devices, including inked tracking cards in tunnels, insect traps, and rodent bait stations, were in place at the ports of departure and facilities where equipment and supplies were stored. The cargo ship's holds were fumigated for insects. Transport vessels required a certified clean hull to travel to the island. A dive inspection of the *Norfolk Guardian* discovered biofouling on its hull and the invasive organism Mediterranean fan worm (*Sabella spallanzanii*) in the seachests. A hull clean and treatments of the seachests were completed and inspected before each voyage to the island.

Animal Control Products (ACP now trading as Orillion) based in Whanganui, New Zealand, produced 65.5 t of Pestoff® 20R Rodent Bait containing 20 ppm brodifacoum between 21 April 2016 and 3 May 2016. ACP analysed samples from each 500 kg batch of bait, measuring toxicity using Liquid Chromatography Mass Spectrometry with a detection limit of 1×10^{-5}% (0.1ppm). The agreed acceptable range was 16 ppm to 24 ppm brodifacoum by weight.

The bait was packed in four-walled paper bags each containing 25 kg of bait and transported and stored on Antipodes Island in large plywood boxes (pods) portable by forklift and helicopter. The maximum safe load capability of the helicopters determined the size of the pods (each contained 28 bags of bait and weighed a total of 805 kg). The weatherproof pods included a large plastic liner to protect bait against water ingress.

On 23 May 2016, the *Evohe* departed Dunedin, New Zealand, for Antipodes Island with 12 of the project team onboard. On 25 May 2016, the *Norfolk Guardian* departed Timaru, New Zealand with seven project team members, three helicopters, bait in 94 pods, 30 t of jet fuel and 20 t of sundry equipment and supplies. Two 1.6 tonne diggers were taken to the island to prepare a level site for the helicopter hangar. A satellite dish was installed, providing a fast internet connection. The *Evohe* remained at the island while the cargo ship was present, transferring personnel between ship and shore, and ready to respond in case of an incident over water during helicopter unloading of the ship.

Poison baiting

Bait uptake trials were conducted on Antipodes Island in winter 2013 to assess the palatability of the proposed bait to mice and the potential risks to non-target species. The trial used a non-toxic version of Pestoff® 20R Rodent Bait with the biotracer pyranine added. Baits were spread by hand over 6 ha at 16 kg/ha. Subsequently, mice were captured in a grid of Longworth live capture traps and land birds were captured with hand nets. Captured individuals were inspected for signs of bait consumption using a UV light. Observations of birds interacting with baits were also recorded. Bird faeces were collected opportunistically along a transect and inspected under UV light. Faecal samples were assigned to a species by visual inspection or by DNA analysis for a subset of samples that tested positive for pyranine (Elliott, et al., 2015).

A boundary flight recorded the treatment area as 2,114 ha before baiting commenced. The boundary was flown again more tightly before treatment two, recording the area as 2,075 ha. An advisory team (technical advisor, chief pilot and assistant project manager) assisted the project manager with finalising the load site location and layout, and daily assessment of conditions for baiting. AS350 helicopters, directed by Tracmap GPS systems, spread

65.5 t of 2 g Pestoff® 20R Rodent Bait from underslung bait buckets to complete two comprehensive treatments. The nominal application rate was 16 kg/ha for treatment one and 8 kg/ha for treatment two. A minimum interval of 14 days between treatments was preferred, to increase the likelihood of bait availability for emergent young if mice were breeding. Parallel flight lines were set at 45 m apart for a usable swath width of 90 m, giving 50% overlap of baiting swaths to minimise the risk of gaps. During each treatment, additional bait was applied to the coastline, steep slopes (50° to 70°), cliffs (greater than 70°) and other areas of concern to the pilots or identified by geospatial analysis as having potentially insufficient coverage. An observer in the back of the helicopter monitored distribution of bait on cliff baiting flights, which were undertaken at about 40 metre vertical increments.

Bait was made available inside storage containers and the interior and sub floor spaces of buildings by hand spreading or placing baits in bait stations. A bait station comprised a numbered shallow clear petri dish with ten Pestoff® 20R Rodent Bait pellets. These were placed in each compartment or room of a structure and checked daily. A total of 72 bait stations were placed in structures on 18 June. Baits were thrown by hand to achieve coverage of approximately four bait pellets per square metre under the hut and Castaway Depot and in the open wastewater drain. Toilet pits were checked daily and a handful of baits were scattered down each pit as required to maintain availability to mice. Holes were drilled in the floor of the helipad and hangar to access the subfloor space, and baits dropped through. Mouse activity was monitored around the accommodation area using inked tracking cards secured in tunnels (tracking tunnels) and baited with Pestoff® 20R Rodent Baits; and three trail cameras focused on bait stations under the hut and Castaway Depot. Approximately 4 kg of bait was used for structure baiting.

West Windward Island (7.0 ha) and East Windward Island (8.5 ha) were not baited during the first treatment as it was unknown if mice were present. These islands were monitored for mice between treatments using ten inked tracking cards baited with peanut butter and placed in tunnels (tracking tunnels) for 12 nights. Bollons Island (52.6 ha) was believed to be mouse-free prior to the operation but six tracking tunnels were installed between bait treatments for 12 nights and baited with peanut butter to provide further confidence in its status.

Monitoring to determine if mice had been eradicated occurred in late summer 2018, approximately 18 months after the baiting operation. By this time, a surviving mouse population should have recovered to detectable levels. Late summer was chosen as any breeding would have peaked and juveniles would have been present. Monitoring for mice was undertaken using 280 inked tracking cards in tunnels baited with peanut butter and distributed along 28 transect lines. Each transect comprised 10 tracking tunnels spaced 200 m apart. The transects were distributed extensively across Antipodes Island. They were placed in all habitat types, particularly in areas where mice had previously been in high abundance (e.g. near penguin colonies) and adjacent to inaccessible terrain. Tracking cards were checked and replaced approximately every five days for a period of three weeks. Supplementing this, two rodent detection dogs and their handlers searched the island for mice between 21 February and 15 March 2018. The dogs searched in accessible areas across the plateau and southern coast.

Non-target species

A non-target species technical advisory group recommended a strategy for managing risks to native species that did not include captive management but relied on natural populations outside of the treatment area. This strategy became part of the application to DOC, as administrators of the site, for consent to spread bait. Three of the four endemic land bird taxa were considered at risk from either primary or secondary poisoning. Bollons Island (52.6 ha) and Archway Island (6.2 ha) were excluded from the treatment area during planning because evidence from historic studies of invertebrates (Marris, 2000; McIntosh, 2001; Russell, 2012) and limited monitoring for mice on Bollons Island in 2014 (B. Rance pers. comm. 2014) gave sufficient confidence that mice were not present. These islands provided a natural refuge of 58.8 ha, 1.5 km north of Antipodes Island, where species would not be exposed to bait.

Baseline monitoring of endemic land bird taxa was conducted on Antipodes Island between 2013 and 2016 including immediately prior to bait application in winter 2016. Post-eradication monitoring occurred in the weeks after bait application in July 2016, and in the summers of 2017 and 2018, to record any population impacts of the operation. Distance sampling (Buckland, et al., 2001) was used to estimate the density and abundance of the endemic Antipodes parakeet (*Cyanoramphus unicolor*), Reischek's parakeet (*Cyanoramphus hochstetteri*), and the endemic subspecies of the New Zealand pipit (*Anthus novaeseelandiae steindachneri*). The perpendicular distance to individuals or groups of birds was measured from transect lines of variable length to the nearest metre using a laser range-finder. Transects were distributed throughout the island and repeated as often as practicable. The aim was a sample of 60 to 80 encounters of each species for robust modelling of the detection probability and resultant population density. The technique relies on sightings of birds, so sampling was generally avoided when the weather was wet and cold as birds are less conspicuous. The computer software 'Distance 6.2' (Thomas, et al., 2010) was used to analyse the data and compute population estimates. As the number of detections recorded was low for many of the survey periods, data were pooled and a global detection function was computed, from which survey specific estimates of density were calculated (Buckland et al. 2001). Visual comparison of point estimates and their 95% confidence intervals were reinforced using a comparison of Poisson rates (`poisson.test`; R Core Team, 2013) for three paired pre- and post-toxin application survey dates and departures from a hypothesis of no change in density tested.

Antipodes snipe (*Coenocorypha aucklandica meinertzhagenae*) were monitored by recording the number of snipe seen per hour by observers traversing the island on foot, to give an encounter rate. The change in encounter rate between years was assessed using a generalised linear model with negative binomial errors.

To determine if the breeding success of Antipodean albatross was impacted by the operation, the fledging success of Antipodean albatross chicks within 50 m of the load site was recorded in summer 2017 by visiting the nests prior to chicks fledging. The results were compared with fledging success of chicks, alive at the time of bait application, in two study areas on Antipodes Island.

No formal searching for potentially poisoned animals was done but carcasses found opportunistically were examined. The gut cavity was opened and inspected for haemorrhaging and or the presence of green bait in the stomach or intestines indicating poisoning by brodifacoum. Liver samples were collected from the carcasses of pipits and snipe and stored frozen. Samples were sent to Landcare Research and analysed using High Performance Liquid Chromatography with a detection limit of 1×10^{-6}% (0.001ppm).

Project communication

Public engagement was measured by recording the number of media articles about the project (on television, radio, print) and visits to the project's website www.milliondollarmouse.org.nz) and Facebook page (www.facebook.com/milliondollarmouse) during the operational phase.

RESULTS

The baiting operation was implemented and completed in winter 2016. Insufficient resourcing in the first year of planning and competition with other organisational priorities put pressure on the project team and risked delaying implementation. The development of project knowledge and a wealth of experience enabled quality advice from DOC's IEAG. Their strong support maintained focus on objectives and influenced the prioritisation of resources in the preparation phase. Procuring helicopter services and a cargo ship were the crux of logistics planning but proved difficult due to a small pool of suitable suppliers and complex processes. Over a year and a half was spent investigating options and developing trust with potential suppliers to prove the viability of the work and find capable operators who were willing to commit.

Calibration of bait buckets gave a usable swath width of 90 m for standard buckets (360° spread) and 40 m for the deflector bucket (180° spread). Pre-departure trials identified important improvements in systems and componentry including changes to the pneumatic feed from helicopters to the bait bucket, replacement of incorrectly sized bracing elements on the hangar and refinement of the system for its construction. Trials identified that lifting helicopters by the rotor head was the best technique to manoeuvre them in and out of the ship's hold.

The toxicity of all 131 batches of bait supplied met the contract standards. The average toxicity was 19.8 ppm of brodifacoum and the range was 16.5 ppm to 23.9 ppm ± 7%. The operational team arrived at Antipodes Island on 27 May 2016. It took approximately 90 minutes to extract each helicopter from the ship's hold and ready them for flying. Ship unloading was completed with 250 loads flown ashore over 12 days with suitable weather for helicopter operations occurring periodically on five of those days. Helicopter long-line operations to unload and load the ship were challenging and required precision from the pilots and a strong communicator on the deck of the ship to inform the pilot of the position of the hook and help direct the work. The construction team of six people established the field camp, completed complex site preparations and safely installed temporary infrastructure within 11 days before departing with the transport vessels on 7 June 2016. An emergency response exercise was conducted on 8 June to practice helicopter recovery of a person from the water with a rescue scoop net and a rescuer in a human sling on a long-line.

Readiness for baiting was achieved by 9 June 2016 but poor weather delayed baiting until 18 June 2016 when a brief respite in conditions allowed baiting of a small area (54 ha). This gave the opportunity for an initial test of personnel, loading systems and equipment ahead of better weather windows. The baited area incorporated the field camp and load site, enabling structure baiting to be completed to make bait available early in the programme around the accommodation area where there was the highest risk of alternative food sources for mice. Aerial baiting continued incrementally as the weather allowed until coverage was complete. Suitable weather windows for baiting operations were generally short, and conditions were changeable and generally windy. The longest continuous period of bait application achieved was 3.5 hours. Each day's baiting built on previous work using a "rolling front" approach, with the aim of minimising the area needing rebaiting if work was interrupted for too long.

Treatment one was completed on 29 June 2016 with bait application occurring on 18, 21, 22, 27, 28 and 29 June. The interruption after baiting on 22 June was greater than three days, so the last two bait swaths sown that day were sown again on 27 June with 50% overlap. A total application of 45.6 t of bait was applied during treatment one at an average rate of 21.6 kg/ha. No mouse sign was detected on either of the Windward islands so neither were baited, increasing the area where land birds would not be exposed to bait to 75.3 ha.

Treatment two commenced on 8 July, continued to 10 July and was completed on 12 July 2016. A total of 19.9 t was spread at an average application rate of 9.6 kg/ha. The average sowing rate for both treatments combined was 31.2 kg/ha, including application of all the contingency bait. Contingency bait was additional bait (20% of the planned total) taken to mitigate the risk of loss or damage during transport and storage, or of the treatment area being larger than expected. The rate of bait spreading averaged 1.79 t/hr for the first treatment and 0.93 t/hr for the second, giving an overall average of 1.44 t/hr. The interval between treatments was at least 16 days for 97% of the area, and between ten and twelve days for the remainder. Few technical issues with bait spread were encountered and none limited operations.

Rainfall data were collected daily, and some form of precipitation fell most days. A total of 7.9 mm fell in the 48 hours following application of 15.6 t of bait on 22 June in treatment one. Bait degradation was not formally monitored. However, visual inspection showed baits were weathered but generally intact at the start of treatment two, 20 days after application.

Analysis of GPS flight records for aerial bait spread showed that comprehensive bait coverage was achieved with no apparent gaps. The total maximum amount of bait taken from all bait stations set up for structure baiting was 240 g of the 4 kg available. Most of the bait take occurred in the first three nights and 73% of consumption occurred by night six. Imagery from a trail camera showed mice picking up and carrying away the 2 g bait pellets. Two mice were last recorded taking bait on 7 July, 20 days after application. Dissection of a mouse trapped nearby on the same day showed the stomach and intestines were green and full of bait.

Table 1 Incidental dead bird finds on Antipodes Island following bait application.

Species	Autopsy	Brodifacoum (µg/g) ± 6%
Antipodes parakeet *Cyanoramphus unicolor*	1 poisoned	Unknown
Reischek's parakeet *Cyanoramphus hochstetteri*	1 poisoned	Unknown
Pipit *Anthus novaeseelandiae steindachneri*	3 poisoned	0.028; 0.034; 0.01
Snipe *Coenocorypha aucklandica meinertzhagenae*	2 no sign	0.015; 0.031
Mallard duck *Anas platyrhynchos*	1 poisoned	Unknown

Table 2 Comparison of Poisson rates at two time points pre- and post-application of toxin on Reischek's parakeet, Antipodes parakeet and Antipodes pipit. Rate ratios, their 95% CI's and tests of departure from a hypothesis of no change in density between surveys are reported. Rate ratios <1.0 indicate population decline and those >1.0 population increase between surveys.

	Comparison of Poisson rates between surveys		
	Pre-drop 2016 & Post-drop 2016	Pre-drop 2016 & Jan/Feb 2018	Post-drop 2016 & Jan/Feb 2018
Reischek's parakeet	0.17 (0.13–0.23)**	0.85 (0.63–1.17)#	4.97 (3.92–6.30)**
Antipodes parakeet	0.57 (0.36–0.95)*	2.91 (1.81–4.88)**	5.09 (3.81–6.77)**
Antipodes pipit	0 (0.05–0.10)**	1.38 (1.08–1.76)*	19.44 (13.84–27.94)**

** *P* <0.001; * *P* <0.05; # not significant

No mouse sign was detected from 7,170 tracking tunnel nights and searching with dogs during mouse monitoring in summer 2018. The search effort and the evidence were reviewed by DOC's Island Eradication Advisory Group and the eradication of mice from Antipodes Island was declared successful in March 2018.

Non-target species impacts

Bait trials in 2013 demonstrated 100% uptake of the bait by mice and suggested a risk of primary poisoning for pipits but not for parakeets or snipe (Elliott, et al., 2015). During the eradication operation itself, eight dead birds of five species were found incidentally and all had been poisoned (Table 1). The associated search effort was at least 103 hours of extensive field work for monitoring land birds. Additionally, staff walked an 800 m route between Reef Point and the load site (Fig 1) almost daily for the six weeks between initial bait application in the area and departure. During the operation, some pipits were observed occasionally pecking at baits and some baits were found to have been chewed by parakeets, but most baits were untouched.

Despite the use of a global detection function, low numbers of observations led to large confidence intervals about density estimates derived from distance sampling (Figs 2, 3 and 4). Prior to 2016, only the sampling of Reischek's parakeets in October 2014 (61 encounters) reached the desired sample size of 60 to 80 encounters. In 2016, pre-baiting sampling for Antipodes parakeets (22 encounters) and post-baiting sampling for pipits (40 encounters) failed to reach this target. Overall, more sampling was done immediately post-baiting in 2016 (329 encounters) than before (186 encounters) due to time constraints. Poor weather also often constrained the method. The results (Table 2; Figs 2, 3, and 4) suggest that a significant number of pipits and parakeets probably succumbed to brodifacoum poisoning immediately following the application of bait. However, the populations of pipits and both parakeet species were able to persist and have increased greatly each year, recovering to densities that are similar to or higher than pre-eradication estimates by summer 2018 (Table 2; Figs 2, 3 and 4). Pipits have responded particularly strongly with very large year on year increases in density estimates since 2016. Anecdotal observations in summer 2018 were consistent with the reported increase. On most occasions when monitoring team members sat down in the field, pipits would immediately appear and walked around and on them, finding food items such as caterpillars within minutes (F. Cox, pers. comm. 2018).

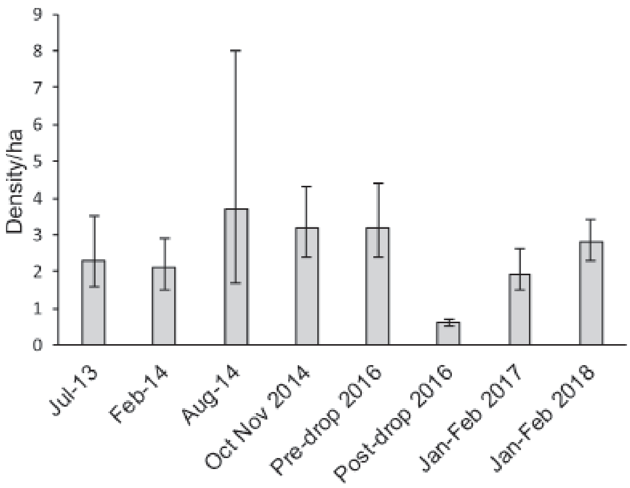

Fig. 2 Distance sampling results for Reischek's parakeets, Antipodes Island.

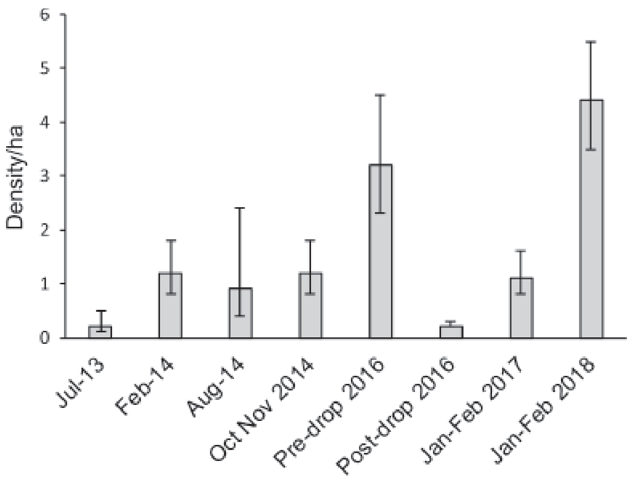

Fig. 4 Distance sampling results for pipits, Antipodes Island.

Table 3 Results of snipe encounter rate surveys recorded on Antipodes Island between 2013 and 2017.

Year	Person hours	Snipe seen	Snipe seen per hour	Change between years (%)	p
2013	341	38	0.1079		
2014	206.75	26	0.1322	123	0.4938
2015	140.5	17	0.1279	97	0.9267
2016	178	6	0.0330	26	0.0085**[a]
2017	224	8	0.0345	105	0.9373
2018	783	132	0.1640	475	0.0001***[b]

[a] Note significant difference in encounter rate between 2015 and 2016 prior to the eradication operation.
[b] Note significant difference in encounter rate between 2018 and 2017.

Snipe have been monitored each summer between 2013 and 2018. Snipe were more abundant in 2018 than ever before, but there has been considerable inter-annual variation in snipe abundance and the difference between 2018 and all the other years is not significant (Table 3). The between-year change in snipe abundance is probably more informative. Significant changes in snipe abundance occurred in 2015–2016 (a decline) and 2017–2018 (an increase). The large decline (72%) in the snipe encounter rate between 2015 and 2016 occurred before the mouse eradication so was not a result of the poison operation. The reason for this is unknown. There was a small, non-significant increase in the snipe encounter rate between 2016 and 2017 (Table 3), suggesting little or no by-kill of snipe during the mouse eradication. In contrast a dramatic increase (475%) occurred in snipe encounters between 2017 and 2018.

Helicopter activity did not have a detrimental effect on nearby Antipodean albatross chicks. All seven chicks within 50 m of the bait loading site were alive at the completion of operations and six out of the seven of them (86%) fledged successfully in early 2017, comparable with 90% outside the load site.

Scientists visiting Antipodes Island in summer 2017 and summer 2018 also noted a greater abundance of moths and the endemic fly (*Xenocalliphora antipodea*) than before the eradication of mice, observing them on flowers of the native groundsel (*Senecio radiolatus*) and Macquarie Island cabbage (*Stilbocarpa polaris*). This endemic fly was also abundant inside the Antipodes Hut for the first summer in over 20 years of visitation. A gathering of hundreds of large noctuid moths, suspected to be *Graphania ustistriga*, was also observed for the first time in 2018 despite 10 previous month-long summer visits to Antipodes Island between 1996 and 2017 (K. Walker, pers. comm. 2018). Large caterpillars, suspected to be larvae of the same noctuid moth species were regularly seen and observed being preyed on by pipits (K. Walker, pers. comm. 2018).

Project communication

Media coverage of the operation included seven prime-time television news stories and several radio interviews, print and online stories. Social media engagement peaked in June 2016 with 23,906 views of the MDM website and 71,967 on the MDM Facebook page. DOC social media also peaked at 77,710 views for the month. Outreach was amplified through the communications networks of project partners, the Morgan Foundation, WWF-New Zealand and Island Conservation.

DISCUSSION

A robust plan was formulated and delivered despite initial difficulties sourcing shipping and helicopter services. Complex projects require good resourcing in the planning phase and organisational prioritisation with significant scale up in resourcing for the preparation phase. Key factors for the delivery of the project were a) quality technical advice, b) single point accountability for overseeing the work and a team approach during preparations and operational phases, c) use of experienced personnel in key roles, d) a proven bait product, e) dependable and tested equipment, f) extensive contingency planning, g) a partnership approach with suppliers and e) the financial and moral support of private and public partners.

The brevity and inconsistency of weather opportunities in this environment showed the importance of being prepared and effectively using every opportunity to complete baiting. Additional skills and operational experience improved team performance and self-sufficiency. Equipment could generally be maintained on site and situational decision-making benefitted from the advice of senior team members. High speed internet access and video production capabilities enabled the team to communicate the project directly and engage an audience. Pilots' long-lining capabilities for ship operations could be considered a separate skill from baiting and, if necessary, pilots with specific skills should be engaged for the task. Similarly, coastal baiting with the deflector bucket requires specific attention and experience.

Non-target impacts

Monitoring evidence suggests the adverse effects of the operation on land birds were short lived. These impacts are expected to be outweighed by the long-term benefits to native species from the permanent removal of competition with mice. The risk to non-target species was effectively limited by relying on natural populations on Bollons and Archway Islands where they weren't exposed to bait. Prior to the mouse eradication, both parakeets and the pipit had rarely been observed making flights of more than 100 m on Antipodes Island, so while they are capable of crossing the 1.5 km strait between Bollons Island and the main Antipodes Island, it must have been a rare event. The risk of parakeets and pipits, resident on Bollons and Archway Islands, being killed by poison when they commuted across the strait was judged low. This reasoning eliminated the need to catch and maintain a captive population. During the bait uptake trial neither parakeet species was detected eating bait, yet both species were killed by the poison. Parakeets may have become habituated to the bait during the operation because of the longer exposure (more than 35 days) and changing palatability of baits as they weathered relative to the non-toxic trial (14 days). The large variability in population density estimates derived from distance sampling were largely driven by the relatively low encounter rates for all three species monitored using this method and should be treated as indicative only. More data would have improved the robustness of the results as would an improved sampling design to account for only recently discovered shifts in winter distribution for both parakeet and pipits. This, however, is difficult to achieve for such a remote and expensive site to visit and for one that frequently experiences less than ideal survey conditions in generally time-constrained survey periods.

It is unlikely that recruitment alone could account for the apparent rapid recovery of pipits and parakeets by summer 2017 (Figs 2, 3, and 4), suggesting the distance sampling results overestimated the losses and/or recovery. For both parakeet species, the large increases in population density, relative to post-baiting lows, were observed before most chicks had fledged (G. Elliott pers. comm. 2017). Pipits are unlikely to have raised more than one clutch by January 2017 which doesn't account for the nearly 500% increase in the population density estimate in summer 2017 since their post-baiting low. The similarly large increase in the estimated density of pipits between 2017 and 2018 (Fig. 4) is more likely to be real considering the observations of field staff.

The very large increases in the encounter rate of snipe and the density estimate of pipits in summer 2018 are presumed to be the result of large increases in the abundance of invertebrates following the eradication of mice and the resultant increases in reproductive output and survival.

Effective distance sampling for pipits within dense coastal vegetation, a habitat favoured by pipits in winter, was problematic. The short time-frames available during the operation for monitoring immediately before and after baiting meant distance sampling occurred in variable conditions and with variable effort across different habitat types, which may have exaggerated the estimated population declines following bait application. The extraordinarily large estimate of pipit population density pre-baiting in 2016 (Fig. 4) is possibly biased by proportionally greater sampling effort of abandoned penguin colonies (where pipits and parakeets are now known to congregate in winter) relative to that within the island interior (and where most of the 2013 counts were done). This reinforces the uncertainty of results.

The seasonal timing of distance sampling for land birds before and after baiting was also inconsistent (Figs 2, 3 and 4). The observed changes in seasonal distribution of these species therefore makes the use of a global detection function (which assumes constant detectability across surveys) problematic and dilutes direct comparability of the density results. Changes in detectability caused by movements to and from the coast may be biasing the results and at least partly account for the relatively low population density estimates so soon after the bait spread. It is recommended that results from surveys done at the same time be pooled if sufficient data are available.

The eradication of mice from Antipodes Island is a huge achievement for conservation in New Zealand. Hundreds of years of ecological devastation by mice has been halted and indigenous wildlife has started to recover. The importance of the result is reflected by the national and international protection of the site, recognising its special natural heritage values. The result provides momentum to New Zealand's Predator Free 2050 initiative and is a step closer to the vision of a New Zealand Subantarctic Islands region free of mammalian pests. Of the five island groups in the region, only Auckland Island now has mammalian pests: pigs (*Sus scrofa*), cats (*Felis catus*) and mice (*Mus musculus*). Over time it is expected that the invertebrate fauna on Antipodes Island will recover to reflect the abundance and species diversity recorded on Bollons Island and Archway Island, where no mice were present. It is hoped that species of larger-bodied ground invertebrates (for example tenebrionids), reduced to low abundance, will recover and others which became extinct on Antipodes Island through predation by mice (for example the unidentified weta and *Loxomerus* sp.), can be successfully reintroduced from the offshore islands where they may survive. The population densities of land bird species are expected to further increase and stabilise with the recovery of food sources and lack of competition with mice. Absent burrowing seabirds, for example black-bellied storm petrel, are also expected to recommence breeding on Antipodes Island. Further monitoring for land birds will occur opportunistically on an annual basis in conjunction with albatross research. Broader outcome monitoring will be repeated in approximately five to ten years' time and will include a repeat of invertebrate sampling, sampling of the seabird species breeding on Antipodes Island and measurement of change in vegetation monitoring plots.

ACKNOWLEDGEMENTS

The project drew on the support of hundreds of people. Special thanks to the DOC team, the operational team, public supporters, project partners, suppliers, DOC's Island Eradication Advisory Group, Kath Walker and Helene Thygesen.

Abstract A successful ground-based eradication of black rats (*Rattus rattus)* was undertaken on the remote, uninhabited Shiant Isles of north-west Scotland over winter (14 October–28 March) 2015–16. The rat eradication was carried out as part of the Shiants Seabird Recovery Project, which aims to secure long-term breeding habitat for protected seabirds and to attract European storm petrels and Manx shearwaters to nest on the Shiants. Throughout the eradication operation, teams were stationed on two of the three main Shiant islands (Eilean an Tighe, Eilean Mhuire), with access to the third (Garbh Eilean) via a boulder causeway from Eilean an Tighe. Bait (Contrac® blocks containing the anticoagulant bromadiolone 0.005% w/w), was deployed in a grid of 1,183 bait stations covering all areas of the islands and sea stacks. Bait stations were set 50 m apart, with intervals reduced to 25 m in coastal areas of predicted high rat density. Difficult areas were accessed by boat and cliffs of ~120 m in height were accessed by abseiling down ropes made safe using either bolted anchors or ground stakes. The team of staff and volunteers worked through difficult conditions, deploying bait and monitoring intensively for any surviving rats using a combination of tools. The islands were declared rat free in March 2018. This ambitious and challenging project has greatly enhanced UK capacity in rodent eradications for the purposes of conservation.

INTRODUCTION

The Shiant Isles is a group of small, uninhabited islands that lie in the Minch (57.9° N, 6.4° W), ca. 6 km east of the island of Lewis and Harris, north-west Scotland. Of the Shiants' three main islands, the largest two: Garbh Eilean (GE, 88 ha) and Eilean an Taighe (ET, 54 ha) are connected by a boulder causeway, and ~500 m to the east of GE lies Eilean Mhuire (EM, 31 ha). A chain of sea stacks, the Galtachan, lie to the west of GE (Fig. 1).

Archaeological evidence documents previous inhabitation of these islands by humans dating back perhaps to the Iron Age (Foster, 2000) but since the 18th century the Shiants have remained uninhabited, and the last remaining building (the 'bothy' on ET, close to the boulder causeway) is occupied only during visits by the islands' owners, or by tourists.

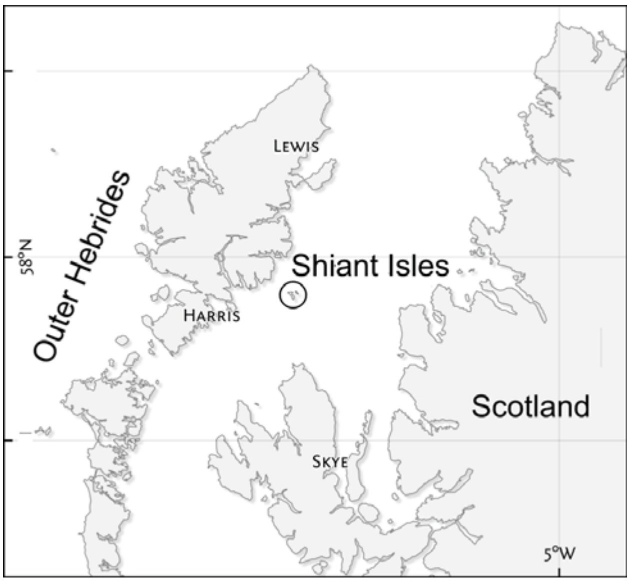

Fig. 1 Location of the islands in the wider area of north-west Scotland.

The Shiants consist mainly of dolerite sills, formed by intrusion of igneous rock between overlying sedimentary rock strata. These sills were then exposed to reveal impressive, columnar structures that now rise steeply to a height of ~ 150 m at their highest point on GE and have been eroded to form extensive boulder scree areas, particularly on the east side of GE (Walker, 1930). The smallest of the three main islands, EM, has cliffs rising to around 80 m, and more conglomerate substrate than ET and GE (Walker, 1930; Gibb & Henderson, 1996).

Habitats present on the islands range from blanket bog and wet heath across the interior of GE and ET, to fertile, species rich grasslands along the coasts of GE and ET and across ME. The maritime environment has a strong influence on the composition of the islands' vegetation and soils have been enriched by guano from centuries of seabird occupation and from past human cultivation. The three main islands have all been historically grazed by sheep (*Ovis aries*) (counts of sheep performed year-round gave estimates of 50 to 80 per island). A colony of grey seals (*Halichoerus grypus*) breeds on the islands, and both common seals (*Phoca vitulina*) and otters (*Lutra lutra*) are frequent visitors. Other than the sheep and an introduced population of black rats (*Rattus rattus*) there are no other known resident populations of terrestrial mammals.

The remoteness of the Shiants, their large amount of suitable habitat and proximity to feeding grounds makes the islands ideal breeding sites for various seabirds. Their importance is internationally recognised through designation as a Site of Special Scientific Interest (SSSI; site code 8575) and as a Special Protection Area (SPA; EU code UK9001041) for breeding populations of puffins (*Fratercula arctica*) (approximately 10% of the UK breeding population, Mitchell, et al., 2004), razorbills (*Alca*

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 138–146. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

torda), common guillemots (*Uria aalgae*), European shags (*Phalacrocorax aristotelis*), black-legged kittiwakes (*Rissa tridactyla*), and northern fulmar (*Fulmarus glacialis*), and wintering barnacle geese (*Branta leucopsis*). The seabird assemblage also includes great skua (*Stercorarius skua*), black guillemots (*Cepphus grylle*), herring gulls (*Larus argentatus*), common gulls (*L. canus*), great black-backed gulls (*L. marinus*) and lesser black-backed gulls (*L. fuscus*). White-tailed eagles (*Haliaeetus albicilla*) returned to breed on the islands in 2014 after an absence of over 100 years, following the re-introduction of the species to Scotland (Love, 1983). Other seabirds such as European storm-petrel (*Hydrobates pelagicus*) and Manx shearwater (*Puffinus puffinus*) have not been recorded as breeding at the Shiants, despite the large amount of suitable habitat for these birds. Both of these species are of international conservation concern. At the last major census, European storm petrels breeding on the isles of the UK and Ireland were estimated to number 125,000 pairs, representing 3–11% of the global population. In the same census Manx shearwaters were estimated at 332,000 pairs breeding in the UK and Ireland, with the majority found on the islands of Rum, north-west Scotland (120,000 pairs), Skomer, Wales (102,000 pairs) and Skokholm, Wales (46,000 pairs, Mitchell, et al., 2004). A further survey of Manx shearwaters on Rum has also estimated 70,000 breeding pairs at the Rum colony (Murray & Shewry, 2002).

Rats (*Rattus* spp.) are among the highest risk invasive species, having had devastating effects on native wildlife on island groups such as New Zealand (Towns, et al., 2006) and worldwide through predation, and both competition for and modification of habitat (Jones, et al., 2008). Rats have been recorded on more than 80% of the world's island groups (Atkinson, 1985), but their successful removal from islands ranging in size from less than 1 ha to 12,875 ha has been pioneered in New Zealand and is being applied across the globe. In the UK, rats have been successfully eradicated from islands ranging in size from just one hectare (e.g. Inchgarvie, Firth of Forth, Scotland) to 1,300 ha (Canna & Sanday, Scotland) (Ratcliffe, et al., 2009; Thomas, et al., 2017a; Bell, 2019). Of the successful UK island rat eradications, all were of brown (Norway) rat (*Rattus norvegicus*) except in the case of Lundy, which included populations of both brown rat and black rat (Thomas, et al., 2017a; Bell, 2019). The removal of rats is essential where predation either limits productivity or threatens to lead to the complete loss of important seabird colonies.

Black rats were introduced to the Shiant Isles (accidentally, it is assumed) by humans, either through stock movements by previous island inhabitants or by shipwreck (e.g. Haswell Smith, 2004), though no evidence has established how the rats arrived. The rats are thought to have had negative impacts on the seabirds at these islands as follows. Diet analysis at the Shiants has indicated that rats consumed a range of material of marine origin (Stapp, 2002) as well as vegetation and invertebrates present at the Shiants (Stapp, 2002; Bell, 2013). The stable isotope ratios of carbon and nitrogen, extracted from rat tissues of individuals caught at seabird colonies were closer to those from tissues of seabird origin than those of rats caught from areas away from seabird colonies (Stapp, 2002). This indicated that in the seabird breeding season, coastal colonies of rats were likely to have fed upon on seabird eggs and chicks.

Following a detailed assessment of UK islands with invasive, non-native species the Shiant Isles were identified as being a priority site for rat eradication because of their abundance of potential petrel and storm-petrel breeding habitat (Ratcliffe, et al., 2009). A successful rat eradication at these islands would additionally benefit the existing colonies of protected seabirds. Since the islands lie approximately 6 km offshore and are uninhabited by humans, the risk of natural invasion by brown rats from the nearest islands of the Outer Hebrides is considered to be low. A feasibility study commissioned by the Royal Society for the Protection of Birds (RSPB), and undertaken by Wildlife Management International Ltd (WMIL) in April 2012, found that eradication of the black rat population at the Shiants was feasible (Bell, 2013).

Subsequently, the Shiant Isles Seabird Recovery Project (SSRP) was established as a four-year partnership between the islands' owners (the Nicolson family), RSPB and Scottish Natural Heritage (SNH). The four core aims of the project were: i) to eradicate the invasive black rat population; ii) actively encourage petrels (European storm petrel and Manx shearwater) to nest at the islands; iii) audit island biosecurity at UK SPAs and iv) increase UK capacity in island restoration. Funding for the project was provided by the EU LIFE fund (LIFE13/NAT/UK/000209 LIFE+ SHIANTS), SNH, and RSPB.

The eradication component of the SSRP was undertaken over the period 2015–2016. An open tender process was used to invite operators to bid for a contract to undertake eradication work at the Shiants. This resulted in the selection of WMIL to carry out the eradication operations. The eradication set up, methods and technical operations will be reported on here.

METHODS

Pre- and post-eradication monitoring

Monitoring of the two main islands' (ET and GE) existing seabirds, land birds, vegetation and invertebrates was carried out for one year before the eradication and for the subsequent three years post-eradication. The aims of this ecosystem monitoring were to detect changes, if possible, and hence assess the benefits of the eradication. Full methodology and results for this will be presented elsewhere. A population census of all seabirds, carried out by RSPB and SNH, was undertaken at the Shiants during June 2015, as part of SNH's programme of Common Standards Monitoring of protected areas (SSSIs and SPAs) (Taylor, et al., 2018). A pre-eradication assessment site visit was undertaken during July 2015 to finalise plans, logistics, and health and safety requirements.

Permits and authorisations

A Habitats Regulations Appraisal (HRA) was carried out by SNH to assess the likelihood of any adverse impact of the rat eradication on the qualifying features of the SPA. This required a full Appropriate Assessment under the Conservation (Natural Habitats, &c.) Regulations 1994 (as amended). In addition, a full assessment of the Operations Requiring Consent (ORC) was also undertaken for the Shiant Isles SSSI. Justification of the chosen rodenticide (bromadiolone) formulation, estimated quantity needed, and method of application was presented in the Appropriate Assessment and ORC application, detailing how the operation would be undertaken across all islands and sea stacks of the Shiants. A licence under the Wildlife & Countryside Act (1981) was granted to cover possible disturbance to breeding golden eagles (*Aquila chrysaetos*) and white-tailed eagles which are specially protected by Schedule 1 of the Act. Planning permission was obtained from the Comhairle na Eilean Siar (Western Isles Council) to allow the temporary installation of portable cabins on the island to store rodenticide bait and provide shelter for winter eradication teams. For the installation of two temporary moorings, a five-year marine license (issued by Marine Scotland) was granted for which an annual fee was paid to the Crown Estate. Assessments of archaeological sensitivity were carried out in person by experts from the Comhairle nan Eilean Siar and also by RSPB. Maps of archaeologically sensitive sites were used to ensure that these features were not disturbed by placement of cabins, bait stations or by the passage of workers around the islands during the eradication.

A detailed health and safety plan was written in collaboration by RSPB and WMIL. This outlined living and working protocols and the establishment of emergency procedures. As part of health and safety requirements, the islands were zoned to indicate areas considered too dangerous to access without the use of support ropes. Rope access was hence deemed necessary to place bait and to check bait stations on steep vegetated slopes or ground ending abruptly at steep cliffs.

Contracts with two local boat operators (Sea Harris Ltd and Engebret Ltd) were established in order to provide boat access to and around the Shiants through the winter operations. An invitation to quote was issued, with the subsequent selection of contractors based on project needs, cost, and suitability of boat service provision.

Rodent anticoagulant resistance tests

An assessment of potential resistance of the rats on the Shiants to bromadiolone rodenticide was carried out by Reading University (Vertebrate Pests Unit), using protocols developed to extract and sequence DNA for the identification of anticoagulant resistance mutations in brown rats (Pelz, et al., 2005; Prescott, et al., 2010). A similar protocol developed specifically for black rat rodenticide resistance testing was not available. However, the approach used represented the best option available because of the lack of rodenticide resistance work that had been undertaken on black rats at the time of the eradication. Rat DNA samples were collected by project personnel from ET in July 2015. Snap traps placed inside tunnels were set overnight and baited with peanut butter. These were visited early the next morning and any rat specimens caught were collected and dissected. A portion of the tail was placed in 100% ethanol for subsequent rodenticide resistance testing. Morphometric measurements (body length, tail length, hind foot length, ear length) were recorded. Stomach contents, sex and reproductive status were also assessed for all of these trapped rats (Bell & Boyle, 2015). All DNA samples were archived for reference in case of resistance or reinvasion by rats at the islands.

Equipment preparation

Off-island preparation of equipment included the construction of 0.75 m long bait stations (Fig. 2) from lengths of 10 cm diameter plastic drain coil. Help was sought from local community volunteers from the Isle of Harris and construction of approximately 700 bait stations was carried out over two days at the Harris Volunteer Centre in Tarbert. The remaining bait stations were constructed by project personnel off and on the Shiants. Bait stations and other equipment were airlifted to the Shiants over two days as part of the set-up phase of the eradiation.

Access to challenging terrain

Camps were established on ET and EM for the winter teams. Portable cabins were installed for safe storage of rodenticide baits and shelter for winter eradication teams. The flat-packed cabins were airlifted to the islands by helicopter in October 2015 and constructed on-site. The existing bothy on ET was re-roofed during the summer of 2015 and was also used as a base camp during the winter operation. Two moorings were installed close to ET, to improve safety for boat access. Boats were used to land on less accessible areas such as the Galtachan sea stacks, and a large rock to the east of EM.

Rope access training was undertaken by seven WMIL and RSPB personnel. Bolts were set in rock at the top of twelve rope access routes (eleven on ET and one on EM). A further eight routes (one on ET, two on EM and five on GE) were accessed using ropes secured by anchors manually set up using a series of three lashed metal stakes.

Non-target mitigation

Measures to prevent secondary poisoning of eagles were provided by the establishment of diversionary feeding protocols. Dead rabbits (*Oryctolagus cuniculus*, collected by manual trapping at a nearby site on the Isle of Harris) were attached to two tables located on GE, with motion activated cameras set up to monitor activity. The diversionary feeding was made available to the eagles from October 30, 2015 until March 17, 2016. However, no fresh food was attached to the table after 12 November 2015 because bait take had reduced to such low levels that the risk of secondary poisoning was deemed negligible. It was also noted that eagles were only intermittently present at the islands, and there was no evidence, e.g. from motion activated cameras, to suggest that diversionary food was utilised by any eagle. Wire clips were fitted to all bait stations after a raven was seen to open one and access the bait – no further instances of non-target vertebrate species accessing bait were observed.

Bait quantity

An estimate of the quantity of rodenticide needed for the eradication was calculated as follows during the planning phase. An application rate was assumed of 0.28 kg rodenticide per bait station (i.e. 10 blocks per station in 684 bait stations on a 50 × 50 m grid; 1.12 kg/ha) for the first four weeks, then 0.14 kg per bait station (0.56 kg/ha) for the subsequent four weeks and 0.056 kg per bait station (0.224 kg/ha) for the remainder of the operation, with consumed bait replenished at each check. Each application, or "round" of bait station checks was expected to take one day using a team of 10 people. It was expected to require at least 30 complete rounds (with replacement of bait) of each station to ensure the eradication of all the rats. At this rate, up to four tonnes of bromadiolone (LD50, oral ingestion 1.125 mg/kg, Meehan, 1978) were estimated to be required to cover the combined island area (171 ha) over approximately five months. Note, that although the stated LD_{50} for bromadiolone as given by the manufacturer is 0.525 mg/kg (Bell Laboratories Material Safety Data Sheet) this is based on laboratory-bred brown rats. Wild populations of black rats may be more tolerant to bromadiolone (Sridhara & Krishnamurthy, 1992). Individual and sex-specific variations in toxicity of bromadiolone to black rats have also been reported (Garg

Fig. 2 Bait station shown open, with rodenticide blocks wired in place.

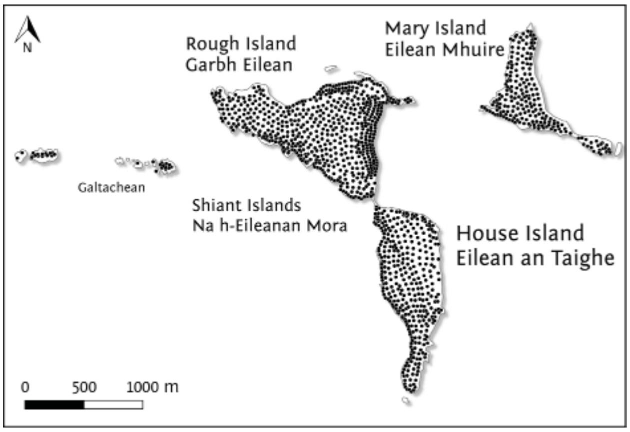

Fig. 3 Map of the bait station grid.

& Singla, 2014). Therefore, a higher LD_{50} was assumed here (Meehan, 1978), to account for these differences.

The actual application rates, bait station grid and number of days to complete a full bait station check during the eradication were different to those calculated in the planning phase due to operational requirements, predicted high rat density areas (i.e. coastal areas) and adaptation to both bait consumption and rat behaviour.

Bait application

Island-wide baiting grids with a total of 1,183 bait stations (Fig. 2) were established across all islands and sea stacks (347 on ET, 594 on GE, 207 on EM, 28 on Galtachan, four on Arch Island and three on Seann Chaisteal) during October 2015. Bait stations were spaced at 50 m intervals across the islands, and 25 m along coasts and through areas of boulder scree e.g. the large area of boulders known as Carnach Mhòr on GE (Fig. 3). This grid spacing has become the current UK best practice protocol for rat eradications (Thomas, et al., 2017b). Rodenticide bait and rat monitoring tools were placed on the Galtachan sea stacks on 17 October 2015.

A team of between two and four people was stationed on ET throughout the operation with a break of one week over the Christmas period. A second team of between two and three people was stationed on EM on a week on/ week off schedule. Rotation of people within these teams occurred on a weekly basis, where weather permitted safe access for boat transfers. Baiting commenced at the islands on 4th November (Table 1). Cereal-based wax blocks (28 g Contrac® All-weather Blox™ (Cas No. 28772-56-7, EU 528/2012), containing the anticoagulant rodenticide bromadiolone at 0.005% w/w) were initially placed loose within bait stations. Regular checks were then made. Stations that were accessible on foot were checked between 16 and 23 times with an average of 6–8 days between checks (Tables 1 and 2). Rope access routes were checked between 3–13 times with an average of 10–15 days between checks (Tables 3 and 4). Frequency of checks at rope access routes was limited by the availability of trained staff on each island and the length of time required to check relatively few bait stations on the routes. The rodenticide blocks were wired in to bait stations starting from the seventh round of baiting on GE, round eight on EM and round nine on ET, with all bait wired in by 8 January 2016 (Tables 1 and 3). Records of bait application at each station were kept in waterproof notebooks and transferred to an electronic database each night. Bait was replaced if damaged by weather or slugs, or at the sign of rat incisor marks. An alternative bait, a soft block (100 g Romax® Rat CP™ (Cas No. 5836-29-3, UK UK-2016-1003), containing the anticoagulant coumatetralyl at 0.0375% w/w), was wired into bait stations (one block alongside the Contrac® blocks) during January and February 2016 (depending on the island) (Tables 1 and 3). This provided an alternative bait for rats not consuming the Contrac® blocks.

Monitoring

During baiting operations, personnel regularly searched for carcasses, including any dead or dying rats present at the surface. Systematic monitoring for surviving rats commenced at the islands on November 28, 2015 and continued for 14 weeks, in tandem with baiting. Monitoring stations were set up at every bait station and at intervals half way between bait stations. Monitoring tools employed included: non-toxic flavoured paraffin wax blocks (chocolate, peanut butter, peanut essence, aniseed); soap; tracking tunnels; snap traps and motion-activated cameras. After 14 weeks, intensive monitoring was reduced and permanent monitoring stations were established at key locations (Fig. 4, Fig. 5) on the three main islands where early detection of any surviving black rats, or an invasion of brown rats, would be likely. These comprised 44 commercially available Protecta™ boxes and ten wooden rodent motels baited with non-toxic chocolate wax blocks (Fig. 4). Monitoring stations were checked in winter of October 2016, January 2017, March 2017 and November 2017, with replacement of old blocks each time. Regular checks were also carried out in the summer (April–August 2016–2018) during island monitoring as part of the Shiants Seabird Recovery Project.

Following the placement of rodenticide and monitoring tools at the Galtachan sea stacks, subsequent checks on 4 November 2015 and 27 February 2016 revealed no rat sign or bait take. The sea stacks were assumed to be rat free and were not treated with further rodenticide during the eradication phase.

A database of all baiting, monitoring, and other activities was maintained throughout the eradication. Observations of potential non-target species, carcasses, and other relevant information were documented throughout the operation.

RESULTS

Bait consumption

Consumption of bait was higher around the coasts of all islands and was the highest around areas of known seabird colonies (Fig. 6). Rats consumed approximately 270 kg (or 9666 blocks) of Contrac® bait in total, mainly during the phase when blocks were loose in bait stations and available for rats to remove whole and cache (Fig. 7). Consumption of Romax® blocks by rats was zero.

An estimate of the numbers of rats present at the time of the eradication was made as follows. Assumptions were made that: each block removed by rats was consumed in its entirety by a single rat; all rats consumed between three and 24 times the lethal dose of bromadiolone (where a lethal dose is delivered by consuming 9.5 g of bait corresponding to approximately one third of a block, assuming an LD_{50} of 1.125 mg/kg for black rats). Hence, it is estimated that there were between 1,208 and 9,666 rats present on the Shiants at the start of the eradication (assuming between one and eight blocks were taken by each rat before death). The mean (± SE) of 4.6 ± 0.1 blocks consumed per bait station overall leads to the estimation that there were 2,099 ± 97 rats on the Shiants. This is lower than previous estimates for black rat on the Shiants; 22–85 rats/ha (3,762–14,535 rats) in 1998 (Key, et al., 1998) and 14–27 rats/ha (2,394–4,617) in 2012 (Bell, 2013). Methods used and timings of each of these population estimates vary.

* Romax® Rat CP™

Interference with bait stations by non-target species was low. Invertebrates, particularly slugs, consumed some bait (1.78 kg). Sheep were estimated to consume 19.6 kg of bait released by kicking up the stations. Ravens and crows were observed to take bait (10.9 kg) by pulling out wires and removing bait station lids, until a more secure wire fastening system was established. No evidence was found of non-target species being affected by the rodenticide.

No carcasses showing signs of anticoagulant ingestion were collected. An adult golden eagle carcass discovered on 15th November was autopsied and showed no signs of anticoagulant poisoning, and the state of decomposition suggested it had almost certainly died before the start of the baiting operation. Diversionary food provided throughout the operation was not removed by any species.

Table 2 Frequency of replenishment of bait stations accessible by foot. Mean number of days (± SE) between the first day of each bait station check; range in number of days to complete check and total number of checks given in parentheses.

Island	Number of days between the first day of each bait station check
Eilean an Tighe	6.2 ± 1.0 days (2–27 days; 23 checks)
Garbh Eilean	6.7 ± 1.0 days (3–22 days; 20 checks)
Eilean Mhuire	8.1 ± 1.8 days (2–27 days; 16 checks)
Total (all islands combined)	6.9 ± 0.7 days (2–27 days; 16–23 checks)

Table 3 Frequency of replenishment of bait stations accessed by rope. Mean number of days (± SE) between the first day of each bait station check; range in number of days to complete each check and total number of checks given in parentheses.

Island	Number of days between the first day of each bait station check
Eilean an Tighe	10.8 ± 1.7 days (4–24 days, 13 checks)
Garbh Eilean	13.5 ± 2.3 days (2–23 days,11 checks)
Eilean Mhuire	14.4 ± 3.2 days (2–29 days, 9 checks)
Total (all islands combined)	12.7 ± 1.3 days (2–29 days; 9–13 checks)

* Romax® Rat CP™

Bait stations near to coasts were affected by weather, with 60 washed away during large storms (resulting in a loss of 9.5 kg of bait). A total of 84 kg of bait (from 583 stations) was removed by hand because of damage by mould or dampness that could have rendered it unpalatable to rats.

Rat sign and monitoring

Four rats were found dead at the surface on GE (one fresh carcass on 7 November 2015, four days after baiting commenced); two fresh carcasses on 11 November 2015 (seven days after baiting commenced) and one desiccated carcass on 4 February 2016 (90 days after baiting commenced). Rat sign was recorded on flavoured wax at three monitoring points following the start of the initial baiting phase. These were at three different cliff stations on ET (on 13 December, on 14 December and on 26 February). Monitoring at these cliff stations through March 2016 did not yield any further rat sign. The detection of incisor marks on the flavoured wax block in February 2016, when other food sources were beginning to become available, was treated as a possible survivor from the eradication. To establish whether any rats had survived, in October 2016 rope access teams re-established 470 monitoring stations

across the three islands with a focus on the cliff stations on ET. Four checks were completed on EM and ET and three checks on GE, finding no sign of rat presence. Permanent monitoring stations on ET, GE and EM were checked monthly in the summer (April–August) and every three months outside the summer season until February 2018. A month-long intensive monitoring check was carried out on all islands and sea stacks in February 2018, with the declaration of rat-free status made on 2 March 2018.

Rodenticide resistance testing

Although some mutations were present within the section of genome sequenced, these mutations were not the same as brown rat mutations known to confer genetic resistance to bromadiolone.

DISCUSSION

Eradication of black rats at the Shiant Isles was one of the four core aims of the Shiants Seabird Recovery Project, now successfully achieved.

The Shiants black rat eradication was an ambitious undertaking on a remote, uninhabited island group, with no existing infrastructure or facilities except the bothy on ET. The operation required the establishment of safe working environments and the provision of shelter, for example, on EM where there are no existing structures on an island of 80 m height. The lack of sanitation, water supply and electricity necessitated basic living conditions and robust and appropriate waste management procedures. Weather influenced operations throughout, sometimes becoming so severe as to prevent access to various parts of the island group. The terrain of the Shiant Isles is steep across many sections of each island, hence the need for rope access at various points. The use of extensive rope access, in particular, allowed a neat solution to the problems of challenging access and a ground-based operation. Other methods, such as bait stations deployed at the end of lines, may have been more difficult to monitor and would also have necessitated the close approach to cliff edges (also requiring support ropes in order to comply with health and safety requirements). As well as the challenging access on foot, the need to address separate islands at the same time by boat presented further logistical and personnel considerations.

New challenges had arisen since the feasibility study (2012) including changes in the profile of the boulder causeway connecting ET and GE resulting in reduced access on foot to GE from the main camp on ET. White tailed eagles had established a breeding site at the islands and mitigation actions were required to address potential secondary poisoning of these predators, which had not been necessary at the time of the feasibility study. This highlights the need to review feasibility studies as an ongoing process within the planning phase.

A number of valuable lessons were learnt during the course of the eradication. In light of the challenges faced by working in difficult conditions, the operation was delivered to a high standard by an effective team. Rope access elements worked well as a result of the thorough training, and of equipment and safety considerations which were appropriate to the operation. Once established, procedures concerning training, preparation, boating and accommodation all worked well because conditions had been considered thoroughly as part of a detailed health and safety plan. Boat access arrangements allowed sufficient access to the separate islands to achieve baiting and monitoring throughout. The whole operation provided positive input into the nearby economy of Lewis and Harris over the winter months. At the end of the eradication phase, the establishment of permanent monitoring stations provided early detection capability, which is necessary as part of delivering long term biosecurity at the islands.

Periods of heavy workload for personnel involved in eradication preparations resulted from time and resource pressures during the preparation phase. There was a need for careful planning of logistics, the satisfying of legal obligations, the need to train local personnel and set up health and safety. As a result, UK-based capacity for undertaking eradications for conservation purposes has been greatly enhanced, and the need for detailed planning from early on has been highlighted. A dedicated logistics coordinator would have been a useful additional staff member to have had in place.

Technical rope access training required a further investment of time and resources and, although the number of trained personnel was sufficient to be able to carry out checks, this did limit the total number of checks possible. Successful communication between team leaders and volunteers took place regularly throughout the operation but has been noted as an area in which continued focus is important in complex operations. Lessons learnt from this eradication will form part of a full project review planned by RSPB.

A lack of work on the genetic resistance of black rats to bromadiolone posed a potential problem, since it was not possible from the start to confidently predict whether alternative bait types might be needed. However, the consistent lack of rat sign across the islands following baiting with bromadiolone, and zero take of the alternative rodenticide, indicates that there was no genetic resistance of rodents to bromadiolone at the Shiant Isles.

The project has contributed to building UK capacity for delivering rat eradications, biosecurity and incursion response through its training of staff. Local community members at the Western Isles were involved in bait station assemblage, service provision (e.g. boats) and volunteer work during eradication operations. Providing safe breeding habitat and maintaining rodent-free status at important island sites will be an important part of the long-term legacy of protection for UK seabirds.

ACKNOWLEDGEMENTS

The Shiants Seabird Recovery Project is a partnership between the Nicolson family as island owners, RSPB and SNH. Funding was provided by the EU LIFE+ fund (LIFE13/NAT/UK/000209 LIFE+ SHIANTS), SNH and RSPB.We are extremely grateful to all volunteers engaged in preparations for the eradication and at the islands during the campaign. Eradication volunteers were: Stuart Burbidge, Alister Clunas, Alex Cropper, Cindy Denaro-Barrett, Molly Heal, James Hedges, Amy King, Tara Proud, Tegan Newman, Sandy Ogilvie, Ross Packman and Fritha West. Kate Langley, and volunteers (Phil Bertin, Shona Bertin, Heather Board, Cindy Denaro-Barrett, Richard Denaro-Barrett, Dan Fitzsimmons, Fiona Lassen, Caroline Magne, John Masterton, Anne Milne, Marie Newman and Liz Struthers) assisted by RSPB staff (Vicky Anderson, Laura Robertson and Niall Currie) helped to create hundreds of bait stations at the Harris Volunteer Centre, Tarbert. Paul St Pierre and Jaclyn Pearson assisted at the islands during the set up of the bait station grid.

The help of Reading University Vetebrate Pest Unit, who carried out rodenticide resistance testing work, is gratefully acknowledged. Jill Harden (RSPB) and Kevin Murphy (Comhairle nan Eilean Siar) provided essential archaeological assessment and advice. Boat operators Engebret Ltd and Sea Harris Ltd provided transport and logistical support throughout the operation. Air-lifting of bulk equipment to the Shiants was carried out at the beginning of the operation by PDG helicopters. Remote rope access technician training was provided by Stuart Johnson of Climb Industries Ltd and co-workers, and Adam Long of Access Techniques Ltd (at time of final check for rats). Lee Ashton provided key guidance during the establishment of health and safety procedures. We would like to acknowledge the generous support of Bell Laboratories for providing bait and traps.

The effect of Norway rats on coastal waterbirds of the Falkland Islands: a preliminary analysis

S. Poncet[1], K. Passfield[2], A. Kuepfer[3] and M.A. Tabak[4,5]

Abstract The Falkland Islands have been affected by anthropogenic-induced habitat modification including introduction of invasive species and grazing by livestock. Introduced Norway rats are known to have a large effect on native Falklands passerines but their effect on other native birds has not been explored. We investigated the effects of several environmental variables, including the presence of Norway rats and chronic grazing by livestock, on an assemblage of 22 species of coastal waterbirds by comparing species richness and relative abundance of birds among 65 rat-infested islands, 29 rat-eradicated islands and 76 historically rat-free islands. Bird count data from 299 km of coastline were used to estimate relative bird abundance, expressed as the number of individuals per kilometre of coastline for each species. Our study provided three key results. First, coastal waterbird abundance on islands historically without rats was twice as high as that on islands where rats were present. Second, bird abundance on rat-eradicated islands was intermediate between that of historically rat-free and rat-infested islands. Third, habitat modification by grazing appeared to reduce bird abundance in both rat-free and rat-infested habitats. From a conservation perspective, this study suggests that rat eradication programmes in the Falkland Islands are effective at restoring coastal waterbird abundance and would be even more so if carried out in conjunction with restoration of native coastal plant communities.

INTRODUCTION

The Falkland Islands are an archipelago of 477 islands (Falkland Islands Government, 2014) that differ in size, habitat modification and presence of introduced species. This creates unique opportunities to examine the effect of anthropogenic factors and stochastic events on the distribution and abundance of native species (Hall, et al., 2002; St. Clair, et al., 2011).

Human colonisation of the islands in the late 1700s led to considerable changes in native flora and fauna. Grazing by livestock caused a reduction of almost 80% in the coastal grasslands of tussac (*Poa flabellata)* (Strange, et al., 1988), which greatly affected bird species and populations (Strange, 1992; Woods, 1984; Woods & Woods, 2006). Major changes to bird populations are also attributed to the introduction of Norway rats (*Rattus norvegicus*)*,* black rats (*R. rattus*), house mice (*Mus domesticus*), cats (*Felis catus*) and Patagonian foxes (*Lycalopex griseus*) (Woods & Woods, 2006; Falklands Conservation, 2006). Norway rats are now present on about half of the archipelago's islands (Tabak, et al., 2015a) and are known to have a large effect on the abundance and diversity of Falklands' native passerine species (Hall, et al., 2002; Tabak, et al., 2015b), while the black rat has been recorded on one island only. Cats are known to prey on thin-billed prions (*Pachyptila belcheri*) (Matias & Catry, 2008), although nothing is known of their impact on other Falkland bird species. Mice impact small burrowing petrels and some passerine species (Rexer-Huber, et al., 2013) and Patagonian foxes reduce the breeding success of coastal waterbirds (Poncet, 1998). Prior to the arrival of these invasive predators, the only terrestrial mammal was the endemic warrah or Falklands wolf (*Dusicyon australis*)*.* Restricted to the two largest islands (East Falkland and West Falkland), this native canid may have been present for at least 70,000 years before being exterminated in 1876; craniodental evidence and first-hand accounts indicate that the warrah was an efficient predator, subsisting on penguins, geese and seals (Slater, et al., 2009). Beyond all doubt, it must have had a major impact on the distribution and abundance of all wildlife species on East Falkland and West Falkland.

The effects of introduced predators and their removal on passerine and seabird species have been relatively well documented for many islands world-wide (Ebbert & Byrd, 2002; Courchamp, et al., 2003; Rauzon, 2007; Kurle, et al., 2008; Towns, 2011; Veitch, et al., 2011), including the Falkland Islands (Woods, 1970; Strange, 1992; Woods & Woods 1997; Hilton & Cuthbert, 2010; Poncet, et al., 2011; Tabak, et al., 2014) where the eradication of Norway rats from 80 islands since 2001 provides a large-scale experiment for evaluating wildlife response to the removal of rats. Studies have shown that successful eradications result in a higher species richness of passerines (Hall, et al., 2002) and an increase in abundance of both passerines (Tabak, et al., 2015b) and invertebrates (St. Clair, et al., 2011). However, nothing is known of the impact of introduced predators on Falkland's shags, gulls, wildfowl, waders and birds of prey (referred to hereafter as coastal waterbirds) or of the response of these birds to rat eradication.

The evaluation of the subsequent recovery of native species and ecosystems following alien species eradication is an essential part of the process of determining the success of an operation (Courchamp, et al., 2011). In this study, we examined the potential effect of several environmental variables on the distribution and abundance of a coastal waterbird assemblage consisting of 22 species of ground-nesting, coastline-foraging birds. Using estimates of relative bird abundance (individuals per unit of coastline transect length) and species richness as the response variables, we compared bird populations on tussac islands that were historically rat-free, with those that were rat-infested and those where rats had been eradicated, and we examined bird response to habitat modification by grazing. We hypothesise that (1) the presence of rats would reduce bird abundance and species richness; (2) bird abundance on islands where rats had been eradicated would be higher than on rat-infested islands; and (3) long-term grazing of native habitats would reduce bird abundance and species richness.

METHODS

Study area

The Falkland Islands archipelago (12,200 km^2) is situated approximately 500 km east of continental South America between latitudes 51°S and 53°S in the South Atlantic Ocean. It consists of the two large island masses East Falkland (6,480 km^2) and West Falkland (4,450 km^2), 475 smaller vegetated offshore islands (an island being defined as any vegetated land surrounded by water at low tide) and numerous associated rocks and stacks (Falkland Islands Government, 2014), totalling over 6,000 km of coastline. Surveys of all bird species were conducted on 168 offshore islands, and on East Falkland and West Falkland. The majority of islands included in this study were remote and uninhabited, requiring access by boat.

Coastlines surveyed were typical of most rocky offshore tussac islands with upper littoral and intertidal zones of gently to moderately sloping rock, shingle or boulder, occasional small sand beaches and short stretches of sheer cliff on exposed coasts (Strange, 1992). Coastline vegetation on ungrazed islands was dominated by the native grass tussac (*Poa flabellata*), which grows up to 3 m tall and forms dense canopies. On islands grazed by livestock, plant communities were dominated by short swards of grasses and herbs.

Data collection

Surveys were carried during the breeding season (September to May) between 2008 and 2014. All surveys were conducted in favourable weather conditions and by the same two observers (S. Poncet and K. Passfield). Environmental characteristics for each transect and each island, and the identity of each bird species and the number of birds detected were recorded following a standardised data collection protocol (Tabak, et al., 2015b). Surveyors walked along the coastline at a slow and consistent pace, noting birds that moved ahead or accompanied the surveyor to avoid counting the same bird multiple times. Counts were of adults and subadults; breeding status and social structure were also recorded. The geographical location of individuals, pairs and groups of birds was recorded using a hand-held global positioning system (GPS) receiver (Garminmap 62). Introduced predators were detected visually or by field signs typical for each species.

The sampling unit (transect) on each island consisted of a 100 m-wide swathe of coastline extending from approximately 20 m inland of the high tide mark out to approximately 80 m offshore. The inland distance of 20 m was determined on the basis that this is the maximum distance at which most birds would be visible or heard by an observer walking along the shoreline. Transect length was obtained from the surveyor's GPS track. Surveys involved walking at least 1 km of coastline.

For each transect we recorded the date, local time at the start and end of survey, transect length, observer name, wind speed and direction, cloud cover, temperature, precipitation, tide state, geographic region, grazing intensity and dominant vegetation.

For each island we recorded rat eradication status, island surface area and percent of island covered in tussac using data sourced from the Falkland Islands Biodiversity Database (Falkland Islands Government, 2014). Island coastline perimeter was obtained either from the observer's GPS track data or by using mapping software to measure coastlines on map sheets 1–29 (Directorate of Overseas Surveys, 1962).

Study species

All bird species (native, non-native, resident, vagrant and migratory) encountered on transects were recorded. The number of individuals of most species was also counted. Most shoreline species are of high to very high detectability and occur in habitats that are generally open to view from long distances (Woods & Woods, 1997), there being no trees or woodlands on the islands. Species that were not easily detected (burrowing petrels which nest underground) were not counted, and nor were penguins and black-browed albatross for which the coastline survey methodology was not suitable due to the amount of time required to count large concentrations of colonial seabirds.

In this study, 22 shoreline species were grouped to form an assemblage called coastal waterbirds. These were defined as any non-passerine species that relies on the littoral and sub-littoral zones for breeding, wintering and/or foraging, and they include waterfowl, waders, a bird of prey and some seabirds (Table 1). The majority of species are common and widespread around Falklands' coasts and forage predominantly on shoreline and inshore coastal habitats (Woods & Woods, 1997). Species detected on surveys that did not conform to this definition were passerines, southern giant petrels (*Macronectes giganteus*), upland geese (*Chloephaga picta*) and ruddy-headed geese (*C. rubidiceps*). The five introduced mammalian species recorded were feral cats, black rats, Norway rats, house mice and Patagonian foxes.

Data analysis

Relative abundance and species richness

Relative abundance of each coastal waterbird species for all 170 islands surveyed was estimated as the number of individuals counted divided by the total length of transects (in kilometres) walked on that island. Species richness of an island was defined as the total number of coastal waterbird species detected in transects on each island.

Ecotypes

The 170 islands were grouped into six different 'ecotype' categories based on several specific environmental variables (Table 2). Variables were the presence or absence of Norway rats (distinguishing between historically rat-free and rat-free following successful rat eradication), the presence or absence of heavy grazing, and the presence or absence of tussac-dominant vegetation along an island's coastline. The relative abundance and species richness for the coastal waterbirds was calculated for each of these ecotypes.

Effect of environmental variables on bird abundance and species richness

We modelled the relationship between response variables (total relative abundance and species richness of the coastal waterbird assemblage) and a number of potential driving environmental variables for a subset of 139 islands using Generalised Linear Models (GLMs). The predictor variables included in these models were the presence or absence of rats (excluding islands where rats had been eradicated), the presence or absence of heavy grazing, the percent of an island covered in tussac grass ("tussac cover"), island coastline perimeter and weather and tide at the time of survey. Data from the two largest islands East Falkland and West Falkland were excluded from these GLM analyses because the difference in coastline perimeter

Table 1 Summary of the abundance of all 42 passerine and non-passerine bird species recorded on coastal transects on 170 islands in the Falkland Islands.

Total	28,633		170	299.12	228

[1] Mainland East and West Falkland: grazed and/or massively modified by past grazing; Norway rats, mice and cats present; no Patagonian foxes.
[2] Tussac islands with Norway rats: tussac dominant along the coastline; not permanently grazed and/or not massively modified by past grazing; no cats, no ship rats, no Patagonian foxes, no mice.
[3] Tussac islands without Norway rats: tussac dominant along the coastline; not permanently grazed and/or not massively modified by past grazing; no cats, no ship rats, no Patagonian foxes, no mice.
[4] Tussac islands where Norway rats have been eradicated: tussac dominant along the coastline; not permanently grazed and/or not massively modified by past grazing; no cats, no ship rats, no Patagonian foxes, no mice.
[5] Non-tussac islands with Norway rats: little or no tussac; permanently grazed and/or massively modified by past grazing; no cats, no ship rats, no Patagonian foxes, no mice.
6 Non-tussac islands without Norway rats: little or no tussac; permanently grazed and/or massively modified by past grazing; no cats, no ship rats, no Patagonian foxes, no mice.

between these islands and the smaller islands resulted in a disproportionate influence on model output. The full model contained all covariates of interest, and an intercept term and was described as where the response variable was either relative abundance or species richness of the coastal waterbird assemblage. A Gaussian distribution with an identity link function was used to describe the relative abundance response variable while a Poisson distribution with a log link function was used to describe the species richness variable. We also ran all possible reduced models, containing all possible combinations using these covariates, and calculated Akaike Information Criterion corrected for small sample size (AIC_C) for each model. For each set of models, we conducted model averaging on the best models (those with $DAIC_C < 7$), to obtain a single ensemble model for relative abundance and species richness (Burnham & Anderson, 2002). All calculations and modelling were conducted using R v.3.2.2 (R Core Team, 2015).

The individual effects of each of the above covariates on the response variable were also analysed. Discrete covariates (rats and grazing) were analysed using Welch's two sample t-test; continuous covariates (percent tussac cover and coastline perimeter) were analysed using Analysis of Variance (ANOVA).

The effect of Norway rat status on bird abundance and species richness

We also analysed the relationship between response variables and the potential driving environmental variable of Norway rat status (rat-infested, rat-free and rat-eradicated) for a subset of 155 tussac islands of less than 10 km perimeter and less than 200 ha. Bird data for ecotypes II, III and IV (Table 2) were analysed using a Kruskal-Wallis test with a Bonferroni post-hoc test to assess the effect of rat eradications on bird abundance. A one-way ANOVA with Tukey HSD post-hoc test was used to assess ecotype effect on species richness (Table 3).

RESULTS

Data overview

A total of 42 bird species (of which 22 were classed as coastal waterbirds) and 36,000 individual birds were recorded along 299.12 km of coastal transects on East Falkland, West Falkland and 168 offshore islands (Table 1; Fig. 1). The majority (156) of these offshore islands were predominantly tussac-covered, uninhabited and ungrazed; the other 12 islands had little or no tussac cover and were

Table 3 Results of the Kruskal-Wallis test with Bonferroni post-hoc tests of effects of rat status on relative abundance and of the one-way ANOVA post-hoc tests of effects on species richness of coastal waterbirds, on 155 tussac islands of which 70 were historically rat-free, 57 were rat-infested at the time of survey and 28 had been successfully cleared of rats.

Coastal waterbird	Test used	Kruskal-Wallis and ANOVA results	Post hoc results (p-value; difference in mean)	
			Rat-infested vs rat-free	*Rat-infested vs rat-eradicated*
Relative abundance	Kruskal-Wallis with Bonferroni	$\chi^2 = 166.339$ df = 153.2 p = 0.000	0.000; -3.866	0.008; -2.794
Species richness	ANOVA with Tukey HSD	F (153.2) = 2.715 p = 0.069	0.485; 0.540	0.056; 1.417

Table 4 Model-averaged estimates for each parameter on relative abundance and species richness of the coastal waterbird assemblage on 139 islands for 214.15 km of coastline surveyed. Low magnitude of covariate values (i.e. values that are close to zero) indicate that the variable has a weak or insignificant effect on the response, while high absolute values indicate that the variable is important in predicting the response.

	Model-averaged estimates for coastal waterbirds				
	Intercept	rats (present)	heavy grazing (present)	coastline perimeter (km)	percent tussac cover
Relative abundance	140.07	-69.33	-4.46	-0.13	0.28
Species richness	8.07	0.04	-0.01	1.34	0.00

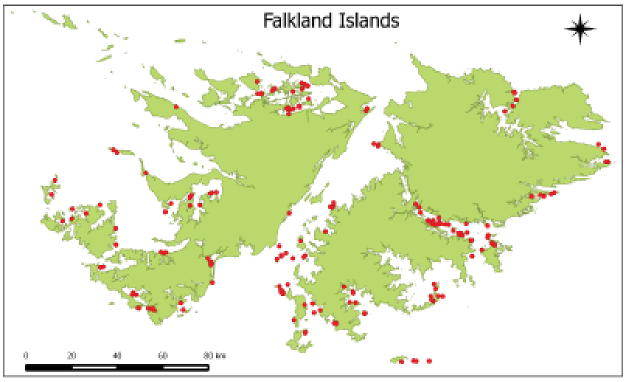

Fig. 1 The Falkland Islands showing islands where coastal bird surveys were undertaken.

grazed year-round by sheep (Table 2). Offshore islands ranged in size from 0.1 to 5,600 ha. The average length of coastline surveyed was 1.3 km; the entire coastline perimeter was surveyed on 58 of the smallest islands of less than 125 ha. Seventy six islands had one predator only (Norway rat); 63 had never had any introduced predators; 29 had been formerly occupied by one predator only (Norway rat) which had been subsequently eradicated and was absent at the time of bird survey. East Falkland and West Falkland, (collectively referred to as 'mainland') had cats, mice, Norway rats, permanent human settlements and year-round grazing by sheep and cattle. None of the islands had black rats or Patagonian foxes.

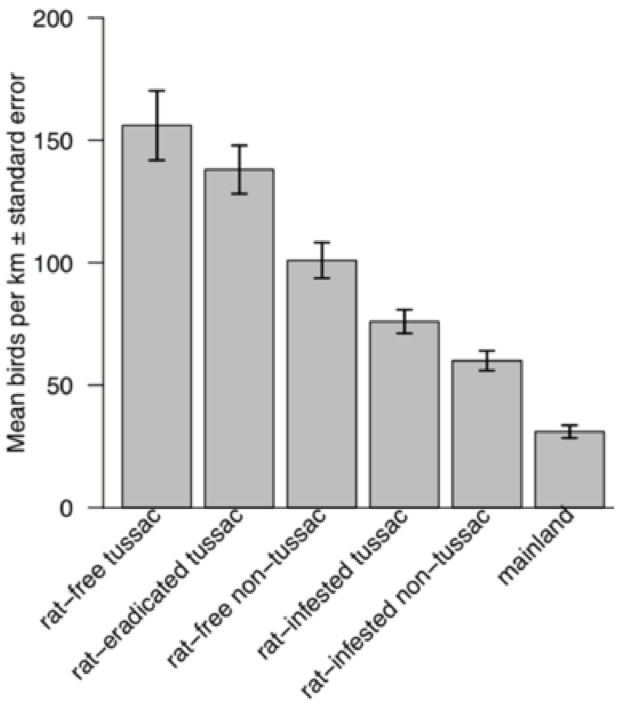

Fig. 2 The relative abundance (birds per kilometre of coastline surveyed) of the Falkland Islands coastal waterbird assemblage in six different ecotypes.

Coastal waterbirds accounted for 80% of all individual birds detected; species with the highest number of birds detected were the rock shag (*Phalacrocorax magellanicus*) and Falkland steamer duck (*Tachyeres brachypterus*), the latter being present on all islands (Table 1). Coastal waterbird abundance varied considerably between ecotypes. It was highest in predator-free tussac habitats, followed closely by rat-eradicated tussac habitat and lowest on the grazed (non-tussac) mainland coastlines where rats, mice and cats were present. It was twice as high in rat-free tussac habitat than in rat-infested tussac. A similar pattern emerged for non-tussac (i.e. grazed) islands where abundance in rat-free habitat was also nearly twice as high as that of rat-infested habitat. Overall, bird abundance in rat-free habitats, regardless of their tussac and grazing status, was higher than that in all rat-infested habitats. However, grazing also appeared to exert some effect, in that abundance was systematically lower in non-tussac habitat compared to tussac (Table 2, Fig. 2).

Effect of environmental variables on bird abundance and species richness

GLM analyses of the coastal waterbird relative abundance data from the subset of 139 islands (214.15 km of coastline) indicated that the model best supported by the data included the presence of rats (Table 4). Heavy grazing appeared to have a slightly negative effect on relative abundance; coastline perimeter of an island and the percent of an island covered in tussac had a negligible effect. Rats, heavy grazing and percent tussac cover had no effect on species richness. Coastline perimeter, however, may affect species richness, with more species being present on larger islands. The covariates depicting weather at the time of

Table 5 Results of Welch's two sample t-tests and ANOVA on the effect of rat presence, heavy grazing, percent of an island covered in tussac and coastline perimeter on the relative abundance of the coastal waterbird assemblage on 139 islands for 214.15 km of coastline surveyed.

	Welch's t-test		ANOVA
	t-value	p-value	F-value
Rats (present)	-4.63	0.0000	
Heavy grazing (present)	-2.85	0.0069	
Percent tussac cover			13.37
Coastline perimeter			6

Table 6 Results of Welch's two sample t-test and ANOVA on the effect of rats, heavy grazing, percent of an island covered in tussac and coastline perimeter on the species richness of the coastal waterbird assemblage on 139 islands for 214.15 km of coastline surveyed.

	Welch's t-test		ANOVA
	t-value	p-value	F-value
Rats (present)	0.47	0.6405	
Heavy grazing (present)	2.05	0.0513	
Percent tussac cover			0.77
Coastline perimeter			0.30

survey (i.e., wind speed, precipitation, cloud cover, and tide) did not appear in any of the best models (those with DAIC$_C$ < 7), so we concluded that they did not affect bird abundance or species richness. The effects of individual covariates analysed using Welch's two sample t-test results indicate a highly significant negative effect of both rats and heavy grazing on the relative abundance of coastal waterbirds. ANOVA results show that relative abundance increased significantly with percent tussac grass cover on an island and decreased with coastline perimeter (Table 5). Welch's two sample t-test and ANOVA results indicate that species richness is not affected by rats, heavy grazing, percent tussac cover on an island or island coastline perimeter (Table 6).

Effect of Norway rat status on bird abundance and species richness

Kruskal-Wallis tests with Bonferroni post-hoc tests showed that there was a significant effect of rat status on coastal waterbird abundance (Table 3). Bird abundance differed significantly between rat-infested and historically rat-free islands and between rat-infested and rat-eradicated islands, indicating that rat eradication resulted in an increase in coastal waterbird abundance. There was no significant difference in abundance between historically rat-free and rat-eradicated islands, which may possibly indicate that bird populations had nearly fully recovered following eradications. Results from the one-way ANOVA showed no effect of rat status on species richness.

DISCUSSION

The presence of Norway rats was the most important factor in predicting the relative abundance of the coastal waterbird assemblage (Table 4). Rat presence had a strong and significant negative effect on bird abundance (Tables 3, 4 and 5). This negative effect and the significant recovery benefits of rat eradication are like those observed for passerines (Hall, et al., 2002; Tabak, et al., 2015b). In contrast, rats did not affect species richness of the coastal waterbird assemblage.

Heavy grazing and the percent of tussac cover on an island also had significant negative effects on coastal waterbird abundance (Tables 2 and 3). Previous work has shown that grazing has a negative effect on bird abundance (Batáry, et al., 2007). In the Falklands, grazing led to the disappearance of the majority of the coastline's original vegetation of tall native grasses and shrubs which, in a landscape devoid of trees, provided optimal breeding habitat for the majority of the islands' bird populations. The impact of grazing is reflected in the higher bird abundance of rat-free tussac coastlines (ecotype III) compared to rat-free non-tussac (grazed) coastlines (ecotype V; Table 2).

An indication of the effectiveness of rat eradications in restoring coastal waterbird populations is shown by the large difference in bird relative abundance between rat-eradicated and rat-infested islands (Table 2). Abundance levels on the former are nearly twice as high as on the latter and approximate those of historically rat-free islands (Table 3) indicating that significant increases in coastal waterbird populations are likely when rats are eradicated. The importance of rat-free tussac islands (ecotype II) for Falkland bird populations is clearly demonstrated by the statistically significant difference in relative abundance of coastal waterbirds on these islands compared with rat-infested tussac islands (ecotype III) where relative abundance is 50% less. However, it is the coastlines of East Falkland and West Falkland (ecotype I where Norway rats, cats and mice are present and the impacts of grazing and destruction of native habitats are widespread), that show the largest response with a five-fold reduction in bird abundance. The impact that mice and cats exert on coastal waterbird species of the Falklands is largely unknown (Matias & Catry, 2008; Rexer-Huber, et al., 2013), although negative impacts have been assumed (Johnson & Stattersfield, 1990). Suggestions that the likely impact of the endemic warrah (*Dusicyon antarcticus*) on bird abundance was continued by later anthropogenic mammal introductions (notably cats) (Hall, et al., 2002) is an important consideration in any assessment of the potential of East Falkland and West Falkland for future vertebrate pest eradications.

CONCLUSION

Our study of the effect of environmental variables, and notably predators and over-grazing of native vegetation, on coastal waterbirds has identified the potential for differences in relative abundance of these species to serve as indicators of ecosystem recovery following rat eradications and habitat restoration activities. It is a first step in understanding the range of environmental factors that influence the distribution and abundance of Falkland coastal waterbirds. However, caution is required when interpreting differences as they may be caused not only by the balance of predation effects of Norway rats upon birds or by grazing impacts and habitat alteration but also by other indirect effects such as annual oceanographic and climate variations, biogeographical factors, island size and mesopredator release of birds (Watari, et al., 2011).

Future work will aim to determine the impact of these factors on individual species. Additionally, conducting repeated visits on islands will allow for future models to incorporate estimates of each species' detection probability. An improved understanding of how coastal bird distribution and abundance is affected by ecosystem processes is essential for informing future eradications in the Falkland Islands and for monitoring other large-scale landscape-level ecological changes to the Falklands coastline and its inshore marine environment.

ACKNOWLEDGEMENTS

Fieldwork for this research has been supported by funding from a number of organisations since 2008; they include the Antarctic Research Trust, Shackleton Scholarship Fund, Falkland Islands Government, Royal Society for the Protection of Birds, United Kingdom Overseas Territories Environment Programme, United Kingdom Joint Nature Conservation Conservancy, Falklands Conservation, Bleaker Island Farm and Falkland Islands Company. We are grateful for permission from landowners in the Falklands to access privately owned islands and we thank the following individuals for their contributions to the development of this research: Ian Fisher, Carlos Martinez del Rio, Nick Rendell, the late Ian Strange, Clare Stringer, Eric Woehler and Robin Woods.

Abstract The introduction of invasive rats, goats, and rhesus macaques to Desecheo National Wildlife Refuge, Puerto Rico led to the extirpation of regionally significant seabird colonies and negatively impacted plant and endemic reptile species. In 2012, following the successful removal of goats and macaques from Desecheo, an attempt to remove black rats using aerially broadcast rodenticide and bait stations was unsuccessful. A review of the operation suggested that the most likely contributors to the failure were: unusually high availability of alternative foods resulting from higher than average rainfall, and insufficient bait availability. In 2016, a second, successful attempt to remove rats was conducted that incorporated best practice guidelines developed during a workshop that focused on addressing the higher failure rate observed when removing rats from tropical islands. Project partners developed a decision-making process to assess the risks to success posed by environmental conditions and established go/no-go decision points leading up to implementation. Observed environmental conditions appeared suitable, and the operation was completed using aerial broadcast of bait in two applications with a target sowing rate of 34 kg/ha separated by 22 days. Application rates achieved on the ground were stratified such that anticipated high risk areas in the cliffs and valleys received additional bait. We consider the following to be key to the success of the second attempt: 1) monitoring environmental conditions prior to the operation, and proceeding only if conditions were conducive to success, 2) reinterpretation of bait availability data using the lower 99% confidence interval to inform application rates and ensure sufficient coverage across the entire island, 3) treating the two applications as independent, 4) increasing the interval between applications, 5) seeking regulatory approval to give the operational team sufficient flexibility to ensure a minimum application rate at every point on the island, and 6) being responsive to operational monitoring and making any necessary adjustments.

Keywords: bait availability, environmental conditions, operational monitoring, regulatory approval

INTRODUCTION

Tropical islands are rich in biodiversity but are susceptible to invasive species. Invasive species are the leading threat to island biodiversity (Tershy, et al., 2015), with invasive rodents known to be particularly harmful (Towns, et al., 2006). Eradications have been successful in removing invasive species (Veitch, et al., 2011), allowing island species to recover (Jones, et al., 2016), however there has been a greater record of success on temperate islands than on tropical islands (Russell & Holmes, 2015).

The two rodent eradication attempts (failed, then subsequently successful) on Desecheo Island, Puerto Rico offer an opportunity to explore the challenges of tropical rodent eradications. Here, we highlight the key changes that were made to the operational strategy during the second attempt, the role of the recently developed recommended best practices for tropical rodent eradications from Keitt, et al. (2015), and chronicle the recently confirmed successful project.

Study area

Desecheo is a small (117.1 ha) hilly island (18° 23’ N, 67° 29’ W) situated in the Mona Passage about 17 km offshore of the west coast of Puerto Rico (Fig. 1). Desecheo is composed of a peak of volcanic calcareous rock with a mosaic of grassy patches, shrublands, woodlands with candelabra cacti, and semideciduous forests dominated by *Bursera simaruba* (Woodbury, et al., 1971). The highest point is nearly 200 m with steep slopes ranging from 20 to 35 degrees

Historically, Desecheo was a major seabird rookery and in the early 1900s tens of thousands of seabirds nested on the island (Wetmore, 1918; Meier, et al., 1989) and it is home to three single-island endemic and two native reptile species (Evans, et al., 1991) and a US Endangered Species Act listed threatened cactus, higo chumbo (*Harrisia portoricensis*). Desecheo was originally set aside as a wildlife preserve in 1912, but the introduction of invasive goats (*Capra hircus*), rhesus macaques (*Macaca mulatta*), feral cats (*Felis catus*) and black rats (*Rattus rattus*), and human uses of the island, had a substantial impact on the island’s habitat, contributing to the collapse of the large seabird populations (Evans, 1989; Meier, et al., 1989).

In 1976, the island was transferred to the US Fish and Wildlife Service (USFWS) who currently manage it as

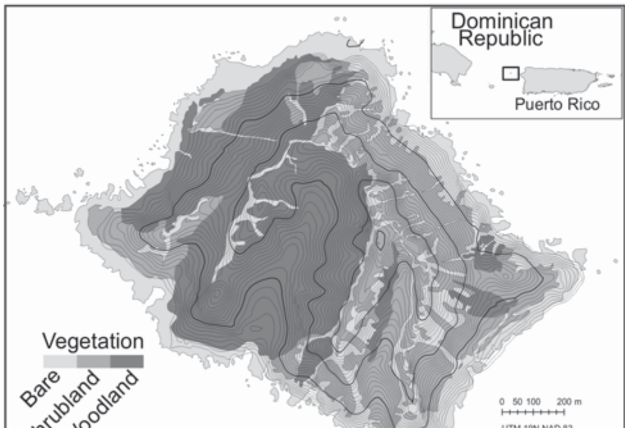

Fig. 1 Desecheo National Wildlife Refuge, located 17 km west of Puerto Rico in the Mona Passage.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 154–161. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

Desecheo National Wildlife Refuge. To restore the island, the USFWS and collaborators removed feral cats in 1987 (Evans, 1989), feral goats in 2003 and the rhesus macaque population was reduced to being functionally extinct (i.e. reproduction ceased with only one wild macaque known to remain on the island) between 2009 and 2015 (Hanson, et al., 2019). In the absence of herbivory from goats and macaques, island species showed evidence of recovery, the higo chumbo resurged from the suppression caused by herbivory (Figuerola-Hernández, et al., 2017) and researchers detected seabirds prospecting for suitable habitat and attempting to nest on the main island in small numbers. However, recovery of the island ecosystem would not be possible until rats were removed.

MATERIALS AND METHODS

Project planning

Planning for the removal of black rats on Desecheo began in 2007 through the National Environmental Policy Act (NEPA) review process. The Finding of No Significant Impact (FONSI) identified aerial application of cereal bait pellets containing brodifacoum as the preferred alternative.

The ‘dry’ season from January to April was considered the ideal period for baiting because food for rats would be limited due to the dry environmental conditions and there was a higher likelihood of suitable weather for conducting an aerial application. Field trials were conducted in February and March 2009 and 2010 to evaluate rodent breeding status, presence of naturally occurring foods, abundance of non-target bait competitors, bait application rates, and detection capabilities of rodent surveillance devices.

Rats trapped during the 2009 (n = 33) and 2010 (n = 70) field trials indicated that rat reproduction appeared to be low during the dry season with no juvenile rats caught and no captured females showing signs of lactation or foetal development. The mean hermit crab density surveyed in 2010 was 696 crabs/ha but densities were higher in woodland sites (833 crabs/ha) than in shrubland sites (61 crabs/ha). Tomahawk live traps proved to be an effective surveillance device for rats with a 25% capture rate in 2009 and 55% in 2010.

In 2009, bait availability trials using a placebo biomarker in woodland habitat showed that bait applied at 18 kg/ha remained available in most plots for at least three days. The second trial in 2010 showed similar results for the same habitat. However, plots located on ridges in shrubland habitat exhibited a much faster rate of bait disappearance. Bait consumption by ants, considered to be in higher numbers on the island’s exposed ridgelines, was suspected to be one of the key factors driving this result. Monitoring during the trials also demonstrated, through non-toxic biomarker bait, that native and endemic reptiles could be exposed. Additionally, all surveyed hermit crabs in woodland sites tested positive for the presence of biomarker; this, together with high densities of crabs, indicated that hermit crabs would be a significant consumer of rodent bait.

Based on trial data, a bait application strategy was designed to achieve a bait density on the ground of 18 kg/ha during the first application followed approximately 10 days later by a second application targeting 9 kg/ha. Desecheo has a planar area (2-dimensional) of 117.1 ha including the offshore islets, and a topographical surface area (3-dimensional) of 134 ha; the surface area is 13% higher than the planar area. To account for the island’s steep topography, bait was sown at a rate of 20 kg/ha followed by 10 kg/ha to achieve the bait density required on the ground.

2012 eradication attempt

Brodifacoum Conservation 25-D (Bell Labs, Madison WI) 2 g pellets were applied aerially by helicopter in March 2012 using a spreader bucket slung below the helicopter. To minimise the risk of bait entering the marine environment, bait was applied along the coastal zone with a directional half swath bucket (deflector) and in the interior with a full swath starting and stopping inside of the coast. A full coastal swath was flown inland of the coast at the interface of the coastal and interior zones to provide sufficient overlap or ‘safety buffering’ and reduce the risk of bait gaps and areas of lower than target bait density (Fig. 2).

Additionally, to offset suspected ant consumption and supplement aerial broadcast in high risk areas bait stations were established at an interval of 25 m along two parallel transects on the ridgelines. Ant stations armed with Amdro®Pro fire ant bait (0.73% hydramethylnon) were placed within 1.5 m of each bait station. Stations were checked at least weekly and bait was replaced as needed for six weeks.

Bait availability transects were established across two of the same habitats as the trials (woodland and shrubland) measuring 1 × 25 m. The number of pellets in each transect was standardised and plots were sampled for seven consecutive days after each aerial broadcast or until all pellets had disappeared. At each visit, the number of pellets remaining was counted.

A captive programme was undertaken to hold representative samples of two endemic reptiles as a preventive action to reduce the risk of population-level impact from the application of rodenticide. A reptile mark-recapture monitoring study was done between February and April 2012 to confirm that the use of brodifacoum did not cause any observed population-level impacts in wild reptile populations on Desecheo (Herrera Giraldo, et al., 2019).

A live rat was found and captured 12 days after the 2nd application at the field camp and a buffer of bait stations was deployed in trees surrounding the field camp. No bait take was observed, and no additional rats were seen during the next week staff were on island.

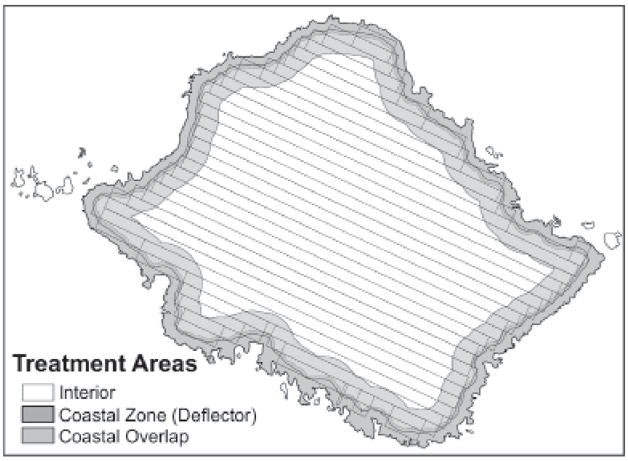

Fig. 2 Bait application strategy showing flight plan used to minimise bait into the marine environment with interior flight lines starting and stopping inside the coastal edge, a coastal half swath (deflector) along the coastal edge, and a full swath coastal overlap at the interface of the interior and coastal zones.

Eradication failure

Rats were not detected during fieldwork in October 2012 (six months post-operation), but in March 2013 (one-year post-operation) rats were observed and captured. Subsequent analysis of remote cameras deployed in 2012 showed the first rat detection in November 2012. Genetic testing indicated the eradication operation was not successful and the presence of rats was not the result of a reintroduction (i.e. operational failure).

To determine reasons why the operation may have failed, a review of the project investigated if rats *could not* eat a lethal dose because of gaps in bait coverage, insufficient bait availability, resistance to the toxin in the bait, or that the bait was not toxic enough; or if they *would not* eat a lethal dose of bait because of the palatability of the bait, availability of natural food resources, or breeding behavioural changes (i.e. pregnant females or emerging pups). Resistance to the toxin in the bait, bait toxicity, and bait palatability were not considered likely because the bait product had a proven record of success and rats captured during the biomarker trials showed a high level of acceptance. Despite implementing in the 'dry season', rainfall leading up to the operation was significantly higher than it was prior to either of the placebo bait trials, which may have resulted in a subsequent increase in the availability of natural food resources for rats and probable rat breeding. Bait disappeared quickly in several of the woodland plots with all bait disappearing within two to three nights of each application, likely the result of the significant crab densities in the woodland habitat. Finally, while there were few true gaps in bait coverage some areas during the first bait application received bait at less than half the prescribed rate. Thus, insufficient bait availability due to localised low bait densities during the first bait application and invertebrate bait competition, and an increase in the availability of natural food resources and rodent breeding due to above average rainfall, were identified as factors that could have individually or collectively contributed to the failure.

Tropical rodent eradication failures

About the same time that the 2012 attempt failed there were several other high-profile rat eradication failures on tropical islands, including Wake Atoll, western tropical pacific; Enderbury, Phoenix archipelago; and Henderson Island, Pitcairn group (Keitt, et al., 2015). A subsequent analysis of historical data showed that tropical rat eradications fail more than twice as often as temperate eradications (Russell & Holmes, 2015), resulting in a workshop attended by global experts to evaluate the possible reasons for this higher risk of failure and recommend solutions. The result of this workshop was a paper that provided recommended guidelines for rat eradications on tropical islands using aerial broadcast of brodifacoum (Keitt, et al., 2015).

Revised project approach

Starting in 2014, a steering committee of project partners (USFWS, USDA, and Island Conservation) was established to evaluate how to conduct a second attempt, the available strategy options, and how to manage ongoing project risk. A revised operational strategy was developed based on information from the review of the 2012 attempt and the recommended guidelines produced during the workshop on tropical rodent eradications (Keitt, et al., 2015). The following highlights the key changes:

1) Monitoring environmental conditions prior to the operation and proceeding only if conditions were conducive to success

A comprehensive review of factors influencing environmental conditions on Desecheo was conducted showing that rainfall and soil moisture content were key drivers of resource availability, typical of Puerto Rican subtropical dry forests. Inter-annual variability was evaluated using monthly rainfall totals and vegetation greenness, as a proxy for resource availability, between 2000 and 2013. Vegetation greenness was derived from remote sensing analyses using 30 m resolution 16-day MODIS Enhanced Vegetation Index (EVI) data. EVI data were smoothed using the HANTS algorithm (Roerink, et al., 2000) and mean monthly EVI were extracted from pixels that intersected the island using R (R Core Team, 2016).

Four assessments were conducted between three months and one week prior to implementation to evaluate the risk that short-term climatic changes could trigger higher biological productivity on the island prior to an irretrievable commitment of resources. Increased greenness represented more food availability via plants and invertebrates, and thus, increased opportunities for rodent breeding and increased bait competition due to invertebrate abundance. Each assessment included a review of regional climatic summaries, regional forecast products, and local weather conditions. Additionally, four island site visits were conducted to measure local rainfall, plant fruiting and flowering productivity, canopy cover and rodent breeding. To assist in data collection an automated logging rain gauge (WeatherShop, California, U.S.), three time-lapse cameras taking two photos per day (Day6Outdoors, Georgia, U.S.), and eight standardised photo point locations, were established on island.

A summary of conditions following each assessment was provided to the project steering committee for review. These summaries provided a subjective evaluation based on the team's knowledge of the island and the recommendations were used as part of a holistic evaluation of risk factors facing project implementation to make an operational go/no-go decision.

2) Reinterpretation of bait availability data

Using recent guidelines from Pott, et al. (2015) and data from the 2012 eradication attempt, bait availability was recalculated based on the lower-limit for a 99% t-based confidence interval. The linear rate at which bait disappeared was estimated by calculating the slope from four days of bait availability: 5.97 kg/ha per day in the woodland plots during the 2012 eradication attempt. This daily disappearance rate was used to calculate a conservative target bait density on the ground of 30 kg/ha to ensure that bait was available to rats for approximately five consecutive days after each application.

3) Treat the two applications as independent events

Following the guidelines outlined in Keitt, et al. (2015), the second attempt targeted the same application rate for each application and the target interval between application was increased to approximately 24 days. Two critical habitats, the valleys and steep cliffs identified in the review as areas of concern, were earmarked for additional supplemental bait application. On Desecheo, the predominant valleys and cliffs run perpendicular to one another, such that flights that are parallel to one are perpendicular to the other. To mitigate concerns about the impact on bait density caused by bait shadows on steep terrain (i.e. more bait downslope than upslope) and the higher rat and non-target bait consumer densities in the valleys observed during the 2012 attempt, additional flights were flown parallel to the valleys and cliff features to achieve higher application rates in these areas.

4) Seeking regulatory approval to give the operational team sufficient flexibility to ensure a minimum application rate at every point on the island

Some areas of Desecheo received bait below the desired bait density during the 2012 attempt. For the second attempt, the operational team sought regulatory approval to achieve a minimum bait density across every point on the island. This allowed for the retreatment of any areas that were estimated to be below the desired minimum bait density and limited the total amount of bait that could be applied per application rather than the application rate.

The project review also noted that the bait application strategy used to minimise bait in the marine environment created a risk of bait gaps and/or lower than planned baiting rates between coastal and interior zones. Regulatory approval was sought to ensure sufficient bait was available to treat the interface between the interior and coastal zones. This provided the flexibility to achieve the desired minimum bait density while also minimising bait entering into the marine environment.

5) Responding to operational monitoring in real time

To ensure quality coverage, bait sowing rates were carefully monitored and the helicopter shut down every five loads to download GIS files and review progress. During each application, a GIS specialist produced bait application maps estimating bait densities achieved on the ground. These data were used to identify any possible errors in flight lines, GPS logging, or bait application rates. Any gaps, identified as areas larger than 20 × 20 m receiving less than 15% (5 kg/ha) of the target bait density, were re-treated.

Greater emphasis was placed on operational monitoring than in 2012, including the deployment of additional bait availability monitoring transects and ground-truthing of bait application rates across the island. Additionally, communications between the environmental monitoring and bait application teams were improved by conducting the bait loading on island so that key project personnel were in the same place. In 2012 bait loading was done in Rincón approximately 17 km away on the main island of Puerto Rico. Following the first bait application, and prior to the second, a review of all operational data was conducted to allow for adjustments to the operational strategy.

2016 eradication attempt

The second eradication attempt was conducted in March and April 2016. The baiting strategy used was similar to the 2012 attempt albeit with an increased application rate and additional supplemental treatments along the cliffs and valleys. As in 2012, the sowing rate during the 2016 attempt was increased from 30 kg/ha to 34 kg/ha to accommodate the 3-dimensional surface area to ensure the desired bait density on the ground.

To allow comparisons with bait availability data collected during the previous field trials and the 2012 attempt, 25 m^2 sample transects were monitored in the woodland and shrubland habitats using the previous protocols. Additionally, a circular hoop sampling method (1 m^2) was used to estimate bait density on the ground following each application and collect additional bait availability across five different treatment zones.

Confirmation

In April 2017, one year after implementation, staff returned to the island and deployed chew tags, tracking tunnels, and live traps to confirm the absence of rats. Additionally, images from trail cameras were collected and analysed.

RESULTS

A summary of key differences between the two attempts is outlined in Table 1.

Environmental conditions

On first arrival at Desecheo Island on February 19, 2012, initial impressions were that the island's vegetation was more lush and green than observed during the same period in 2009 and 2010. Personnel recorded a total of 25.5 mm of precipitation on Desecheo between 10 March and 2 April 2012. Opportunistic necropsies of a small number of rats (n = 6) found dead during the 2012 operation showed one female rat with three embryos, and a male and the same female showed subjectively significant abdominal fat. However, the monitoring team did not observe any small juvenile rats suggesting breeding was not widely occurring for any prolonged period beforehand.

Retrospective analysis of precipitation recorded at the Rincón, Puerto Rico station (the closest point to Desecheo) showed that rainfall between January and March 2012 was above the annual average, and in February 2012 precipitation was 2.9 times higher than the 34-year average and the third highest rainfall for the month of February since 1968 (NOAA, 2015). Further, the remote sensing

Table 1 Summary of key differences between the 2012 and 2016 eradication attempts on Desecheo.

Factor	2012	2016
Month	March	March/April
Rainfall 6 months prior	4603 mm	772 mm
Rainfall during	25.5 mm	35.56 mm
Rodent breeding	One pregnant female observed (n=6)	None observed (n=44)
Canopy Cover	Flush vegetation	Post-peak vegetation followed by unproductive flowering after 31 mm rain event
Target bait density	18 kg/ha, 9 kg/ha	30 kg/ha, 30 kg/ha
Average application rate	17.1 kg/ha, 9.1 kg/ha	40.3 kg/ha, 39.9 kg/ha
Interval between applications	9 days	22 days

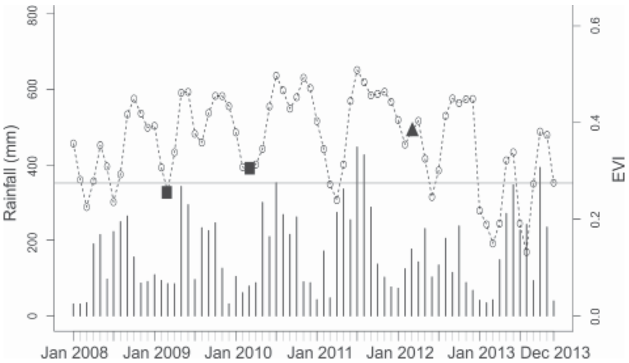

Fig. 3 MODIS Enhanced Vegetation Index (EVI) showing vegetation greenness vs rainfall in inches from Aguadilla, Puerto Rico. Dashed line represents EVI where higher EVI means greener and lower EVI means drier vegetation. Stacked lines represent rainfall in millimetres. The solid horizontal line represents the mean EVI for March, black squares EVI during placebo trials and black diamond EVI during the 2012 eradication.

analyses showed that March 2012 had significantly higher EVI than the same period during either of the 2009 or 2010 trials (Fig. 3).

During the assessment trips leading up to the 2016 attempt, observations showed that the island, while lush and green, was in post-peak greenness and starting to dry out in January 2016. This corresponded with a delayed and short wet season, likely the result of a record drought throughout much of Puerto Rico in 2015 (NOAA, 2015). By February there was a significant reduction in canopy cover; however, a significant rain event (31 mm in 24 hours) resulted in a large increase in canopy cover by March, mostly restricted to *Bursera* trees. Increased flowering was noticeable on some herbaceous shrubs and vine species; however, the fruits produced were not considered to be an alternative food source for rats. Increases in canopy cover continued through March, but by April 2016, after the second application of bait, most flower and fruit production had been abandoned. An irruption of caterpillars occurred after the second application, consuming much of the fresh *Bursera* growth (Shiels, et al., 2017).

Between 25 January and 10 April 2016, a total of 105.9 mm of precipitation was observed on Desecheo. Almost half of this precipitation was the result of two single events. In comparison, Rincón received a total of 239.3 mm of precipitation in the same period.

A total of 44 rats was captured during the 2016 attempt, all animals captured were adult size and none of the females showed signs of pregnancy, although some females showed indications (fat deposits and engorged uterine blood vessels) that breeding could have occurred soon after.

Bait application

During the 2012 eradication attempt, 3,588 kg of bait was applied on Desecheo as required by regulatory compliance, which resulted in an average application rate of 17.1 kg/ha and 9.1 kg/ha. An interval of nine days separated the first and second bait applications. Additionally, a total of 127 kg of bait was used in 107 bait stations placed along the ridges. The target application rates (18 kg/ha and 9 kg/ha) were at the upper limits allowed by regulatory requirements and the operational team was cautious in their approach with 1,000 kg of available bait unused. While the average application rates (total bait divided by island area) achieved were 17.1 kg/ha and 9.1 kg/ha, 76% of the island had a bait density on the ground below the target, with 8% less than half the target rate during the first application and 50% of the island below the target, with 4% less than half the target, during the second application.

In 2016, 10,650 kg of bait was applied according to regulatory compliance, resulting in an average application rate of 40.3 kg/ha and 39.9 kg/ha separated by 22 days. Regulatory approval was sought to allow for the retreatment of areas with less than the target bait density, ensuring a minimum bait density at every point across the island.

Table 2 Bait availability results from placebo trials and both eradication attempts on Desecheo. Bait availability is expressed as the 99% lower limit t-based confidence interval of mean bait availability to represent the “worst-case” scenario rather than the average case.

Habitat	Year	Plots	Target bait density (kg/ha)	Lower limit bait availability (kg/ha) after one day	Lower limit bait availability (kg/ha) after three days
1st Application					
Woodland	2009	6	18	0.5	0
	2010	9	18	3.2	0
	2012	5	18	6.9	0
	2016	6	45	7.8	0
Shrubland	2010	6	18	0	0
	2012	7	18	11.5	4.9
	2016	6	30	23.6	14.8
2nd Application					
Woodland	2009	6	18	-	-
	2010	9	18	-	-
	2012	5	9	0	0
	2016	8	45	36.0	24.0
Shrubland	2010	6	18	-	-
	2012	7	9	8.3	5.7
	2016	6	30	30.0	27.5

Using this strategy 11% of the island received less than the target bait density and 2% received less than half the target during the first application. During the second application 31% of the island received less than the target bait density and1% less than half the target.

A review of operational monitoring data following the first application during the 2016 attempt showed that bait disappeared faster than anticipated in the woodland valley habitat. In response, a total of 100 bait stations were installed in the valleys spaced at least 25 m apart. Bait stations were filled the day after aerial broadcast and elevated in trees wherever possible to reduce bait take by crabs. Each station was checked and replenished (if needed) three times during a three-week period. A total of 22.25 kg of bait was used in bait stations.

There was a small increase in the number of non-target carcasses observed between the 2012 (n = 4) and 2016 (n = 17) attempts, although a larger team was surveying the island for a longer duration in 2016. Few non-target species presented a high-risk exposure pathway so significant mortality was not expected following the 2016 attempt despite the increase in total bait applied to the island. Additionally, biological samples of rats, reptiles, and invertebrates were collected before and after the 2016 attempt to evaluate the persistence of brodifacoum in the environment four years after the 2012 attempt, if still detectable, and following the 2016 attempt, results of which will be reported elsewhere.

Bait availability

Observed bait availability was represented as the 99% lower limit confidence interval of mean bait availability (Table 2). The lower limit was used instead of mean availability to represent the "worst-case scenario" of bait availability rather than the average. During the first applications of both the 2012 and 2016 attempts, estimated bait availability reached zero in the woodland plots within three 24-hour periods despite the difference in application rates (Fig. 3).

Confirmation

A biosecurity monitoring trip was conducted seven months after the second attempt in November 2016 during which 10 A24 GoodNature traps, 40 bait stations, 10 Tomahawk live traps, 50 chew tags and 10 trail cameras were placed near possible landing sites. In April 2017, a total of 179 chew tags, 22 tomahawk live traps, 21 trail cameras and 20 tracking tunnels were placed across the island over a nine-day period for a total of 1,074; 124; 3,108; and 114 detection nights, respectively. No signs of rats were detected on any device during either monitoring trip. Following confirmation, monthly biosecurity monitoring trips between September 2017 and March 2018 continued to check the surveillance devices with no detections of rats.

DISCUSSION

The failure of the rat eradication on Desecheo in 2012 provided an excellent opportunity to better understand the reasons for failure, build upon the lessons learnt from other failed projects, and design a second attempt that addressed the key challenges. Keitt, et al. (2015) lays out a suite of recommendations to increase the probability of success for tropical rat eradications using aerial broadcast of brodifacoum based on reviews of several failed projects and input from a large group of experts. Desecheo was the first of these failed projects to be implemented a second time and enables review of the operational changes that contributed to operational success.

Environmental conditions

On tropical islands rainfall is a key driver of primary productivity and resulting elevated vegetation density is associated with an increase in rodent population densities (Harper & Bunbury, 2015). Like other dry tropical islands, primary productivity and resulting resource availability in the dry season on Desecheo (January–April) can be variable and is highly dependent on the amount of soil water recharge generated from successive rainfall events in the previous year's wet season (July–December) and the timing and amount of rain during the dry season. Environmental conditions leading up to the 2016 attempt were drier than those in 2012, primarily as an artefact of long term drought conditions experienced in 2015, resulting in lower primary productivity, less resource availability, and lower probability of rodent breeding. We feel that these 'favourable' conditions contributed to project success and had conditions leading up to the 2016 attempt been like those observed in 2012 the project would have been postponed.

Even though environmental conditions, and their subsequent implications for project success, are difficult to predict, the subjective assessments conducted on Desecheo were critical to the steering committee's confidence in proceeding with the bait application. They provided an opportunity to critically evaluate project risk and, more importantly, considered the consequences of postponement in advance of a final go/no-go decision. Where possible, future projects can improve stakeholder confidence by identifying the primary environmental drivers that pose risks to project success and developing a process that evaluates these risks to inform a final go/no-go decision. Projects should identify the worst-case scenario of alternative resource availability, non-target bait competitor abundance and rodent breeding, and plan accordingly.

Desecheo was relatively easy to access during day trips, but the deployment of an automated rain gauge and time-lapse cameras and use of remote sensing data provided valuable information on climatic conditions that could be replicated on remote islands. On islands where variability in environmental conditions pose a risk to operational efficacy projects should consider using these tools and others to better evaluate these risks. At the very least, projects can improve the collective knowledge of the challenges facing tropical rodent eradications by documenting and reporting observed environmental conditions, and subsequent perceived risks, leading up to and during implementation.

Bait availability

The review of the first attempt identified inadequate overall or localised baiting rates as one of the more likely causes of failure to eradicate rats. As described in Keitt, et al. (2015) eradications should strive to make bait available to rats for at least four consecutive 24-hour periods to maximise the probability that all rats are exposed to a lethal dose. The interpretation of the bait availability data for the 2012 attempt used mean bait availability to determine sufficient bait availability rather than the lower limit of 99% confidence intervals. Reinterpretation of the placebo trials using the 99% lower limit confidence interval method estimated that with a rate of 18 kg/ha the lower limit of bait availability would reach zero within two to three days. This was further supported by data from the 2012 attempt where the lower limit of bait availability went to zero by the third day after bait application (Fig. 3).

During the 2016 attempt bait availability observed in the transect sampling (25 m^2) roughly followed observations from the 2012 attempt where bait disappeared more quickly

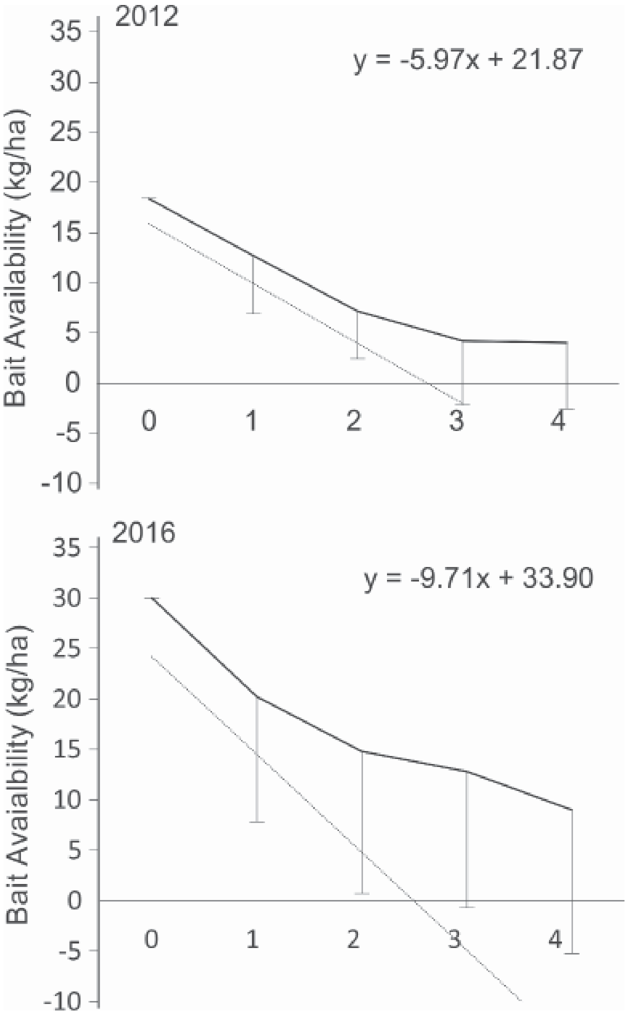

Fig. 4 The mean bait availability from the 25 m² bait availability plots set in the woodland habitats in 2012 and 2016. Day 0 represents the broadcast date and Day 1 represents the first 24-hour period during which bait is available to bait consumers (i.e. day 1 ends 24 hours after the end of bait application). The error bars represent the lower limit for a 99% t-based confidence interval. The trend line represents the bait disappearance rate based on the lower limit.

in the woodland than in the shrubland habitat. Although the revised strategy intended for bait to be available for at least four consecutive 24 hour periods after bait application, the lower limit of bait availability in the woodland plots was similar to the 2012 attempt and reached zero by the third day after bait application despite the nearly two-fold increase in application rate. This highlights some of the challenges tropical rodent eradications face in the presence of non-target bait competitors, supports the methods proposed in Pott et al. (2015) for evaluating bait availability data, and suggests that the higher application rate used in the 2016 attempt may have been necessary in the hermit crab-dense woodland habitat to ensure sufficient bait availability for all rats.

Regulatory approval

One of the criticisms of the 2012 attempt was that some areas received lower than the prescribed rates during the first application, particularly inside the coastal edge. This was potentially a consequence of the complex regulatory environment in the United States and the strategy employed to minimise bait spread into the marine environment. The desired target application rate on the ground was very near the maximum rate permitted by regulation and the operational team needed to strike a balance between achieving the desired application rate while staying within permitted limits. This was not an issue unique to Desecheo as, in general, aerial eradications conducted in the Unites States tend to use less bait than planned, compared to projects conducted elsewhere that use more than planned (Will, et al., 2019).

Leading up to the 2016 attempt the operational team aimed to address this challenge by engaging regulatory partners early in the project process as part of the project steering committee. The operational team justified, and sought approval for, a strategy that focused on achieving a site-specific minimum application rate based on the best available science. The justified strategy estimated the amount of bait needed to achieve a minimum rate at every point across the island, the amount of bait needed for overlapping flights necessary to minimise bait spread into the marine environment while minimising the chance of gaps along the coastal edge, and an additional amount of bait to fill unanticipated gaps and undertreated areas. Particularly in complex regulatory environments, future projects should consider seeking site-specific regulatory approval based on a justified strategy that maximises project success and bait quantities derived from a predicted flight plan.

Operational strategy

The justification for increasing the interval between applications was to reduce the risk posed by the scenario of pups emerging three weeks after the first application. The justification for using the same application rate in both applications was to ensure bait availability in the presence of non-target bait competitors. It should be noted that several tropical island eradications elsewhere have been successful with shorter gaps between bait applications. For example, in Mexico seven projects were successful with durations of 7–10 days between applications (Samaniego-Herrera, et al., 2014, 2017) even though rat breeding was confirmed. Additionally, an interval of three weeks could incur considerable operational costs while personnel and equipment are on standby. Alternatively, rodent breeding risks could be mitigated by increasing the application rate so that bait was available for a longer period, or conduct a third application; however, these would need to be balanced against associated non-target risk. As Keitt, et al. (2015) note, the recommendations should not be considered hard and fast rules as every island is different and we still have much to learn about tropical ecosystems.

The decision to apply additional bait in the valleys and on cliffs was based on the perceived risks justified from observations in 2012. These concerns appear somewhat validated because bait disappeared quickly in the woodland plots following the first application in 2016 despite the increased higher application rate from the 2012 attempt. It is difficult to evaluate what impact this strategy decision had on operational success but this stresses the importance of selecting bait application rates based on the best available science. Additionally, future projects should consider an additional treatment to increase confidence in areas of concern.

Operational monitoring

Intentionally slowing down the bait application in 2016 and reviewing bait density estimate maps improved the quality of the bait application and ensured that significantly less of the island was below the minimum bait density than during the 2012 attempt. Future projects should consider this strategy particularly on small islands where a single load treats a significant proportion of the island, and using bait density estimate maps to identify gaps or low treatment areas (Will, et al., 2019).

The second attempt put emphasis on near-real time information sharing to inform decision-making during the operation. While there is limited opportunity for adaptive management during aerial eradications, where success or failure is largely determined on the day, projects should put processes in place to ensure that data from the field are available to inform operational decision making and risk assessments during project implementation. Comprehensive operational monitoring allows managers to implement any available response options and, more importantly, allows stakeholders to understand project risk as the implementation unfolds.

CONCLUSION

Although we are unlikely to determine the influence environmental conditions, bait applications rates, or the interval between applications have on project success without experimentation, the variability in conditions observed on Desecheo during the 'dry' season and the consistently high rate of bait disappearance in crab-dense areas highlight the importance of understanding an island's ecosystem prior to implementing tropical eradications. The second attempt on Desecheo provided a significant opportunity to reconsider operational strategies for tropical eradications and marks the first of the high-profile failures to be successfully redone following the global review of tropical rodent eradications. The synthesis of recommended guidelines in Keitt, et al. (2015), and the process of reviewing project risks at pre-determined times, were necessary for increasing stakeholder confidence to make a second attempt. Ultimately, the rationale employed during the successful 2016 attempt should increase global confidence in rodent eradications on tropical islands.

ACKNOWLEDGEMENTS

The eradication of invasive rodents from Desecheo was led and funded by USFWS (Caribbean Islands NWR) and supported by Island Conservation and USDA – National Wildlife Research Center. We are very grateful to the donors who provided significant match funding including the David and Lucile Packard Foundation and the National Fish and Wildlife Foundation. In-kind assistance was provided by the Commonwealth of Puerto Rico Department of Natural and Environmental Resources, the Puerto Rico Department of Agriculture, and the Puerto Rico Electric Power Authority and a generous donation of bait by Bell Laboratories Inc. We would also like to thank the many other local companies, agencies, and individuals that assisted during project implementation.

The eradication of black rats (*Rattus rattus*) from Dog Island, Anguilla, using ground-based techniques

E. Bell[1], J. Daltry[2], F. Mukhida[3], R. Connor[4] and K. Varnham[5]

[4] Department of Environment, Government of Anguilla, The Valley, Anguilla. [5] RSPB, The Lodge, Sandy, Bedfordshire, United Kingdom.

Abstract Rat eradication techniques developed in New Zealand are a proven method for removing invasive rodents from islands worldwide. This technology moved rapidly from ground-based bait station operations to aerial application of rodenticides. Rat eradications on tropical islands using similar methods, have not always been as successful as those in temperate regions. As most previous eradications in the Caribbean have been on islands smaller than 50 ha, the eradication of black rats (*Rattus rattus*) from 207 ha Dog Island was a significant increase in size. Reptile and seabird populations on Dog Island had been in decline for a number of years and black rats were identified as the most likely factor. Following the feasibility study in 2007, the Dog Island Recovery Project was launched in 2011. This was a multiple-year project incorporating a ground-based eradication with establishment of biosecurity procedures to prevent reinvasion, alongside long-term monitoring of native species. Bait stations with cereal-based wax blocks containing brodifacoum at 0.005% w/w were established on a 30–50 m grid over the island. Interference with bait stations by non-target invertebrates, particularly crabs, was high and bait stations required moving or elevating to avoid this. However, there was no evidence of any non-target animals being killed or injured by the bait. Eradication success was confirmed in 2014.

Keywords: biosecurity, black rat, brodifacoum, Dog Island, eradication, monitoring, *Rattus rattus*

INTRODUCTION

Dog Island (207 ha) is located 13 km north-west of Anguilla (18.2783°N, 63.2533°W) in the north-east Caribbean and consists of one main island and three smaller offshore cays, East, Mid and West Cay (Sanders, 2006; Hodge, et al., 2008). Designated as an Important Bird Area, the Royal Society for the Protection of Birds (RSPB), Anguilla National Trust (ANT) and Fauna & Flora International (FFI) have monitored the seabird colonies on Dog Island for nearly 10 years and recorded that seabird populations, particularly sooty terns (*Onychoprion fuscatus*) and magnificent frigatebirds (*Fregata magnificens*), had been declining (Campbell, 1991; Sanders, 2006; Holliday, et al., 2007; Hodge, et al., 2008; Daltry, 2010). Dog Island also has a much reduced endemic reptile community consisting of the Anguilla Bank ground lizard (*Pholidoscelis plei*), the Anguilla Bank tree lizard (*Anolis gingivinus*), two species of dwarf gecko (Anguilla Bank dwarf gecko (*Sphaerodactylus parvus*) and Leeward Island banded gecko (*S. sputator*)), and the Anguilla Bank skink or slipperyback skink (*Spondylurus powelli*); surveys in 2009 failed to observe any dwarf geckos or skinks (Hodge, et al., 2003; Daltry, 2010; Hedges & Conn, 2012). Black (ship) rats (*Rattus rattus*) were identified as the most likely factor influencing this decline through predation on eggs, and young or small individuals. Rats are known to have devastating effects on seabird and reptile populations, causing extinctions on numerous islands worldwide (Moors & Atkinson, 1984; Atkinson, 1985; Towns, et al., 2006; Jones, et al., 2008, Harper & Bunbury, 2015). Many islands have been successfully cleared of rats, including more than 30 in the Caribbean, with a subsequent increase in bird and reptile populations (Day & Daltry, 1996; Daltry, 2000; Daltry, et al., 2001; Thomas & Taylor, 2002; Towns & Broome, 2003; Jones, et al., 2008; Varnham & Daltry, 2006; Howald, et al., 2007; Varnham, 2010).

The Dog Island Restoration Project partnership (consisting of Anguilla National Trust (ANT), Anguilla Department of Environment (DOE), Fauna & Flora International (FFI), the Royal Society for the Protection of Birds (RSPB) and the island owner, Anguilla Development Company) commissioned the development of an operational plan to eradicate black rats from Dog Island in 2011 (Bell, 2011) based on an earlier feasibility assessment (Varnham, 2007). Wildlife Management International Limited (WMIL) directed the eradication with the assistance of international volunteers and ANT, DOE, FFI and RSPB staff. The three-phase Dog Island Recovery Project (Phase I eradication of black rats; Phase II long-term monitoring of native species and Phase III biosecurity) began in January 2012.

METHODS

Study area

Dog Island is a low-lying (highest point: 29 m asl), rocky island with three small offshore islets (Mid Cay, West Cay and East Cay). There are several long, sandy beaches, two saline ponds and the rest of the coastline is rocky or has low cliffs (< 8 m high). The island lies within a Marine Protected Area, covering an area of approximately 10 km^2 around the island (Hodge, et al., 2008). The island is popular with visiting yachts and tourist vessels from Anguilla or Saint Martin/Sint Maarten.

Dog Island was originally covered in dry forest or woodland, with shorter vegetation in coastal areas exposed to salt spray, but today is dominated by low, thorny scrub (e.g. *Lycium americanum* and *Castela erecta*) and prickly pear cacti (*Opuntia* spp.) due to herbivory by feral goats (*Capra hircus*). Larger trees including manchineel (*Hippomane mancinella*), sea grape (*Coccoloba uvifera*), white cedar (*Tabebuia heterophylla*) and buttonwood mangrove (*Conocarpus erectus*) can be found around the coastline and occasionally inland.

The island is recognised as an Important Bird Area because it is globally significant for a large number of breeding seabirds, in particular sooty terns and magnificent frigate birds, (Sanders, 2006; Hodge, et al., 2008). Other

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 162–166. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

seabirds include brown boobies (*Sula leucogaster*), laughing gulls (*Larus atricilla*), masked boobies (*S. dactylatra*), brown noddies (*Anous stolidus*) and red-billed tropicbirds (*Phaethon aethereus*) (Holliday, et al., 2007; Hodge, et al., 2008; Daltry, 2010). The commonest land-birds on Dog Island are Caribbean elaenias (*Elaenia martinica*), bananaquits (*Coereba flaveola*) and black-faced grassquits (*Tiaris bicolor*). The island is also frequently used by migratory species travelling between North and South America (Holliday, et al., 2007; Daltry, 2010; Ross, 2011). A total of 48 resident and migratory bird species were confirmed on Dog Island by Richard Brown and Giselle Eagle from January to March 2012 (Bell, 2012).

Dog Island also has an important, albeit reduced, community of endemic lizards (Hodge, et al., 2003; Hedges & Conn, 2012). Notable missing reptiles are the globally threatened Anguilla racer (*Alsophis rijgersmaei*) and Lesser Antillean iguana (*Iguana delicatissima*), which were presumably present in the past. Dog Island would have been connected by a land bridge to Anguilla and indeed the rest of the Anguilla Bank well into the late Pleistocene, likely until 5,000 years ago. Three globally threatened species of marine turtles – hawksbill (*Eretmochelys imbricata*), green (*Chelonia mydas*) and leatherback (*Dermochelys coriacea*) – nest on and forage around Dog Island. Freshly dug holes have been recorded on many of the island's beaches (Hodge, et al., 2003; Daltry, 2010).

There have been few studies of the invertebrate fauna of Dog Island. Varnham (2007) collected samples using pitfall traps, but her specimens have not been identified to date (Daltry, 2010). Hermit crabs (*Coenobita clypeatus*) are present in high numbers, particularly around the coast.

Feral goats are present on the island; a remnant of more extensive grazing practices (Daltry, 2010). These goats are the property of the landowner but are hunted regularly, with or without permission. There are no known native mammals on Dog Island, but it could potentially support native bat species.

It is not known when black rats became established on Dog Island; but this is likely to have occurred sometime after 1613 when rats were first recorded in the Caribbean region (Harper & Bunbury, 2015). There is a history of human habitation on the island (i.e. stone walls and ruins) and rats may have reached Dog Island during this occupation or when ships were wrecked along the shores. Rats have been implicated as causing major impacts on island biodiversity (Towns, et al., 2006; Jones, et al., 2008) and they are known to have effects on important species on Dog Island. House mice (*Mus musculus*) have never been recorded on Dog Island (Varnham, 2007; Hilton & Connor, 2008; Bell, 2011).

Eradication operation

The eradication operation was planned to take place in the dry season (between January and May), when natural foods for the rats are in short supply and when there was little, or no risk of the operation being interrupted by tropical storms or hurricanes. The eradication option adopted for this project was a ground-based poison programme using protective bait stations to reduce risk to non-target species, particularly the reptile and feral goat populations. The eradication programme ran from 8 February 2012 to 4 April 2012 and included establishing the bait station grid, poisoning, monitoring and biosecurity. Biosecurity monitoring ran monthly between April 2012 and February 2014. The final check, species monitoring, and rat-free declaration ran from 10 to 19 February 2014. A core team of ten people completed the eradication, six people completed the biosecurity monitoring and a four-person team completed the final check. Each operational task was undertaken and completed as follows:

Bait station grid

A series of parallel tracks was cut through the vegetation on Dog Island, by a local contracting firm from Anguilla, between 20 November 2011 and 10 February 2012. Three additional lines were completed between 27 February and 6 March 2012. The contracting firm used two mechanised tools; machetes and rakes, to complete the task. One third of the island (the north-eastern end) had lines that were 30 m apart where the scrub was lower and easier to cut and the rest of the island, where scrub was much denser and more difficult to clear, had lines that were 40 m apart; bait stations were placed every 30 m along these lines. Areas of manchineel were not cut by the contracting firm (under arrangement with ANT as they did not want to deal with the toxic plant) during the track cutting phase of the project, but the main areas of manchineel were completed by the eradication team over a one-week period (10–15 February 2012) during the grid establishment phase, and two smaller stands of manchineel were completed over two four-day periods during the baiting phase (2–6 and 12–16 March 2012). Protective gloves and clothing and full-face masks were worn by the team when cutting tracks through the manchineel to avoid the sap and fumes which can irritate or blister the skin and cause breathing issues.

The bait station grid was established between 8 February and 15 February 2012. Bait stations were made from 1.5-litre plastic bottles (with the top and bottoms removed) donated by the public on Anguilla. These stations were pegged to the ground with wire "legs" to prevent movement by wind and/or stabilised with rocks or other material to reduce interference by feral goats. Bait was placed in the centre of the station through either end of the bottle.

Bait stations were placed out on the baiting grid. Mid and East Cays (not shown in the figures) were baited, but bait was laid on the surface (i.e. under vegetation and rocks) as feral goats were not present on the cays and there were few other non-target species present on these offshore islets. Each station was marked with flagging tape to ensure visibility in thicker vegetation.

The entire grid of 1,714 stations was established before being individually numbered and mapped using GPS and added to a GIS-linked database (Fig. 1).

Poisoning

Brodifacoum was used in two formulations: Klerat® (Syngenta, UK), a 20 g, wax-based wax block containing the bittering agent Bitrex™, and Pestoff® (Animal Control Products, NZ), a 24 g grain-based block bait. Both had 0.005% active ingredient and were dyed blue (or green/

Fig. 1 Bait station grid on Dog Island, Anguilla (bait station positions are marked by a black dot).

blue), to be less attractive to birds (Caithness & Williams, 1971; Hartley, et al., 1999; Weser & Ross, 2013).

The poisoning programme commenced on 16 February 2012 and continued through to 30 March 2012. Baits were present in each station throughout the poisoning programme and replaced as required. Two bait blocks were constantly available in each main island bait station throughout the programme. Klerat® was used as the main bait (16 February–20 March and 26–30 March). Pestoff® was only used for checks 20 and 21 (21–25 March) to target any surviving or rats that had avoided Klerat® for any reason.

The bait stations on Dog Island were checked and serviced every 1–4 days. However, the stations on the offshore cays were only checked twice, during suitable weather, on team changeover days when the boat was available. Thus, they had more bait per station (10 blocks) than on the main island. To present the data on bait-take gained from these varied bait station checks we grouped the data into 25 periods or checks (mean (±SEM) = 1.44 ± 0.14 days between checks, range 1–4 days) shown as days from baiting (Fig. 2).

Bait take was recorded in field notebooks by bait station number and the species believed to have consumed or removed the bait as confirmed by sign in and around the bait station (i.e. pieces or fragments with rat teeth marks or crab claw marks, etc.). These data were entered into a database and large-scale maps showing active stations were produced in real-time to enable the team to effectively monitor bait take activity and target any "hot spots". All rat carcasses found were collected and returned to base for incineration to reduce risk for non-target scavengers.

Mitigation measures such as using bait stations to prevent access by goats to the bait, moving bait stations if crabs interfered with the stations and raising the bait stations into vegetation were used to reduce the risk of primary and secondary poisoning to non-target species.

Monitoring

Three distinct periods of monitoring were undertaken as the project progressed. Monitoring points consisted of materials attractive to rats (e.g. chocolate flavoured wax or resin, candles and soap) and tracking tunnels. Intensive monitoring using 3,428 points at 15–20 m spacing was carried out from 12 March 2012 to 4 April 2012 to detect any surviving rats. This was followed by a 22-month period of long-term monitoring using 167 commercial lockable plastic bait stations (placed around the coastline of Dog Island as long-term biosecurity stations) from 5 April 2012 to 9 February 2014. These biosecurity stations were established at high risk areas on the island; around the coast and at seabird breeding sites (Bell, 2012). The final check, using 626 monitoring points and biosecurity stations, was carried out between 10 and 19 February 2014. WMIL, FFI and ANT staff and volunteers carried out the intensive and final checks and ANT staff and volunteers maintained the long-term monitoring. All stations were individually numbered and any evidence of activity (e.g. teeth marks or foot prints) was recorded in field notebooks by number and the species believed to have consumed the wax or soap or marked the tracking plate.

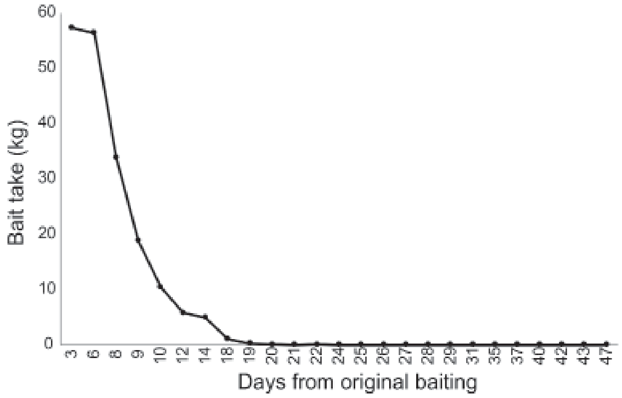

Fig. 2 Amount (in kg) of bait consumed by black rats (Rattus rattus) at each bait check (marked by black dot) during the black rat eradication on Dog Island, Anguilla (Day 1 was 16 February 2012).

Monitoring items were placed inside and outside each biosecurity station as well as halfway between each biosecurity station. Sand traps smoothed out to detect rat foot prints were established on beaches and inner island tracks. Checks for active rat runs and activity (i.e. identifying evidence of predation or scavenging on carcasses, chews on plants, droppings, etc.) at high-risk sites (i.e. ruins, seabird colonies, etc.) were also undertaken.

Each monitoring site was checked regularly, either separately, or during the poisoning phase, together with the poisoning bait station grid. Any rat and non-target species sign found on detection devices was recorded and added to the database.

RESULTS

Bait take was high over most of the island. Green/blue rat droppings appeared within three days and rats consumed 189 kg of bait. The bait take pattern was typical of other bait station rat eradication campaigns (Thomas & Taylor 2002). It was very high in the days immediately after the first bait loading (checks 1–3) and dropped to a relatively low level 20 days after initial baiting (check 10). A small increase was recorded at day 22 after initial baiting (check 12) but dropped away, reaching zero bait take on day 26 after the initial baiting (check 15) (Fig. 2).

Throughout the poisoning phase, 89% of bait stations were visited by rats, with 58% active within nine days of the initial baiting. The high number of active bait stations during the first two bait rounds shows that the rats quickly accepted the bait over most of the island.

The average number of blocks removed was 6.18 (± 0.07) blocks per station (Range: 0–16.05). As shown by Fig. 3, bait take was not evenly distributed over the entire island, with the greatest level of bait take at the eastern end where the main sea bird colony was situated, and the centre of the island. Bait take was also recorded on all the offshore stacks. Rats were also quickly eradicated from the cays as bait was still present when the second baiting visit was undertaken.

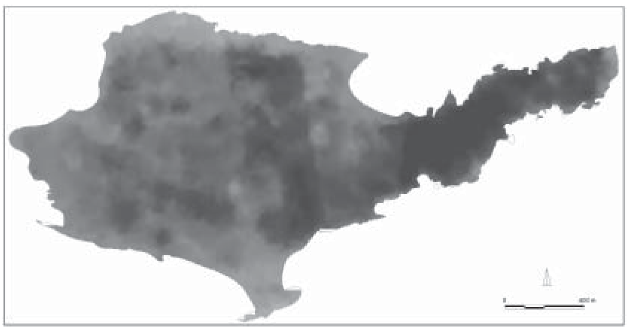

Fig. 3 Distribution of total bait take by black rats (*Rattus rattus*), as bait blocks consumed per station, during the black rat eradication on Dog Island, Anguilla. Darker shading indicates higher levels of bait uptake by rats.

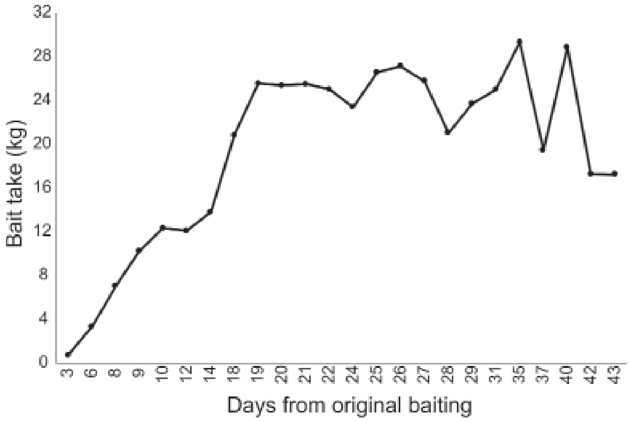

Fig. 4 Amount of bait (in kg) consumed by hermit crabs (*Coenobita clypeatus*) at each bait check (marked by black dot) during the black rat (*Rattus rattus*) eradication on Dog Island, Anguilla.

There was substantial interference by hermit crabs (Fig. 4). The average number of blocks eaten by crabs was estimated at 14.7 (± 0.3) blocks per station (Range 0–48.3). Crabs took a few days to become habituated to the bait, but then crab activity levels remained high (i.e. from days 19–41 over 50% of the stations were visited by crabs each round) (Fig. 4). There were 1,586 (92.5%) bait stations that had crab activity during the poisoning phase and only 128 stations were not affected. Crabs ate an estimated 467.4 kg of Klerat® bait throughout the eradication. There was no evidence that crabs were adversely affected by the bait. Anticoagulants are considered unlikely to affect invertebrates, as most have an open circulation system and have different physical and chemical clotting systems compared to vertebrates (Pain, et al., 2000).

Other non-target species had interfered with the bait to lesser amounts; goats consumed 0.04 kg (2 blocks) of Klerat® bait, ground lizards 0.26 kg (10.8 blocks) of Pestoff® bait, ants 10.9 kg of Klerat® bait and other insects 0.33 kg of Klerat® bait.

No animals, other than rats, exhibited signs of poisoning and no suspicious mortalities were recorded over the 11-week operation. The team was trained to observe non-target behaviour and collect any carcasses. There were 160 rat carcasses collected on the surface during the operation. These carcasses were collected and incinerated on the island to prevent availability to non-target species.

Monitoring for rat presence continued island-wide for two years after the end of the poisoning operation. The last rats were detected on 13 March 2012 during the overlap between the poisoning and intensive monitoring phases and these rats were successfully targeted using Klerat® by 30 March 2012. No rats or sign were detected during any phase of the long-term or final check monitoring. Dog Island was declared rat-free in May 2014.

DISCUSSION

The success of the Dog Island black rat eradication shows that a well-planned, adequately resourced, well-executed programme, supported by the landowner and directed by experienced operators and completed during the dry season can eradicate black rats from a large, arid, tropical island using a ground-based bait station operation. Dog Island is now the largest Caribbean island to be cleared of invasive rats and we believe that similar techniques could be utilised on other, even larger, islands in the Caribbean region.

Once the poison grid was established, the island was cleared of rats within four weeks (25 days from initial baiting). Bait-take showed that the rat population was not evenly distributed across the island. Apparently high concentrations of rats where the seabird colonies are present suggests rats were likely to have been having an effect on these nesting seabirds.

Importantly there were no known non-target species affected by this operation despite intensive searches for carcasses and a high level of interference by land crabs and to a lesser degree by ground lizards, invertebrates and, on one occasion, a goat which ate two blocks of bait. This stands in marked contrast to other operations that have inadvertently poisoned a variety of birds and other native wildlife (e.g. Howald, et al., 2007, Fisher, et al., 2011, Pitt, et al., 2015). Our choice of bait was a critical factor to this success; the primary bait used was Klerat® which was consistently untouched by any vertebrate other than rats (whereas the goat and lizards ate Pestoff® bait only). Klerat® has been equally successful in almost all the previous rat eradications in the Caribbean completed or managed by the authors and others (Day & Daltry, 1996; Daltry, 2000; Garcia, et al., 2002; Varnham, 2003; Varnham & Daltry, 2006; Witmer, et al., 2007; Varnham, 2010).

Ecological surveys conducted prior to the rat eradication operation identified a suite of ecological indicators on Dog Island that were consistent with the impacts of black rats, including the suppressed diversity and abundance of land birds, lizards and plants (Daltry, 2010). Audubon's shearwaters (*Puffinus lherminieri*) were first confirmed nesting on the island in 2012, within a few weeks of eradicating the rats (Bell, 2012). Preliminary surveys in 2014 found significant increases in a number of native species since the rats were eradicated; a two-fold increase in the density of ground lizards, three-fold increase in abundance of land-birds and a three-fold increase in burrow occupancy of Audubon's shearwaters (Bell & Daltry, 2014). Further increases were recorded during routine monitoring in 2016 and are predicted to continue over the next 10–20 years. Birds, lizards, goats, vegetation and invertebrates should be monitored for the next 20 years to detect and assess longer-term changes to the Dog Island ecosystem.

Unfortunately, as long as goats remain on Dog Island, some of the benefits of removing rats may be significantly reduced or fail to occur at all (Daltry, 2010). By preferentially eating all but the most spiny and toxic plants, the goats are maintaining an artificial, plagioclimax vegetation of thorny scrub across most of the interior of the island, which has low diversity and supports relatively few animals. Our cross-island transects, for example, revealed these interior areas had an extremely low density of lizards (Bell & Daltry, 2014). Another major concern about the goat herd is that it attracts parties of hunters who pose a biosecurity risk because their vessels and gear could provide pathways for rodents and other pests to invade the island.

While eradicating rats from Dog Island is a considerable achievement, it is important to stress that keeping this island rodent-free will require constant vigilance and commitment from all agencies, interested parties and the Anguillan community to prevent, detect and respond to any incursions. Prevention of rat re-infestation should be the primary aim. The greatest risk of reinvasion by rats reaching Dog Island is with private vessels, charter boats and fishing boats, particularly those that moor overnight, from Anguilla or the other nearby islands such as the Prickly Pear Cays and Saint Martin. This is especially so when equipment and food are brought to the island. Permanent biosecurity stations have been established on Dog Island and these will be maintained indefinitely by trained ANT staff. An incursion response plan has also been developed by ANT to deal with any rats that may be detected in the future. This shows that the local conservation agencies are totally committed to the restoration of this important Caribbean island.

ACKNOWLEDGEMENTS

This project was carried out with funding from National Fish and Wildlife Foundation (Grant No. 2011-0002-000000 to FFI Inc.) and the Governor's Discretionary Fund (awarded to ANT). The Klerat™ bait was donated by Syngenta Crop Protection AG. We would like to thank Alan Gumbs (Anguilla Development Company, owner of Dog Island), Jacqueline Cestero (Project Manager), Clarissa Lloyd, Janeczka Richardson, Kim Gumbs, Louise Soanes, Devon Carter and Michael Matthew (ANT staff), Jenny Bright and James Millett (RPSB), Robert Bensted-Smith, Sara Calçada, Nav Dayanand, A.E. Lovett and Mary Rider (FFI), Scott Hall (NFWF Seabirds Keystone Initiative), Judy Pierce (US Fish & Wildlife Service), Kirsty Swinnerton and Richard Griffiths (Island Conservation), Mark Birchmore, Alan Buckle, Andy Bywater and Alex Cornish (Syngenta), Bill Simmons (Orillion, previously Animal Control Products, New Zealand), Keith Broome (Island Eradications Advisory Group, Department of Conservation, New Zealand), Sharrine Gumbs (Uneek Supplies), Lee Brooks (Ashley & Sons), Marshall Mitchell (Safe Cargo), Maximo Hodge and Marvin Carty (Trucking), Linda Bottlik (Sunfish Design), Jackie Pacsher (Island Dream Rental), Kathy Haskins, Rachel Haskins-Brodie and Kieron Brodie (Sandy Feet Car Rental) and Hon. Othlyn Vanterpool (Anguilla Scouts). Special thanks to all of the volunteers (Thomas Aveling, Luke Banse, Richard Brown, Chris Clarke, Giselle Eagle, Paul Garner-Richards, Melissa May, Tegan Newman, Matthew Rogers and Sophie Thomas) who worked on Dog Island during the eradication. Emile Lloyd, Rumple Lloyd and Irwin Lloyd provided boat transport to Dog Island. Neville Carty, Ashton Richardson, Khaloni Richardson, Giovani Hughes, Leopold Reid, Clayton Reid, Andrew Brooks, Wells Allwalters, Paul Gillis, Peter Liddie, Movis Connor, Evan Hodge, and Desmond Brooks cut tracks across Dog Island to establish the bait station grid. Kelvin Floyd (WMIL) designed the GIS-linked database and provided Figs 1 and 2.

Abstract Rodent eradications in tropical environments are often more challenging and less successful than those in temperate environments. Reduced seasonality and the lack of a defined annual resource pulse influence rodent population dynamics differently than the well-defined annual cycles on temperate islands, so an understanding of rodent ecology and population dynamics is important to maximise the chances of eradication success in the tropics. Here, we report on the recovery of a Pacific rat (*Rattus exulans*) population on Henderson Island, South Pacific Ocean, following a failed eradication operation in 2011. We assessed changes in the rat population using capture rates from snap-trapping and investigated seasonality by using capture rates from live-trapping. Following the failed eradication operation in 2011, rat populations increased rapidly with annual per capita growth rates, r, of 0.48–5.95, increasing from 60–80 individuals to two-thirds of the pre-eradication abundance within two years, before decreasing (r = -0.25 – -0.20), presumably as the population fluctuated around its carrying capacity. The long-term changes in rat abundance may, however, be confounded by short-term fluctuations: four years after the eradication attempt we observed significant variation in rat trapping rates among months on the plateau, ranging from 36.6 rats per 100 corrected trap-nights in mid-June to 12.6 in late August. Based on mark-recapture, we also estimated rat density fluctuations in the embayment forest between 20.4 and 42.9 rats ha^{-1} within one month in 2015, and a much lower rat density on the coral plateau fluctuating between 0.76 and 6.08 rats ha^{-1} in the span of two months. The causes for the short-term density fluctuations are poorly understood, but as eradication operations on tropical and subtropical islands become more frequent, it will be increasingly important to understand the behaviour and ecology of the invasive species targeted to identify times that maximise eradication success.

Keywords: introduced species, island restoration, Pitcairn Islands, rodents, spatially explicit capture-recapture

INTRODUCTION

The removal of introduced rodents from islands is an increasingly important tool for the conservation of island biodiversity, and has been successful in hundreds of cases (Lorvelec & Pascal, 2005; Howald, et al., 2007; Bellingham, et al., 2010; Russell & Holmes, 2015). Introduced rodents have been eradicated from >580 islands (Keitt, et al., 2015; DIISE, 2016) and rodent eradications are one of the most cost-effective methods of preserving island biodiversity (Howald, et al., 2007; Jones, et al. 2016).

The success rate of rodent eradications has improved as eradication tools and methods become more refined. However, failures still occur, especially on tropical islands where conditions that can increase the risk of eradication failure, such as aseasonal breeding, are more likely (Varnham, 2010; Holmes, et al., 2015). While undesirable, these unsuccessful projects still provide an opportunity to advance conservation science, often through *post hoc* review of operational planning and implementation (Keitt, et al., 2015). However, they also present potentially unique occasions to further understand invasion biology. For example, the population dynamics of surviving rodent populations following such failed eradication attempts are seldom studied (Hein & Jacob, 2015) despite being useful for predicting population dynamics during new invasions (Nathan, et al., 2015).

In particular, there is currently little knowledge on how much time elapses before tropical rodent populations can reach an island's presumed carrying capacity after a severe population bottleneck, but such information could be useful to inform the post-operation monitoring interval that determines whether an eradication operation has been successful or not (Samaniego-Herrera, et al., 2013). On temperate islands, two years encompasses two rat breeding seasons, and is typically sufficient to determine an eradication operation's success. In the tropics, rats have a less constrained timing of breeding, and a breeding cycle as short as four months, so a shorter time may be required to reliably detect a recovering rat population, particularly in wetter conditions (Keitt, et al., 2015).

For many widespread invasive rodents, however, there is a lack of basic ecological knowledge about densities, and the factors affecting the large variation in abundance that is evident for highly versatile invasive rodents (Harper & Bunbury, 2015). Henderson Island (24°20'S, 128°19'W), in the subtropical Pitcairn Islands of the South Pacific, was subject to an aerial poison bait-based eradication attempt of the introduced Pacific rat (*Rattus exulans*) in 2011 (Torr & Brown, 2012). The eradication was unsuccessful, but the cause of the failure was neither operational shortcoming nor due to resistance of rats to brodifacoum pellets (Torr & Brown, 2012; Amos, et al., 2016, Brooke, 2019).

Here, we report on the population recovery of *R. exulans* on Henderson Island up to four years following a failed eradication attempt, and provide information on short-term seasonality in density of Pacific rats using live trapping and a spatially explicit capture-recapture (SECR) framework. We use the obtained estimates in a rapid eradication assessment (Russell, et al., 2017) to provide guidance on the length of a post-operation monitoring period after which an eradication could be considered successful with 95% certainty. These data provide a robust overview of the short- and long-term population variability on an aseasonal sub-tropical island that will inform future conservation management.

MATERIALS AND METHODS

Study area

Henderson Island, a UNESCO World Heritage Site, is a 43 km^2 raised coral atoll in the Pitcairn Islands, South Pacific Ocean, with a tropical climate (Spencer, 1995; Weigelt, et al., 2013). The island was subjected to an unsuccessful aerial eradication attempt of the introduced Pacific rat (*Rattus exulans*) in 2011 (Torr & Brown, 2012). While the ultimate cause of the eradication failure remains unknown, resistance of rats to brodifacoum pellets or operational errors are not considered factors (Torr & Brown, 2012; Amos, et al., 2016).

We conducted our study at the northern end of the island's plateau and along the two accessible beaches, North Beach and East Beach. The plateau substrate is fossilised coral with a uniform, dense native vegetation consisting of mostly of *Pandanus tectorius*, *Xylosma suaveolens* and *Psydrax odorata* (Waldren, et al., 1995). The beach and embayment forest ("beach back") areas have a sandy substrate with a mixed low vegetation and small stands of introduced coconut (*Cocos nucifera*) (Waldren, et al., 1995).

Rat snap-trapping and long-term abundance indices

We estimated rat abundance indices in 2009 (September), 2012 (May and November), 2013 (August), and 2015 (October and November) on the plateau and embayment forest areas of North and East beaches of Henderson using snap-traps, though the precise methods differed because of logistical and time constraints. In all years, however, we set traps between 16:00–18:00 h (all times UTC-8), and checked the following morning between 08:00–10:00 h (Table 1).

We recorded the traps' contents (rat, crab, or snapped and empty) to calculate an index of abundance as the number of rats caught per 100 corrected trap-nights (100 CTN; Nelson & Clark, 1973), where

CTN = Total trap-nights – Trap-nights lost (equation 1);

Trap-nights lost = ½ × (crab captures + snapped traps) (equation 2).

Estimating long-term rat population change

Based on the rat abundance indices derived from snap-trapping, we estimated the annual per capita growth rate, *r*, using the formula:

$$r = \frac{\log\left(\frac{N_t}{N_{t-1}}\right)}{t}$$

(equation 3), where *N* is the population estimate at time *t* and *t*-1, and *t* is the elapsed time, in years, between the two estimates.

To estimate a population growth rate, which requires non-zero values in each time interval if no immigration is assumed, we scaled abundance indices derived from snap-trapping to an island population size. This approach allowed us to have all the population estimates on the same scale, and to include the very small population size in 2011. We extrapolated population size based on live- and snap-trapping data from 2009: based on live-trapping, there were approximately 28 rats/ha (95% confidence interval: 23–40 rats/ha) in the embayment forest of North Beach on Henderson (Cuthbert, et al., 2012), which corresponded to 31.7 rats 100 CTN^{-1} in the same habitat. We extrapolated the density estimate to an approximate population size of 120,000 (range: 104,000–172,000) rats on the island, assuming equal density across all habitat types, and used the relationship between this extrapolated population size and the snap-trapping rate to extrapolate population sizes in other years. For 2011, when no snap-trapping data were available, we used the population estimate of 60–80 individuals that was estimated to have survived the eradication attempt in 2011 based on genetic markers (Amos, et al., 2016). In each year, we proportioned the total population to the three different habitats in which we measured rat abundance based on their relative area: North Beach embayment forest (7 ha), East Beach embayment forest (7 ha), and the island plateau (4,290 ha), and the initial population based on the abundance indices in these three habitats in 2009. We assumed that trapability was constant among years.

Rat live trapping and density estimation

To obtain a robust estimate of rat density and to document short-term fluctuation in rat density over six months, we implemented a spatial capture-mark-recapture programme in 2015 (Oppel, et al., 2019). Rats were live-trapped on the plateau from 28 May to 16 October 2015 during seven primary sessions of 10 consecutive trap-nights each, followed by a window of 10–15 days with no trapping between primary sessions. We established a trap network placed along 3.5 km of cleared paths (Fig. 1), and traps were arranged at distances from 3–20 m along 343 locations, with a different subset of 250 trap locations used during each primary session. Because our original traps (Sherman and Elliott aluminum boxes; model LFA, 23 × 9 × 8 cm, H.B. Sherman Traps Inc., Tallahassee, Florida, USA) were easily damaged by crabs, they were replaced by larger and more robust Tomahawk cage traps in September (27 × 16 × 13 cm, Key Industries, Auckland, New Zealand).

In the embayment forest at North Beach, rats were live-trapped during three primary occasions of 6–10 trap-nights each between 1 August and 19 September 2015 using 38

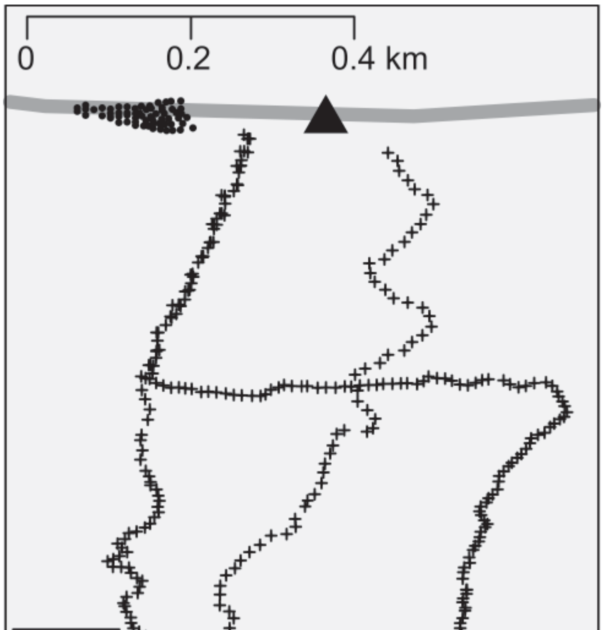

Fig. 1 Map of the path network on the north end of Henderson Island showing the locations of all live traps used in 2015 (+), snap-trapping grid on North Beach (●) and the location of the research camp (▲).

traps arranged in a 6 × 6 configuration with traps spaced 10 m apart, and we expanded the trapping grid to 63 traps in a 7 × 9 configuration for the last primary session.

Before the first primary session in each habitat, traps were deployed, but not opened, for approximately five days to allow rats to overcome neophobia. For each ten-day trapping period, traps were baited with a small (approximately 1 × 1 cm) cube of fresh coconut between 16:00–18:00 h, and checked the following morning between 08:00–10:00 h.

During trap checks each captured rat was fitted with a uniquely numbered ear tag, or the number of an existing ear tag was recorded, and the rat was released next to the trap. We recorded the trap location for each capture and recorded whether traps were available to capture rats or had been rendered ineffective (e.g. by crabs). We estimated a capture index (rats/100 corrected trap nights) for the plateau and the embayment forest for each trap-night using the same equation as above to correct for inactivated traps.

To estimate rat densities, we used spatially-explicit capture-recapture models, which have been used successfully for other rat density estimations on islands (Russell, et al., 2011; Ringler, et al., 2014; Harper, et al., 2015). We assumed that rat home ranges were randomly located with respect to trap locations and stationary within a given primary session, and that the central location of the home range was adequately described by a homogenous Poisson distribution (Efford, 2004; Borchers, 2012). Capture probability of rats at a given trap was based on the distance of the rat's home range centre from the trap and was modelled with a half-normal function in the embayment forest (Borchers & Efford, 2008; Harper, et al., 2015) and a negative exponential function on the plateau where the distribution of rat movements included a long tail of some very large movements >500 m. We estimated density using the function 'secr.fit' in the package 'secr' (Efford, 2016) using R 3.2.5 (R Core Team, 2017) for each habitat and primary session separately, thus allowing for density, capture probability, and the movement parameter, σ, to vary over time and habitat. We did not consider trap dependence. We report estimates of density, capture probability and σ with 95% confidence intervals.

Rapid eradication assessment

During the eradication operation in 2011, a team remained on the island for three months after the bait drop (from August to November), and any future eradication operation will require a similar post-operational period to monitor non-target species (Oppel, et al., 2016). We therefore estimated whether rat monitoring at all 406 trap locations of our two networks could conclude that an eradication had been successful with 95% certainty if no rat was detected during three 10-day trapping sessions up to three months after the bait drop. We also explored whether certainty could be increased if a larger area was covered with traps, and simulated a 30 × 30 m trapping grid over 10%, 30%, and 50% of Henderson Island. We used our empirical estimates of population growth rate and rat roaming behaviour in a rapid assessment tool (REA Shiny; Russell, et al., 2017) assuming a prior probability of success of 83.9% (Russell & Holmes, 2015), no reinvasion (Amos, et al., 2016), and rat dispersal distances of up to 500 m (Oppel, et al., 2019). We present the probability of successful eradication that could be inferred given that no rat was detected during the specified survey effort.

RESULTS

Rat abundance estimates and long-term population recovery

We trapped rats from 11 August to 21 September 2009, catching 233 rats in 734.5 corrected trap-nights overall, or 31.7 rats/100 CTN, with little difference among habitats

(29.0–33.4 rats/100 CTN; Table 2). The eradication attempt in August 2011 reduced the Henderson rat population to 60–80 individuals (Amos, et al., 2016), and eight months after the eradication one rat was caught on the plateau in 96.5 corrected trap nights. From 23–30 November 2012, we caught 9.2–14.8 rats/100 CTN across all three habitats (Table 2).

In 2013, we caught 20.0–73.2 rats/100 CTN, and the abundance index exceeded the pre-eradication estimate in the embayment forest (by more than 100% on North Beach), while the population on the plateau was 62% of pre-eradication levels.

In October 2015, we caught again more rats/100 CTN in embayment forest habitat on North Beach (42.9 rats/100 CTN) than on the plateau (13.2 rats/100 CTN) corresponding to an abundance index similar to pre-eradication conditions in the embayment forest, but only 41% of pre-eradication levels on the plateau (Table 2).

Based on these rat abundance indices, the rat population appears to have recovered rapidly, with annual per capita growth rates ranging from 0.48 to 5.95 (Table 2) during the recovery phase. The estimated number of rats reached peaks of 113%, 219%, and 62% of pre-eradication levels on East Beach, North Beach, and the plateau, respectively, by 2013 (Table 2), two years after the eradication attempt. The annual population growth rate has decreased since 2013 and was slightly negative between 2013 and 2015 (Table 2).

Short-term fluctuation in rat density

Overall in 2015, we recorded a total of 2,826 rat captures in 7,552 corrected trap-nights in our live-trapping network on the plateau and 319 captures in 684 corrected trap-nights in the embayment forest. Trapping rates in the embayment forest were much higher than on the plateau and less variable over time (Fig. 2). On the plateau, the trapping index declined from 36.6 rats/100 CTN in early July to 12.6 rats/100 CTN in late August (Fig. 2). The subsequent increase to 75.8 rats/100 CTN occurred after switching Sherman traps with Tomahawk traps, and any population increase is therefore confounded by a potentially more effective trap type. To account for habitat- and time-specific variation in capture probability, we estimated rat density using spatially explicit capture-recapture models for each primary session.

Rat density in the embayment forest was about 10× higher than that on the plateau (Fig. 2), and there were significant temporal fluctuations in both habitat types: apparent rat densities declined by 50% within one month in the embayment forest, and by 85% within two months on the plateau before recovering to 80% of the original density another three months later (Fig. 2). Lower rat densities on the plateau coincided with increased rat roaming distances (σ), which were generally larger on the plateau than in the embayment forest (Fig. 2). Despite some very long rat movements on the plateau, only three individuals were recorded in both the embayment forest and on the plateau (Fig. 1).

Table 2 Abundance indices of *Rattus exulans* on Henderson Island increased markedly following an eradication attempt in August 2011. August 2011 population estimate from Amos, et al. (2016); 2009 rat population from Brooke, et al., (2010a), and resulting population estimates are calculated from the relationship between rats/100 corrected trap nights (CTN, see text for details) and population size. Annual per capita growth rate, r, is based on exponential population growth.

Habitat	Start – end date	Corrected trap nights	Rats caught	Rats 100 CTN^{-1}	No of rats[a]	% of original popn	Time between surveys (months)	Annual growth rate *r*

[a]Number of rats extrapolated from the relationship between the abundance index and original population estimate and the mean (95% credible interval) from the state-space model used to calculate r. See text for details.
[b]Populations and population changes for October–November 2015 were not calculated because snap trapping removes individuals from the population and biases abundance indices for short time periods.

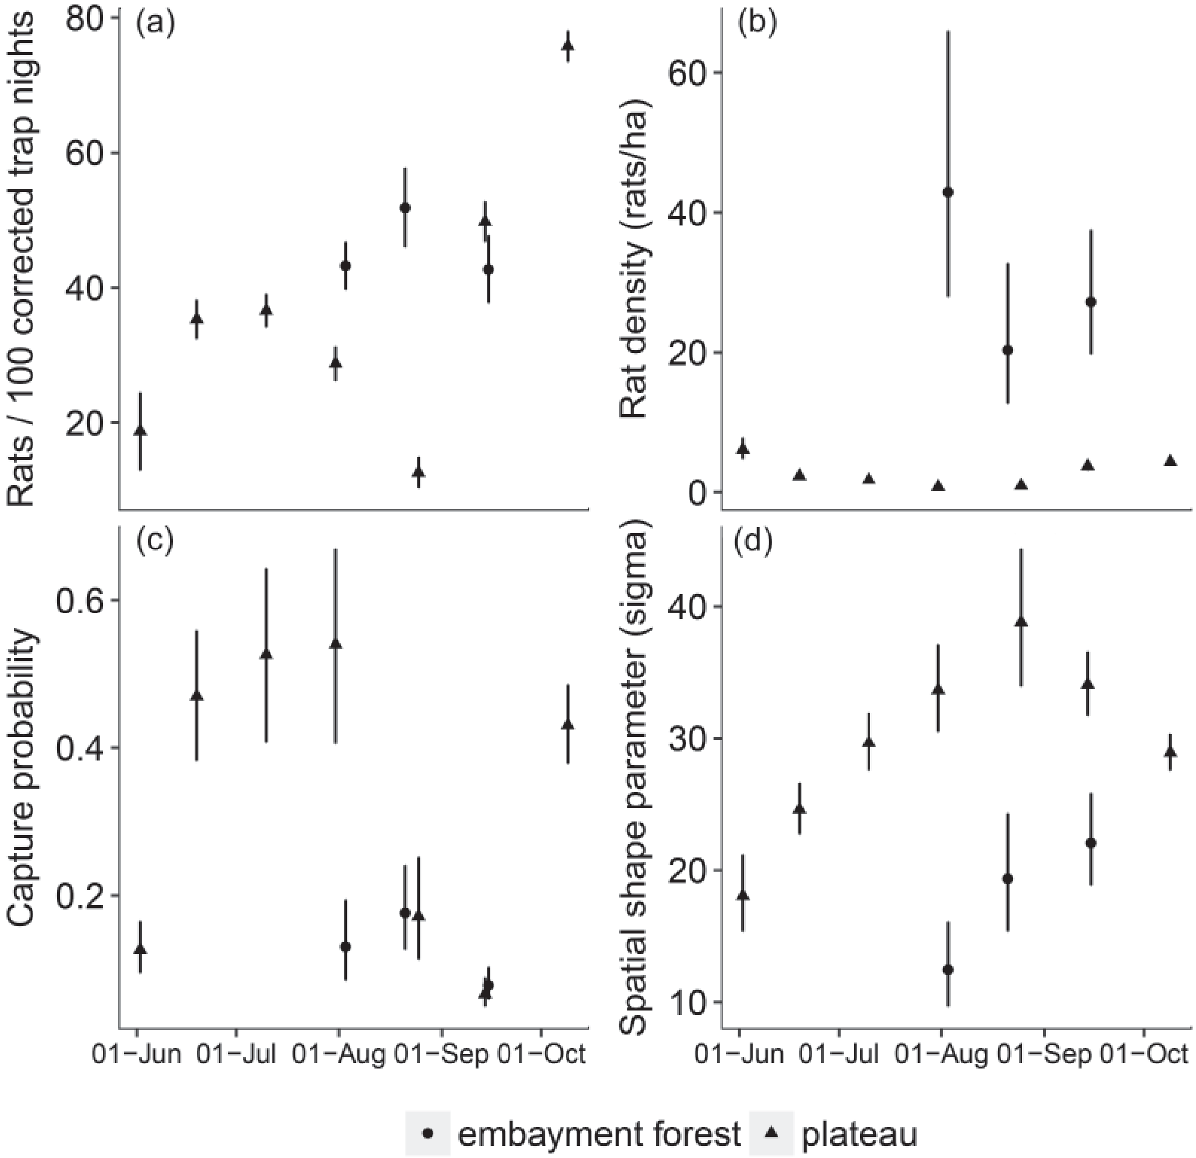

Fig. 2 Rat abundance (a), density (b), capture probability (c), and spatial shape parameters (c) from spatially-explicit capture-recapture analysis of Pacific rats in two habitats on Henderson Island in 2015 (black circles: embayment forest, open circles: plateau).

Rapid eradication assessment

Using the same trapping array as in 2015 for three 10-day trapping sessions at monthly intervals following a future hypothetical eradication attempt on Henderson Island would be insufficient to declare an eradication successful with 95% certainty. When we simulated a larger trapping array, we found that we could only conclude with 95% confidence that the eradication had been successful if no rat was detected within three months on a trapping grid covering at least 30% of Henderson Island. The model indicated that in order to be confident that the eradication had been successful within three months, we would require a 30 × 30 m trapping grid covering one third of the island.

DISCUSSION

Population recovery after a failed eradication

The rat population on Henderson increased rapidly for at least the first 15 months following the eradication operation, with high annual per capita growth rates up to August 2013 (Table 2). As the population approached or exceeded pre-eradication abundances, the growth rate decreased between August 2013 and October 2015, possibly as a result of the population fluctuating around a carrying capacity. These growth rates are broadly similar to the maximum annual growth rates of other rat species (Hone, et al., 2010), and are useful to estimate the probability of success of an eradication during follow-up monitoring (Russell, et al., 2017). Owing to variability in trapping methods and locations, there is considerable uncertainty about the exact size of the rat population; however, our density estimates in the embayment forest in 2015 indicate that rat density in this habitat was very similar to the pre-eradication density estimated in the same habitat at 24–40 rats/ha in 2009 (Cuthbert, et al., 2012). Based on the updated density estimates from the plateau in 2015, we estimate the rat population on North Beach in 2015 to be ~150–300 rats, which is similar to the estimates from the extrapolated relationship between density and abundance indices (Table 2). On the plateau, however, density fluctuated considerably throughout the year (Table 3), and extrapolating to the 4,290 ha of plateau habitat resulted in an estimate of ~3,300–26,000 rats, which is lower than the 48,000 estimate from the relationship with the abundance index. We assumed the relationship between density (rats ha^{-1}) and the abundance index (rats 100 CTN^{-1}) was linear but, on the plateau, this is clearly not the case. Estimating density, however, entails significant work over several months, whereas an abundance index can be determined fairly quickly, in a matter of days. Further work should investigate factors that influence the relationship between these two metrics.

There have been few studies on the recovery of *Rattus* spp. following eradication attempts. In urban Baltimore, Maryland, USA, *R. norvegicus* recovered to pre-control numbers within about 12–18 months (Emlen Jr., et al., 1948), and *R. fuscipes* in Australian eucalypt patches returned to pre-removal densities within two years (Lindenmayer, et al., 2005). In both cases, immigration was the likely cause of the rapid increase (though see Banks, et al., 2011). Genetic analysis from Henderson shows that there was no reinvasion, and that all rats present are descended from 60–80 survivors of the failed 2011 eradication operation (Amos, et al., 2016). Our results demonstrate the rapid recovery of an island population of introduced rodents in the absence of immigration. The time for rodent populations to either recover or reach pre-eradication levels (15–24 months), was similar to the experimental invasion of Saddle Island, New Zealand by mice (*Mus musculus*), where immigration may have supplemented mouse populations (Nathan, et al., 2015), and the time from arrival to near-saturation of black rats (*Rattus rattus*) on Taukihepa, New Zealand (24–36 months; Bell, et al., 2016).

Temporal and spatial variation in rat population density

The shape of the recovery curve of the rat population on Henderson is difficult to determine from the intermittent trapping efforts and due to the high short-term variability. In 2015 we documented three-fold fluctuations in live trapping indices and even larger differences in rat density within just two months (Fig. 2), indicating that there may be pronounced seasonal changes among the rat population that could potentially mask or confound any long-term trajectories. There may also be considerable spatial heterogeneity in rat densities, and rats on Henderson do travel large distances (Oppel, et al., 2019), which further complicate interpretations from sampling a relatively small area of the available habitat. Some rats are relatively territorial, moving <200 m, and others roaming >1000 m (Oppel, et al., 2019).

Our finding that a decrease in rat density coincided with increasing movement rates of rats (Fig. 2) adds a further complication to the long-term comparison of simple trap indices that do not account for capture probability and rat movements. Tropical rodent populations are known to undergo large population fluctuations, which can be driven by short-term changes in resource availability (Adler, 1998; Madsen & Shine, 1999) or extreme climatic events (Ujvari, et al., 2016). We did not observe pronounced plant resource fluctuations in 2015, and most tree species had individuals at various stages of flowering and fruiting between June and October 2015, though invertebrate abundance likely varied through the season (Lavers, et al., 2016). There was also neither a noticeable drought, nor an unusually heavy rainfall event during that period that could have explained the apparent intermittent reduction in the rat population. In the beach embayment forest, the major reduction of rat density between early and late August coincided with the temporal availability of Murphy's petrel (*Pterodroma ultima*) chicks, which may have led to temporary immigration of rats, but would have been unable to sustain a rat population for more than a few days (Brooke, et al., 2010b). Although we do not know whether higher mortality, lower fecundity, or both contributed to the apparent temporal fluctuation that we observed, or whether rats' probability of capture changed significantly over time, the timing of any future eradication operation should coincide with a naturally occurring nadir in the population trajectory to improve the probability of success. The eradication operation in 2011 therefore appears to have been optimally timed if rat population fluctuations are similar every year, but more research is required to examine whether rat populations exhibit predictable seasonality on sub-tropical islands such as Henderson.

The population abundance indices of *R. exulans* on Henderson (14–32 rats/100 CTN with snap-trapping, 12–75.8 rats/100 CTN with live-trapping) appear to be higher than abundance indices of other island rat population. For example, the *R. exulans* abundance index on Hawaii was only 5.65 rats /100 CTN (Sugihara, 1997), presumably because the species is subject to competition and predation (Moller & Craig, 1987); on the Marianas, the trapping rate was also much lower than on Henderson with 3.7 rats/100 CTN (Yackel Adams, et al., 2011). On Honuea, French Polynesia, indices ranged from 5–20 rats/100 CTN, often lower than conspecific *R. rattus* (up to 35 rats/100 CTN; Russell, et al., 2015). Abundance indices of the much larger *R. norvegicus* ranged from 3–9 rats /100 CTN (Drever, 2004; Harper, et al., 2005; Bond & Eggleston, 2015), and those of *R. rattus* from 1.6–35 rats/100 CTN across their range (Blackwell, et al., 2002; Shiels, 2010; Russell, et al., 2015), but reached up to 94.1/100 CTN on some nearshore islands in New Zealand (Russell & MacKay, 2005), and ranged from 60–80 rats/100 CTN on Surprise Island, New Caledonia (Caut, et al., 2009). The

Table 3 Mean (± 95% confidence interval) rat density, capture probability, and movement parameter, σ, in two habitats of Henderson Island in June–October 2015 estimated with spatially-explicit capture-recapture models. Note that different detection functions were used in the embayment forest (half-normal) and on the plateau (negative exponential), and that σ values are not directly comparable.

Habitat	Time period	Density (rats ha^{-1})	Capture probability	σ
Beach embayment – North Beach	Early August	42.92 (27.92–65.98)	0.13 (0.09–0.19)	12.48 (9.67–16.11)
	Late August	20.37 (12.67–32.73)	0.18 (0.13–0.24)	19.35 (15.41–24.29)
	September	27.2 (19.73–37.48)	0.08 (0.06–0.1)	22.08 (18.85–25.86)
Plateau	Early June	6.08 (4.76–7.76)	0.13 (0.1–0.17)	18.06 (15.39–21.19)
	Late June	2.33 (1.95–2.78)	0.47 (0.38–0.56)	24.6 (22.74–26.61)
	July	1.77 (1.49–2.11)	0.53 (0.41–0.64)	29.67 (27.57–31.92)
	Early August	0.76 (0.6–0.95)	0.54 (0.41–0.67)	33.64 (30.52–37.09)
	Late August	0.94 (0.75–1.17)	0.17 (0.11–0.25)	38.78 (33.92–44.33)
	September	3.73 (3.15–4.4)	0.07 (0.05–0.1)	34.05 (31.75–36.51)
	October	4.36 (3.92–4.85)	0.43 (0.38–0.49)	28.92 (27.56–30.34)

much higher trapping rate of *R. exulans* on Henderson is possibly because the species is smaller than congeners and is not subject to either predation or competition because no other mammals or avian predators exist on Henderson, and there is minimal dietary overlap with Henderson's birds (Brooke & Jones, 1995; Jones, et al., 1995; Trevelyan, 1995; Lavers, et al., 2016). In addition, the relatively high temperature and greater resource availability on tropical islands is generally well known to increase rat population size compared to temperate islands (Harper & Bunbury, 2015; Russell & Holmes, 2015). It is important to note, however, that abundance indices of rats exhibit a wide range depending on the rat species, environment, and the presence of competitor or predator species, seasonality, trap type, and the layout and spacing of traps.

Different approaches used to estimate densities also complicate the comparison across different islands (Harper & Bunbury, 2015). Despite the relatively high snap- and live-trapping rates on Henderson, our estimate of rat density is surprisingly low, especially on the coral plateau, where large rat movements were observed (Oppel, et al., 2019) that may have led to high trapping indices despite low density. But even the 10-times higher density in the beach embayment forest appears to be at the lower end of the range found for *R. exulans* on tropical islands (1.2–288 rats/ha; Harper & Bunbury, 2015). A potential explanation for this apparent discrepancy might be that Henderson Island is a relatively nutrient-poor coral atoll, where the maximum population size could be lower compared to more fertile tropical islands. Due to the potential nutrient limitation, the use of a highly attractive bait (coconut) may result in relatively high trapping rates, especially on the plateau where coconut is generally unavailable. Coconut has been implicated as an important factor affecting the eradication success on tropical islands (Holmes, et al., 2015). Our data also suggest that coconut may have facilitated a rapid recovery of the surviving rat population: In 2009, trapping rates were similar in the beach embayment forest and on the plateau, but on all occasions after the eradication attempt the snap-trapping rates on the plateau were considerably lower than in the embayment forest (Table 2). Rats on Henderson would often gnaw into de-husked coconuts, or those opened by land crabs on the beaches. We speculate that the lush embayment forest with abundant coconut may have facilitated a faster return to pre-eradication rat population densities than the scrubby plateau forest where coconut, though present, is scarce compared to the embayment forest.

Previous investigations using live- and snap-trapping indicated that live traps do not have a higher capture probability than snap traps for *R. exulans* and *R. rattus* (Russell, et al., 2015). We observed a much higher trapping rate with live traps than with snap traps in 2015, and our spatially explicit capture-recapture model indicated that rats living along our trail network had an almost 100% probability of being captured at least once in a trap. The variation in capture probability between different trap types highlights the need for consistent monitoring using identical approaches to facilitate valid comparisons over time.

Assessing the probability of eradication success

The failure of the 2011 eradication attempt was opportunistically recorded eight months after the bait drop. Our assessment indicated that an intensive monitoring programme for three months following a bait drop would not have allowed the reliable conclusion that the eradication had been successful, unless at least 30% of the island were covered with a 30 × 30 m trapping grid. Such a trapping effort is unrealistic on Henderson Island. Rapid eradication assessments have so far only been conducted for small islands where the survey effort covered the entire area habitable by rats (Samaniego-Herrera, et al., 2013; Russell, et al., 2017) but because Henderson Island is a fairly large island with impenetrable vegetation it is logistically unrealistic to install a monitoring network across an area sufficiently large to enable an early declaration of success. Depending on where rats that survive an eradication attempt occur in relation to the trap array at the northern end of the island, the potential benefit of post-operational monitoring to facilitate a rapid assessment of success is questionable. By the time surviving rats may be discovered with the limited trap array, the population would have likely grown to a size that would require a new eradication rather than allow a rapid follow-up to kill any remaining survivors. Although post-operational rat trapping on Henderson Island may be useful to rapidly discover eradication failure, it is unlikely that it would allow the confident conclusion of eradication success.

In summary, we found that rat abundance increased rapidly between the failed eradication operation in August 2011 and August 2013 before decreasing from August 2013 to October 2015. Rats on Henderson Island reached two-thirds of their pre-eradication abundance 24 months following their failed eradication, but our estimates of rat density on the plateau of the island suggest that rat density may have been substantially lower than previously assumed (Brooke, et al., 2010a). Studies of failed eradication operations, and the recovery of introduced rodent populations are rare, but of great conservation and operational importance. Our study highlights rodent population fluctuations on a relatively short time-scale, and a better understanding of the regularity and underlying drivers of these fluctuations would be useful to schedule an eradication operation so as to maximise eradication success. As eradication operations on tropical and subtropical islands become more frequent, it will be increasingly important to understand the behaviour and ecology of the invasive species targeted, and more work in this area is required if we are to replicate success on temperate islands.

ACKNOWLEDGEMENTS

We thank the Government of the Pitcairn Islands for permission to work on Henderson Island, M. de L. Brooke, A. Brown, G. Harper, G. Harrison, S. O'Keefe, M. Rodden, J. Warren, and P. Warren for assistance in the field, and J. Hall, A. Schofield, and C. Stringer for logistic support. The crews of the *Braveheart*, *Claymore II*, *Teba,* and *Xplore,* provided transportation to and from Henderson. The David and Lucile Packard Foundation, UK Overseas Territories Environment Programme, Darwin Plus: Overseas Territories Environment and Climate Fund, British Birds, generous donors, and the RSPB, the UK partner in Birdlife International, helped to fund our research. We appreciate the advice of J. Russell and M. Efford on data analysis. Scientific and ethical approval was granted by the Government of the Pitcairn Islands, and the RSPB Council (paper 2/13/62 and protocol EAC 2015/01). Comments from two anonymous reviewers improved this manuscript.

Bait colour and moisture do not affect bait acceptance by introduced Pacific rats (*Rattus exulans*) at Henderson Island, Pitcairn Islands

Abstract Rodent eradications are a useful tool for the restoration of native biodiversity on islands, but occasionally these operations incur non-target mortality. Changes in cereal bait colour could potentially mitigate these impacts but must not compromise the eradication operation. Changing bait colour may reduce mortality of Henderson crakes (*Zapornia atra*), an endemic globally threatened flightless bird on Henderson Island, Pitcairn Islands, South Pacific Ocean. Crakes had high non-target mortality in a failed 2011 rat eradication operation and consumed fewer blue than green cereal pellets. We examined which cereal bait properties influenced its acceptance by captive Pacific rats (*Rattus exulans*) on Henderson Island. We held 82 Pacific rats from Henderson Island in captivity and provided them with non-toxic cereal bait pellets of varying properties (blue or green, moist or dry). We estimated the proportion of rats consuming bait using logistic generalised linear mixed models. We found no effect of sex, females' reproductive status, bait colour or bait moisture on rats' willingness to consume baits. Rats' bait consumption was unaffected by cereal bait properties (colour or moisture). The use of blue bait is unlikely to affect future eradication operational success but may reduce non-target mortality of Henderson crakes. Timing cereal bait distribution in relation to precipitation may also reduce crake mortality without compromising palatability to rats.

Keywords: baits, Henderson Island, island restoration, non-target safety, rat eradication

INTRODUCTION

The eradication of introduced rodents is a common conservation intervention, especially on islands, and has been accomplished on > 580 islands worldwide (DIISE, 2016), with benefits to native biodiversity (Lavers, et al., 2010; Buxton, et al., 2014; Jones, et al., 2016). In some cases, eradication operations may result in non-target morality, and mitigation can include housing captive populations of species likely to be affected, or by using cereal pellets that are less palatable to non-target species (Empson & Miskelly, 1999; Hoare & Hare, 2006; Pitt, et al., 2015; Oppel, et al., 2016a; Oppel, et al., 2016b). In such cases, it is crucial that the mitigation measures do not decrease the likelihood of a successful rodent eradication operation, and that the rodents are exposed to a sufficient quantity of cereal bait, are susceptible to the rodenticide used, and will consume a sufficient dose.

Rarely, though more so in the tropics and subtropics, these eradication operations fail to remove rodents for a variety of operational, biological, and environmental reasons (Holmes, et al., 2015). Eradication success in the tropics is generally lower than in temperate systems because there is less seasonal change in the environment, and consequently a less predictable period of food-resource limitation, which is the ideal time for an eradication operation (Holmes, et al., 2015; Russell & Holmes, 2015). Consequently, understanding which factors may influence rodents' acquisition of a lethal dose of bait are crucial for improving the probability of success in tropical systems (Lamoreux, et al., 2006).

Factors affecting bait acceptance by Pacific rats (*Rattus exulans*), a common introduced rodent in the Pacific Ocean tropics and subtropics (Atkinson, 1985; Varnham, 2010; Keitt, et al., 2015), are poorly known. A number of factors can influence rat food choice, including physical characteristics such as bait colour and hardness (Booth, et al., 1974; Clapperton, 2006; Hegab, et al., 2014). Murine rodents (including rats and mice) have colour vision, including sensitivity in the UV range (Jacobs, 1993; Jacobs, 2009), and there is evidence that cereal bait colour does affect the likelihood of acceptance by rats (Hegab, et al., 2014).

Blue or green cereal pellets are the most effective at reducing avian non-target mortalities, but there is considerable variation in bait attraction among species. Kea (*Nestor notabilis*) and weka (*Gallirallus australis*) were less likely to eat green pellets than blue (Hartley, et al., 2000; Weser & Ross, 2013), whereas North Island robins (*Petroica longipes*) and Henderson crakes (*Zapornia atra*) were less likely to consume blue pellets than green (Hartley, et al., 1999; Oppel, et al., 2016b). Henderson Island, part of the Pitcairn Islands in the South Pacific Ocean, was the site of a failed eradication operation for Pacific rat in 2011, which also resulted in non-target mortality of Henderson crakes (Amos, et al., 2016; Oppel, et al., 2016a). Subsequent work found that Henderson crakes consumed less blue bait than green, and did not consume dry pellets (Oppel, et al., 2016b).

Here we report on the factors affecting Pacific rat bait acceptance on Henderson Island, Pitcairn Islands, South Pacific Ocean. Our goal was to compare Pacific rats' acceptance of both moist and dry cereal pellets of these two colours to determine whether measures to reduce the non-target mortality of Henderson crakes might affect success of future eradication operations on Henderson.

METHODS

Rat capture & acclimatisation

Rats were captured on Henderson Island's plateau using either Tomahawk (27 × 16 × 13 cm, Metal Rat Cage Trap, Key Industries, Auckland, New Zealand) or Sherman (22.9 × 8.9 × 7.6 cm, Sherman Traps Inc., Tallahassee, Florida, USA) live traps baited with a 2 × 2 cm piece of coconut (*Cocos nucifera*). Individual rats' knowledge of coconut prior to its presentation during the cage trial is presumed to be limited, because the areas where rats were captured were > 500 m away from the nearest coconut grove on

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 175–179. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

the island. We chose coconut as bait because it was easily available and highly effective in attracting rats, while alternative baits (*Pandanus tectorius* fruit, peanut butter, chocolate, semolina, soap, and mixtures thereof) largely failed to capture sufficient individuals. Although the choice of coconut as trap bait may have predisposed some trapped rats to exhibit universal acceptance of coconut in the trials (see Results), particularly given the large movements possible in this population (Oppel, et al., 2019), the use of a non-natural food source (e.g., peanut butter, chocolate) may have resulted in capturing only curious or bold rats who will readily accept new food items, which may have biased our assessment of acceptance rate of bait pellets, another novel food item (Booth*,* et al.*,* 1974).

We held 81 rats in captivity for 12 days each during October–November 2015. Rats were weighed using a spring balance to the nearest 1 g, fitted with a uniquely numbered ear tag, and their sex was determined from external anatomy. They were first allowed to acclimatise for four days in sex-specific communal wire cages (70 × 60 × 30 cm) of up to four individuals, where they were fed commercial rodent food (Rabbit and Guinea Pig Muesli, Topflite, Oamaru, New Zealand) *ad libitum* in a single ceramic food dish and water was provided by both a commercial water dispenser (Critter Canteen, SuperPet, Walnut Creek, California, USA) and a large clamshell. Each cage contained four hollow *Pandanus tectorius* logs, with small, loose pieces of coconut bark providing cover and visual barriers. After four days, rats were weighed as before, and moved to individual wire cages (70 × 50 × 30 cm) with the same food and water regime, and environmental enrichment. Rats were considered to have acclimated if, after three days in individual cages, their mass differed by < 10% compared to their mass at capture, and we observed no anomalous behaviour. Rats that had lost > 10% of body mass were allowed two additional days to acclimate and were then reassessed using the same criteria. Any individuals that did not acclimate were not subjected to the experimental trial and were euthanised by cervical dislocation and used in other research (Lavers*,* et al.*,* 2016).

Bait acceptance trial

Individuals which acclimated were assigned randomly to one of four treatment groups based on combinations of bait colour (green or blue) and moisture (moist or dry); cereal bait pellets (nontoxic ~2 g Pestoff 20R, Animal Control Products, Whanganui, New Zealand) were otherwise identical. The pellets were surface coated with dye and did not lose their colour after soaking in water. The green dye was a composite of tartrazine powder (with the Chemical Abstracts Service (CAS) number 1934-21-0), Brilliant Blue powder (CAS number 3844-45-9) and sodium sulphate (CAS number 7757-82-6), and the blue dye was Hexacol Indigo Carmine Supra Blue R2613 (CAS number 860-22-0). Cereal pellets were presented to rats either dry, as manufactured, or moist, after being soaked in water for three hours. Rats received fresh cereal bait pellets and natural foods daily.

Between 06:00-08:00 (UTC-8) on Day 1 of the trial, rats were provided with sufficient natural food (coconut, *Myrsine hosakae* seeds, and whole *Pandanus tectorius* fruit) to ensure that they were sated but not consuming any single food item completely, and a single cereal bait pellet. Food consumption was assessed between 06:00-08:00 on Day 2: if the rat had consumed a significant portion of a pellet (~1 g), the individual's trial was ended and the rat was euthanised. If the bait was not eaten, the rat received a fresh batch of natural food of the same amount as on Day 1 while the number of pellets was increased to five in an attempt to overcome neophobia and increase the number of trial rats consuming bait. This procedure was continued for two more days if needed, with rats receiving 10 and 20 pellets on Days 3 and 4, respectively. Rats that had not eaten bait after Day 4 were given five bait pellets and all natural foods, with the exception of coconut (which was accepted universally), on experimental Day 5. The trial ended the next day regardless of outcome.

Food consumption was monitored daily and all remaining food from the previous night removed and the cage inspected to ensure no natural food item was completely consumed, and any remaining bait pellets counted. The remains of any partially eaten pellets were inspected and the amount eaten estimated to the nearest 25%. Where a natural food item was completely consumed, the result was ignored and the test repeated with the same individual.

All captive rats were humanely euthanised by cervical dislocation at the end of the trial. Females were examined internally to determine reproductive status: breeding was indicated by the presence of foetal pups, a highly vascularised uterus, or lactation.

Statistical analysis

We used logistic generalised linear mixed-effects models (GLMMs) with a logit link to test whether bait acceptance (yes/no) varied as a function of the following fixed factors: sex (female/male), bait colour (blue/green), and bait moisture (moist/dry), and trial day. We treated 'individual' as a random effect to account for potential serial autocorrelation (Bolker*,* et al.*,* 2009). We included main effects only, as the effective sample size would reduce the statistical power to detect the effect of interactions in our dataset. We constructed a series of models with varying biologically meaningful combinations of the terms above, as well as an intercept-only model (Table 1) and evaluated

Table 1 The ranked set of candidate models for examining captive Pacific rats' acceptance of bait on Henderson Island. Models with $\Delta AIC_c < 2$ were considered competitive (i.e. the top 3).

Model	k	AIC_c	ΔAIC_c	w_i
Intercept only	2	214.80	0.00	0.33
Moisture	3	215.89	1.10	0.19
Sex	3	216.62	1.82	0.13
Colour	3	216.85	2.05	0.12
Sex + Moisture	4	217.72	2.92	0.08
Moisture + Colour	4	217.96	3.16	0.07

k: number of parameters, AIC_c: Akaike's Information Criterion adjusted for small sample size, ΔAIC_c: difference between each model and the most parsimonious model, w_i: Akaike model weight.

them in a multi-model selection framework using Akaike's Information Criterion adjusted for small sample size (AIC_c) (Burnham & Anderson 2002). Models with $\Delta AIC_c < 2$ were considered competitive. All models were fit using Laplace approximation in the package lme4 (Bates, et al., 2014) in R 3.3.0 (R Core Team, 2017), and we present mean parameter estimates (β) ± standard error.

RESULTS

We captured 82 rats of which 81 acclimated to the captive trial. Overall, 48% of captive rats (n = 39) consumed the non-toxic cereal pellets. The intercept-only model, where bait consumption varied among individuals, but not with any other factors, received the most support, but models that included the single terms for sex, bait colour, and bait moisture had $\Delta AIC_c < 2.0$ (Table 1). Using each of these single-factor models, there was no difference in bait acceptance between sexes (males: β = 0.532 ± 0.012, females: β = 0.536 ± 0.014), and no effect of bait colour (blue: β = 0.533 ± 0.018, green: β = 0.534 ± 0.018), or moisture (dry: β = 0.540 ± 0.015, moist: β = 0.529 ± 0.012; Fig. 1). Bait acceptance did not differ with females' reproductive status (calculated parameter estimates for breeding: β = 0.539 ± 0.033, n = 17; not breeding: β = 0.543 ± 0.025, n = 22; one individual not of breeding age: β = 0.520). All models that included trial day had $\Delta AIC_c > 4$, so were not considered further (Table 1).

DISCUSSION

We found no evidence for bait colour, moisture, sex, or reproductive status affecting the consumption of bait pellets by captive Pacific rats. Blue and green bait pellets are frequently used in rodent eradication operations (Clapperton, et al., 2015), and the use of blue pellets may therefore reduce the reported non-target mortality among Henderson crakes (Oppel, et al., 2016b) without affecting the efficacy of rat eradication operations.

Rats ingested dry and moist pellets equally, which is important operationally as Henderson crakes do not consume dry pellets (Oppel, et al., 2016b). While rainfall patterns on Henderson are unpredictable and aseasonal (Spencer, 1995), targeting any future eradication operation at periods of low rainfall is unlikely to affect the outcome for rodents, but may reduce the risk of non-target mortality. In the longer term (i.e. longer than the four days used in our captive trial), rainfall will increase the degradation rates of bait, thereby reducing rats' exposure to bait, regardless of their inherent preference to consume bait that is dry or wet (Berentsen, et al., 2014).

The aseasonal breeding often found on tropical islands means that baiting operations are more likely to include breeding females than operations in temperate regions. Concern has been expressed that pregnant and lactating rodents are less likely to eat bait if their nutritional needs are not met by the bait matrix (Keitt, et al., 2015), though this also assumes that rats could identify the nutritional content of bait pellets without consuming a lethal dose (i.e., one pellet; Amos, et al., 2016). Our results suggest that not only are female Pacific rats as likely to consume bait pellets as males, but that, at least for this particular bait formulation, females' reproductive status is unlikely to influence bait acceptance.

Importantly, while only 48% of trial rats consumed bait pellets, this general acceptance rate cannot be used to infer potential acceptance rates in free-ranging rats during an eradication operation. Evidence of higher or lower bait acceptance rates in the wild than in cage trials is equivocal (Clapperton, 2006) but several important limitations

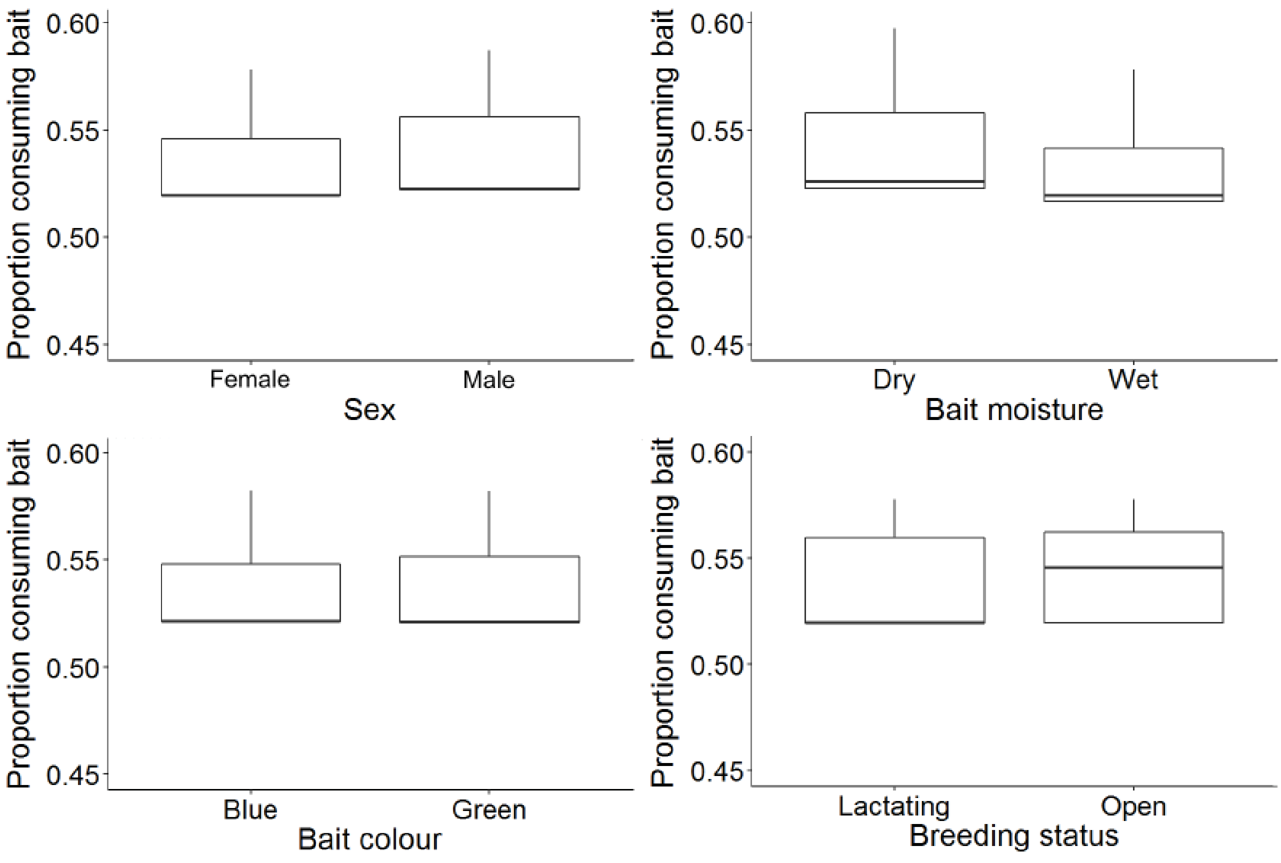

Fig. 1 There was no effect of rats' sex, breeding status, bait colour, or bait moisture on the proportion of Pacific rats consuming bait. Values are from generalised linear mixed models. Dark bars are the median, boxes are the interquartile range, and whiskers the range.

of cage trials have the potential to lower acceptance below what would be typical in the wild. For example, the provisioning of commercial rodent food during the acclimatisation phase ensures an unbiased test of food preference because test subjects are not food stressed (which results in selection of food items based on dietary deficiencies rather than food palatability). However, the chemical composition of food plays an important role in diet selection in free-ranging rats, with individuals self-selecting food based on physiological need (Rozin, 1976). Another major limitation of cage trials, specifically with regard to acceptance of novel food items such as bait, is the absence of social learning. While rats are predominantly solitary foragers, the identification and adoption of novel food items is heavily influenced by social interactions with conspecifics (Galef Jr, 1996). Cage trials should therefore only be considered as useful tools for identifying potential problems that can be explored further by field trials. On Palmyra Atoll, for example, rats were found to prefer coconut over cereal bait pellets in cage trials, but later field trials found adequate bait uptake, and a toxic cereal bait eradication was successful (Buckelew*,* et al*.,* 2006; Alifano & Wegmann, 2011).

CONCLUSIONS

Our findings suggest Pacific rats have no preference between green or blue bait pellets, nor if bait is moist or dry. This suggests that individual variation is a significant driver of bait acceptance, regardless of other demographic parameters (Nathan, 2016). While a baiting operation timed when rats are breeding carries increased risks and is preferably avoided, pregnant or lactating females are as likely to accept bait as non-pregnant females. Any future operation on Henderson Island should use blue bait pellets, and time the operation for dry conditions, in order to reduce non-target mortality of Henderson crakes without affecting rat bait acceptance.

ACKNOWLEDGEMENTS

The authors declare no conflicts of interest. We thank N. Duffield, S. Havery, and A. Skinner, for assistance in the field, J. Kelly, A. Schofield, C. Stringer, and J. Vickery for logistical support, and the Government of the Pitcairn Islands for permission to work on Henderson. Methods were approved by the RSPB Ethical Advisory Committee (protocol EAC 2015/01). The David and Lucile Packard Foundation, Darwin Plus: Overseas Territories Environment and Climate Fund, British Birds and generous donors helped to fund this expedition. Comments from J. Lavers, S. Oppel, I. Robinson, A. Schofield, and three anonymous reviewers improved earlier drafts.

Containment of invasive grey squirrels in Scotland: meeting the challenge

J. Bryce[1] *and M. Tonkin*[2]

Abstract Saving Scotland's Red Squirrels (SSRS), launched in 2009, is a project to stop the decline of core populations of Scotland's native red squirrel. It is a partnership project between Scottish Wildlife Trust, Scottish Natural Heritage, Forestry Commission Scotland, RSPB Scotland, Scottish Land & Estates and the Red Squirrel Survival Trust. The aim is the containment of the invasive non-native grey squirrel, which poses a dual threat to red squirrels through competition and disease transmission. Grey squirrels have replaced red squirrels over much of their former range in England, Wales, Ireland and central Scotland. SSRS controls grey squirrels at a landscape-scale in three strategically selected zones: in north-east Scotland, where the aim is eradication of an isolated grey squirrel population; coast to coast along the Highland Boundary Fault the aim is to prevent northwards incursion of grey squirrels into the Scottish Highlands and Argyll, where red squirrel is still the only species; and in southern Scotland, the aim is now to prevent replacement of priority red squirrel populations by focussing control in areas identified as having the best prospects for the long-term maintenance of red squirrel populations. Control methods involve live cage-trapping combined with humane dispatch. The control network comprises SSRS and Forestry Commission controllers, private landowners supported by EU/government funding and a large number of individual volunteers. The work is dependent on wide public acceptance and active volunteer support. To date SSRS has been successful at significantly reducing grey squirrel geographic range and occupancy in NE Scotland and as well as reducing the incidence of grey squirrels north of the 'Highland Line' to no more than the occasional occurrence. In southern Scotland grey squirrel control has contributed to the maintenance of red squirrel populations despite the continued spread of squirrelpox in grey squirrels. The major challenge now is sustaining the level of grey squirrel control needed to secure Scotland's red squirrel populations in the long term. A new project phase started in 2017, focused on building community action networks until such a time as alternatives means of controlling grey squirrel numbers and disease impacts become widely available.

Keywords: adaptive management, community engagement, land manager, sustainability, trapping effort, volunteer

INTRODUCTION

Grey squirrels (*Sciurus carolinensis*) were introduced into Britain in the 1890s from the US and Canada, including to several release sites in Scotland (Middleton, 1930; Middleton, 1931). The impact of grey squirrels on native red squirrel (*Sciurus vulgaris*) populations was documented relatively early after their introduction (Middleton, 1931; Shorten, 1962), but their range expansion was initially quite modest (Gurnell, 1987). The role of grey squirrels in the replacement of red squirrels was possibly not fully recognised until the 1980s (Lloyd, 1983; Skelcher, 1997; Reynolds, 1998), by which time grey squirrels occupied much of southern and central England and Wales and central Scotland (Lloyd, 1983).

The factors leading to the replacement of red by grey squirrels have been the subject of extensive research (reviewed by Gurnell, et al., 2014b). The evidence indicates that competition with grey squirrels for food resources alone can account for the loss of red squirrels from many forests (Bryce, et al., 2001; Wauters, et al., 2002). However, added to this is the threat of squirrelpox virus, which is carried by grey squirrels and is highly pathogenic to red squirrels (Sainsbury, et al., 2000, Thomas, et al., 2003), greatly enhancing the speed of replacement (Rushton, et al., 2006).

Red squirrels have been protected under UK law since the 1930s and bounty schemes were enlisted to combat increasing grey squirrel numbers in the 1950s (Sheail, 1999). However, low-level, sporadic control has failed to halt the spread of grey squirrels (Lawton & Rochford, 2007). Grey squirrels are already widespread and abundant throughout much of the UK and eradication is not considered to be a realistic option (Gurnell & Pepper, 1993; Pepper & Patterson, 1998). EU Regulation 1143/2014 on Invasive Alien Species lists grey squirrels as species of Union concern, hence Member States are required to take concerted management action to ensure they do not spread any further and to minimise the harm they cause to the environment.

Large-scale control and containment of grey squirrels was originally seen as an interim approach, whilst more sustainable, long-term control measures were developed (Scottish Squirrel Group, 2004; Scottish Natural Heritage, 2010). However, in the absence of a squirrelpox vaccine or immuno-contraceptive, there has been growing support for targeted grey squirrel control to protect red squirrel populations (Scottish Natural Heritage, 2010). Following public consultation, a draft strategy for grey squirrel control in Scotland was published (Scottish Natural Heritage, 2010), which focuses on targeted control to maximise the benefits for red squirrels.

A collaborative project under the heading 'Saving Scotland's Red Squirrels' (SSRS), was formalised in 2009. It is a partnership comprising the Scottish Wildlife Trust (SWT), Scottish Natural Heritage, Forestry Commission Scotland, RSPB Scotland, Scottish Land & Estates and the Red Squirrel Survival Trust. SSRS has become the principal means of coordinating red squirrel protection in Scotland. The focus of SSRS is on applied conservation action, but SSRS has made a concerted effort to collate records and monitor squirrel populations and has worked closely with researchers to inform an adaptive approach. A key challenge to SSRS has been to assess the efficacy and sustainability of control measures. This paper explores some of the work carried out to address these challenges and highlights some of the learning to date.

THE SSRS APPROACH

Co-ordination of grey squirrel control

The main focus of SSRS activity is the co-ordination of grey squirrel control. SSRS aims to co-ordinate grey

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 180–186. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

squirrel control across three strategic control zones (Fig. 1). The aims vary between zones reflecting the degree to which grey squirrels are already established. The Highlands of Scotland are currently free of grey squirrels; grey squirrels are long established in central Scotland (with introductions between 1892–1919) and had spread throughout much of the Central Lowlands by the 1980s; grey squirrels have spread into South Scotland from both the north and from northern England in recent years (Gurnell, et al., 2014a). The grey squirrel population in NE Scotland (Aberdeen and Aberdeenshire) has been recorded for about 30 years (Lloyd, 1983; Staines, 1986), and there is evidence it originates from a separate introduction rather than having spread from grey squirrels elsewhere in Scotland (Signorile, 2013). Squirrelpox was first reported to have crossed from northern England into Scotland in 2005, with the first cases in red squirrels observed in 2007 (McInnes, et al., 2009). The original SSRS aims are listed as follows, although these have been adapted in light of experience as is discussed later.

North-east (NE) Scotland – the original aim was to halt the spread of grey squirrels outwards from the city of Aberdeen;

Central Lowlands – SSRS's work in the Central Lowlands aims to contain the northward spread of grey squirrels into the Highlands and Argyll by carrying out control from coast to coast; along what is referred to as the 'Highland Line' a zone of control extending for some 160 km from just north of Glasgow to Montrose on the east coast.

Southern Scotland – the initial aim was to contain the spread of squirrelpox virus in south Scotland.

Grey squirrel control is currently carried out by a mixture of project staff, land managers and volunteers:

- Working with up to 197 landowners under five-year EU and Scottish Rural Development Programme funding (SRDP);
- Co-ordination via five conservation officers, six full-time and five part-time grey squirrel control officers;
- A trap-loan scheme involving up to 200 landowners, and 500 individuals.

Trapping is also carried out by Forest Enterprise Scotland at key sites on the National Forest Estate. Figure 2 illustrates the coverage of grey squirrel control initiated by SSRS by 2012 (from Tonkin, et al., 2015).

With a view to the long term, SSRS has sought to encourage land managers to carry out grey squirrel control on their own land. Regional conservation staff provide support to landowners applying for funding available through the SRDP to help cover the costs. SRDP contracts require land managers to operate an appropriate number of traps (as advised by SSRS staff) for a minimum number of sessions per year (usually five or six). All the traps are to be set for a minimum number of days (usually 10). SSRS control officers trap with landowner permission, in key gaps in the landowner protection network (Fig. 2). Most of the grey squirrel control occurs between April and the end of September, when grey squirrels are easier to catch. Due to the lack of specificity of other methods and animal welfare considerations (Central Science Laboratory, 2009), the SSRS Standard Operating Procedures specify the use of cage trapping and humane dispatch.

Trapping by SSRS control officers has typically followed the approach of five days pre-baiting and then trapping continuously until no or few further grey squirrels are caught. Traps are then revisited on a rotation. The traps are not located at a standardised density, but instead are grouped in areas of preferred grey squirrel habitats in the target zones. In South Scotland grey squirrel control by SSRS control officers was initially carried out in the area buffering known squirrelpox seropositive cases. The grey squirrels were then sent for laboratory testing for squirrelpox. Hence control effort was reactive and did not take place in the same locations across time.

In NE Scotland, in particular, SSRS is working in peri-urban and urban areas. Initially this created a challenge because large areas of wooded habitats in private gardens and parks were difficult to access, leaving reservoirs of grey squirrels. To address this challenge and to harness the community enthusiasm in other areas, SSRS has successfully instigated a trap-loan scheme. Under this scheme householders take responsibility for setting and monitoring traps (supplied by SSRS) in their garden. They

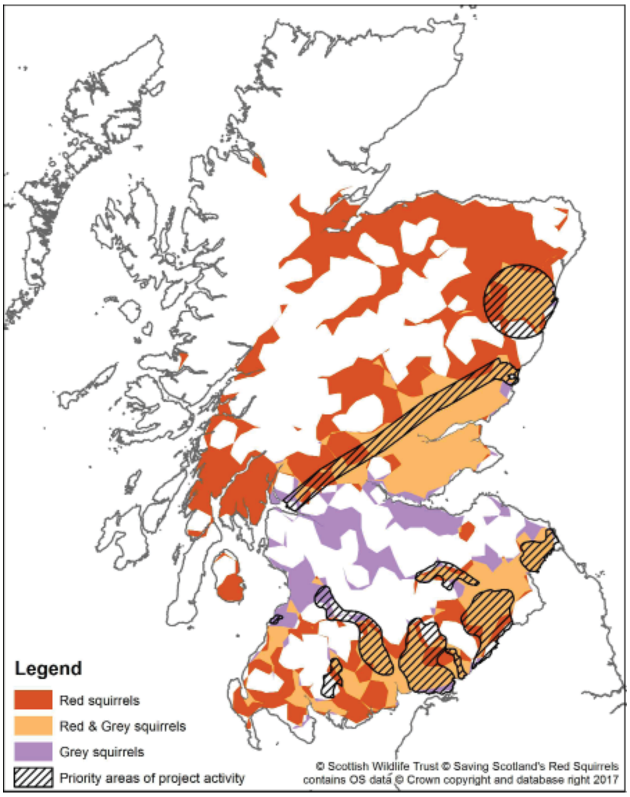

Fig. 1 Map of Saving Scotland's Red Squirrels project control zones.

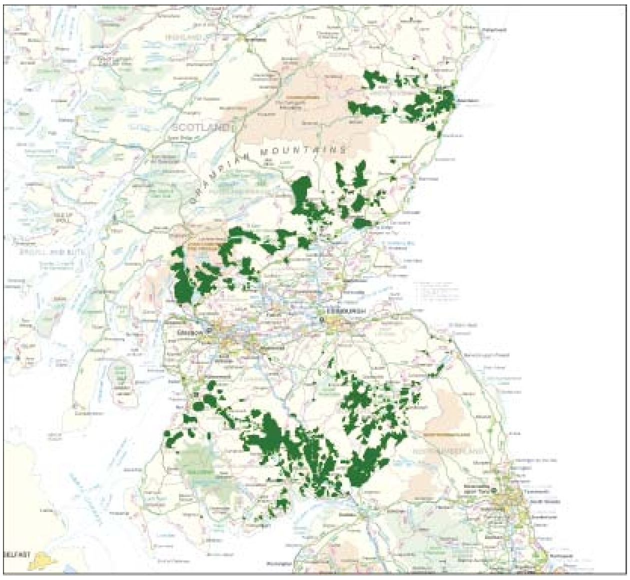

Fig. 2 Red squirrel protection network established across Scotland by 2012 (from Tonkin, et al., 2015).

are matched with a local trapper (gamekeeper or control officer) who is available to carry out humane dispatch. Project staff have also developed innovative trap designs for trapping grey squirrels in city parks to avoid drawing attention to traps.

Grey squirrel control in public spaces and, in particular, the involvement of volunteers requires a high degree of public acceptance, which is not guaranteed (Bertolino & Genovesi, 2003). A targeted approach to control was broadly supported in a public consultation (Scottish Natural Heritage, 2010) and public surveys in Aberdeen and Aberdeenshire have established that despite residents enjoying seeing grey squirrels, there is an appreciation of the need for grey squirrel control due to their impact on red squirrels (Ashbrook Research Consultancy Ltd, 2010).

Evaluation of control measures

Alongside establishing the network of grey squirrel control, SSRS has sought to collect evidence that this work is benefitting red squirrels. This has been critical for securing public funding for grey squirrel control. Three methods were employed by the SSRS in order to evaluate the efficacy of grey squirrel control:

- Evaluation of grey squirrel capture probability from trapping data;
- Annual (presence/absence) monitoring of red and grey squirrel occupancy in the three project areas, and
- Public sightings of squirrels across Scotland that have been catalogued since 2007.

Annual (presence /absence) monitoring of red and grey squirrels has been co-ordinated by SSRS in NE Scotland and the Central Lowlands since 2011 and since 2013 in South Scotland. The surveys are intended to assess if there are changes in squirrel distributions that can be attributed to the project. Nearly 200 volunteers have been mobilised to carry out these surveys. A sample of 2 km ×2 km grid squares or 'tetrads' are surveyed across each control zone. Four baited feeder-boxes are permanently located in woodland within each tetrad. Each feeder-box is checked by volunteers three times over a period of six weeks each spring. Hairs are identified under a microscope and each tetrad is consequently allocated to one of the following four categories: "red squirrels only", "grey squirrels only", "both species", or "neither" species (Fig. 3, Shikhorshidi & Tonkin, 2018). The number of tetrads has increased over time, but comparison of the same tetrads over time enables detection of changes in squirrel distributions. Changes between years have been explored using a replacement index as per Usher, et al. (1992). A positive index represents a change in tetrad occupancy in favour of grey squirrels and a negative index, a change in favour of red squirrels (Usher, et al., 1992).

A programme of squirrelpox surveillance has also helped guide the work in South Scotland. In 2012, grey squirrels were sampled from a systematic sample of locations across the whole of South Scotland to try and establish the full extent of exposure to the virus (10 grey squirrels are sampled from one 10 km square in every 20 km × 20 km square across the region).

RESULTS

Evaluation of grey squirrel capture probability

The project initially aimed to gather data on grey squirrel trapping across all three control zones, however, inconsistencies in recording between the different project delivery models has made it problematic to fully assess the cumulative trapping effort that has been achieved. The control officers' data are the most reliable. The format of other records varies, effort is not always systematically recorded and problems have been encountered (data gathering and ownership) in accessing results of trapping from the land mangers supported by SRDP funding. Forestry Enterprise Scotland controllers' data are included with the control officers' data where this has been possible. The minimum total number of grey squirrels controlled and the trapping effort achieved have been estimated from collated data (SWT pers. comm.). It is estimated that between 2009 and 2016:

- Control officers provided c. 214,000 trap days (the number of traps multiplied by the number of days for which traps are set) and controlled c. 13,000 grey squirrels (Table 1); and
- Up to 197 SRDP contracts were established (Scottish Government Statistics, 2014), with those reporting accounting for 1.1 million trap days and having controlled c. 18,000 grey squirrels Table 1).

Those in receipt of trap loans have not consistently reported trapping effort, however, the trap loan scheme in NE Scotland has made a larger contribution to the red squirrel protection network than elsewhere, with trap loans here accounting for the removal of more than 1,700 grey squirrels between 2010 and 2016 (SWT pers. comm.).

Due to the scale of the task to follow up on missing trapping information, SSRS have sought to collect as complete trapping data as possible for four demonstration areas in order to assess the cumulative impact on grey squirrel capture probability (a proxy for abundance). The size of demonstration areas is not equivalent but as an illustration of control effort (control officer and landowner data), the total number of trap days in 2014 in NE Scotland demonstration area (55 km^2) was 6,614 trap days, in Tayside (222 km^2) was 15,004 trap days, in Argyll & Trossachs (278 km^2) was 6,482 trap days and in South Scotland (604 km^2) was 15,206 trap days (Table 2). Only the NE Scotland and Tayside demonstration areas had generated sufficient time series of data for detailed analysis by 2013 as reported in Tonkin, et al. (2013).

Using all the available trapping data for the NE Scotland Demonstration Area between 2007 and June 2013 and the Tayside Demonstration Area from 2010 to 2012, a GLMM was used to explore the relationship between the probability of grey squirrel capture and a range of explanatory variables including the cumulative control effort for each trap location, taking account of nearby captures. There was found to be a significant negative effect of cumulative control effort on the probability of grey squirrel capture in both areas (Tonkin, et al., 2013). In Tayside the GLMM coefficient was -1.54 (CI -1.99 – -1.09), and in NE Scotland was -0.34 (CI -0.51 – -0.18) (both on link scale of logit model). Effects were found to be stronger in areas with the highest cumulative control effort. In these areas in Tayside the mean capture probability was close to zero and in NE Scotland was seven-fold lower than areas with relatively low effort (Tonkin, et al., 2013,). These results support the premise that trapping is having the desired effect of reducing grey squirrel abundance.

The reactive pattern of trapping in South Scotland in response to detecting squirrelpox, makes the data from this region problematic for assessing the impact of trapping on grey squirrel abundance. Added to this, despite the scale of trapping effort in South Scotland, it was apparent that the virus was still spreading (White & Lurz, 2014; Tonkin, et al., 2015). Hence SSRS sought the help of researchers to assess if containment of the virus was a realistic objective. White & Lurz (2014) used a spatially explicit population model to explore the spread of the disease under a range of control scenarios and levels of effort. Simulated control

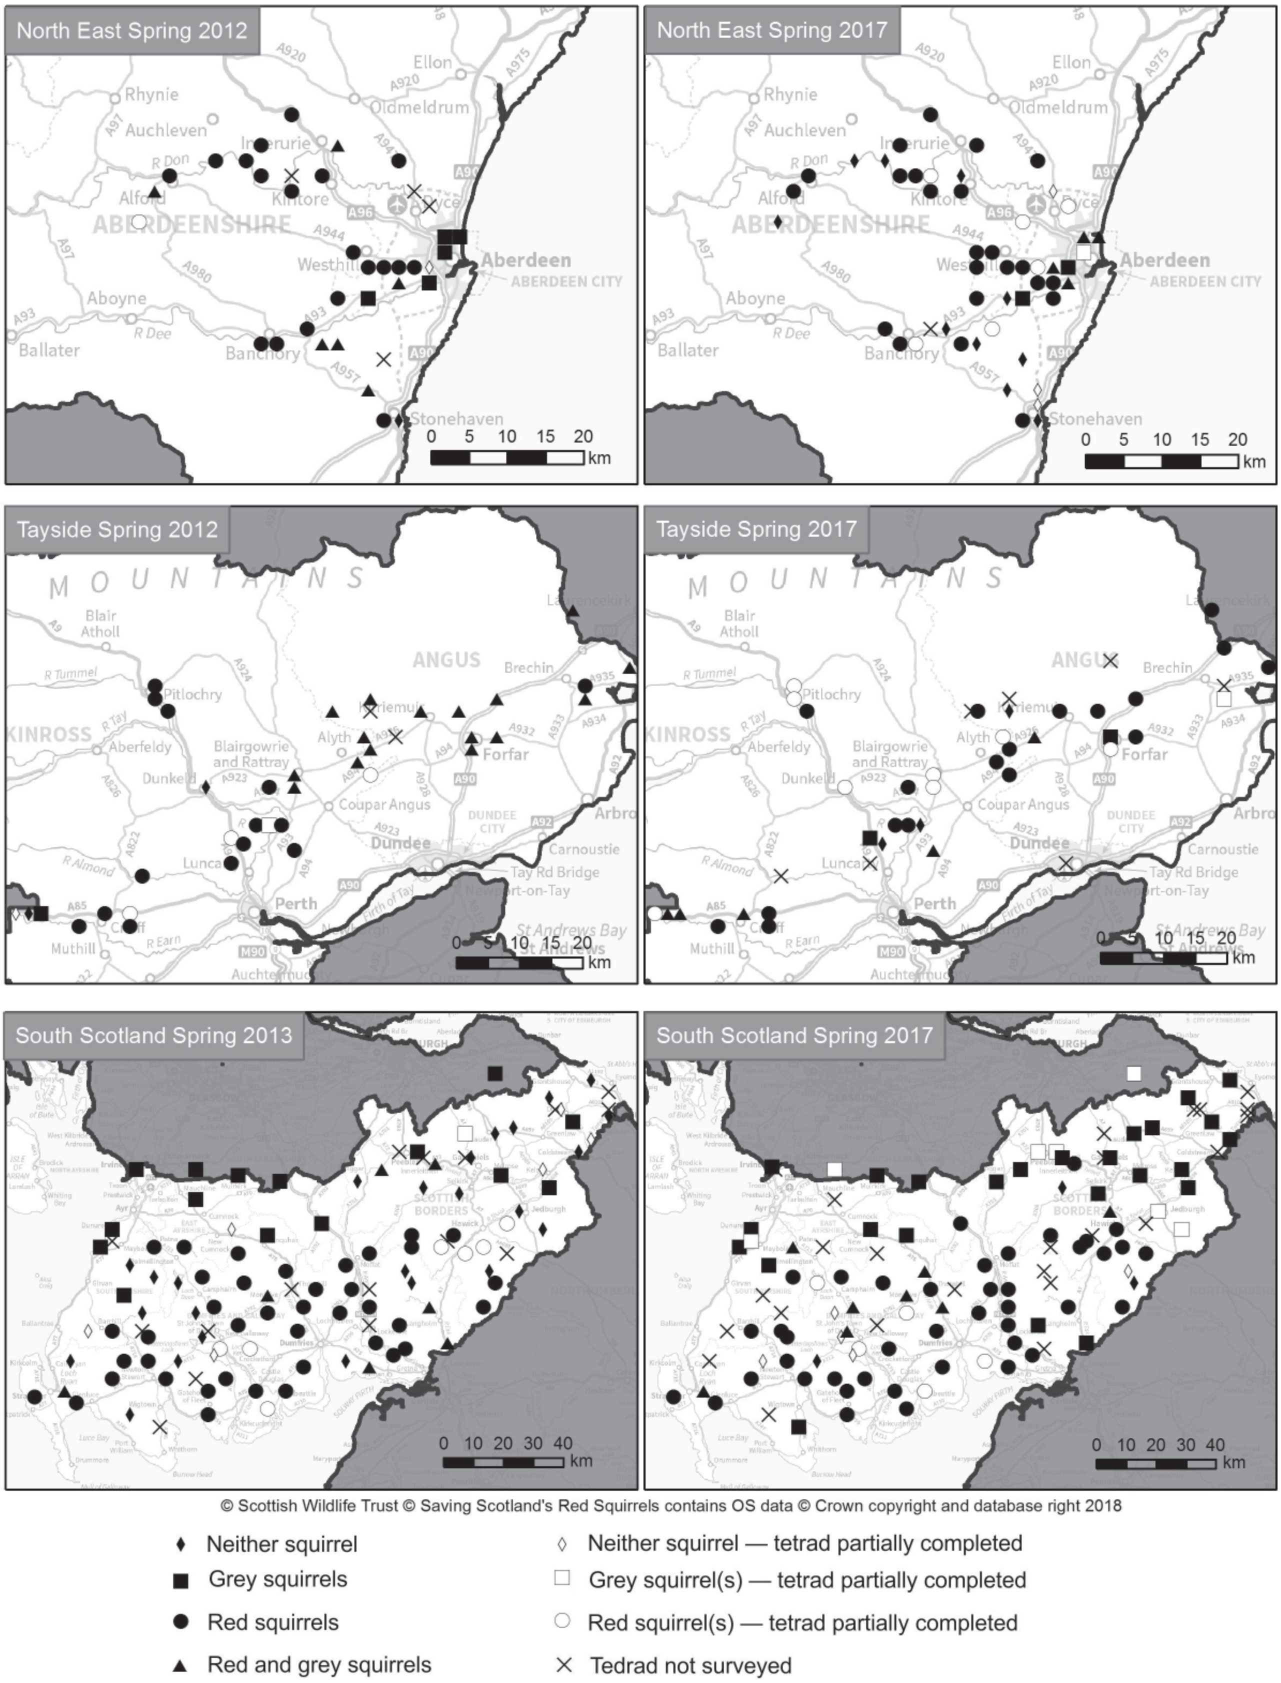

Fig. 3 Results of spring survey tetrads with both species, either species or none detected for a) North-east Scotland b) Tayside and (c) South Scotland for the years indicated (adapted from Shikorshidi & Tonkin 2018).

Table 1 Grey squirrel control achieved in all SSRS regions by control officers and land managers supported by SRDP funding.

	Grey Squirrel Officer Control		SRDP supported land manger control	
Year	Total no of trap days	No of greys captured	Total no of trap days	No of greys captured
2009	6,610	471	7,610	71
2010	18,615	1,637	41,365	510
2011	34,150	2,191	76,906	2,817
2012	40,783	2,797	237,738	3,630
2013	42,991	1,690	256,456	3,730
2014	32,889	1,819	222,031	2,713
2015	27,833	2,013	172,222	3,293
2016	9,776	490	89,316	1,029
Total	213,647	13,108	1,103,644	17,793
Average grey squirrel capture rate/100TN		6.14		1.61

was parameterised to assess the impact of current control measures; approximating the number of grey squirrels removed and adjusting the intensity of control in the model to mirror these levels by varying the area over which control was applied (White & Lurz, 2014). An alternative control scenario involving control along key dispersal routes was also assessed. The projections highlighted that current levels of control would not prevent the spread of the disease across Southern Scotland. Targeted control could help slow the spread of the virus but was unlikely to halt its spread in areas where grey squirrels are already established. However, the modelling also indicated that co-ordinated grey squirrel control should allow local red squirrel populations to persist and their density can recover after disease outbreaks in conifer dominated landscapes (White & Lurz, 2014; White, et al., 2016).

Annual (presence/absence) monitoring red and grey squirrels

The programme of annual presence/ absence monitoring indicates that red squirrel distributions have remained stable and that there have been some reductions in the range of grey squirrels in north Scotland and conversely some expansion in south Scotland (Fig. 3, Shirkhorshidi & Tonkin, 2018). The 2017 results of the tetrads in the north of Scotland as a whole (NE Scotland and Central Lowlands) show a significant change in favour of red squirrels when compared with 2012 (RI=-0.17, P=0.02). Contributing to this is a significant decrease in grey squirrel occupancy across the north and an increase in red squirrel distribution in the north-east, particularly in areas close to the City of Aberdeen; meanwhile red squirrel occupancy has been stable across the Highland Line (Shirkhorshidi & Tonkin, 2018). Although not significant, the overall changes in the south of Scotland have been in favour of grey squirrels (2013–2017 RI = 0.19). This reflects an increase in grey squirrel occupancy (largely outside SSRS areas of operation), whilst red squirrel occupancy appears to have been maintained (Shirkhorshidi & Tonkin, 2018). Whilst noting that squirrel populations experience fluctuations between years relating to seed crops, we interpret the overall trends in occupancy as an indication that SSRS's actions are helping to meet the project aims.

Public sightings of squirrels

Although they do not represent a systematic sample, public sightings help to harness public support and provide an early warning of range expansion of both red and grey squirrels. Sightings are mapped on the SSRS website (SSRS, 2018). For example, public reports have helped illustrate where red squirrels have returned to areas where they had not been recorded in the last 20 or 30 years following grey squirrel control, such as Aberdeen city parks (SSRS, 2017).

There has also been some standardisation and analysis of public sightings of squirrels between 1991 and 2010 across different regions of the UK (Gurnell, et al., 2014a). The data suggest red squirrel occupancy is declining in all regions over this period (at different rates), with the exception of Central Lowlands (east) of Scotland which fluctuates showing little overall change. However, an upward turn in red squirrel occupancy in the last two or three years is noted across all regions, especially South Scotland. Gurnell, et al. (2014a) indicate it is too early to speculate if the apparent upturn in the fortunes of red squirrels is as a result of grey squirrel control or other factors.

DISCUSSION AND FURTHER DEVELOPMENTS

We have described the evidence showing that sustained grey squirrel trapping can reduce grey squirrel abundance and occupancy at a landscape scale (Tayside and NE Scotland). Trapping data from Wales around the same time, indicates that sustained trapping can bring about reductions in grey squirrel populations at a landscape scale (Schuchert, et al., 2014). However, it has also been demonstrated that recolonisation can occur following intensive grey squirrel control after between one and three months (Lawton & Rochford, 2007; Schuchert, et al., 2014). Hence, SSRS are involved in further work to better quantify the level of control that might need to be sustained and, in particular, to put in place more sustainable delivery models.

The collaboration with researchers that started in South Scotland is now focussed on addressing the question of how much control may be required along the Highland Line to prevent grey squirrels from extending their range to the north. A spatially explicit population model (White, et al., 2017) has examined the impact of three levels of trapping intensity on grey squirrel populations in the Central Lowlands. Projections include the presence of squirrelpox virus (as a worst-case scenario) even though it has not yet been detected in this region. The potential density of red and grey squirrels in each 1 km × 1 km patch is derived based on average squirrel densities for the mixture of habitats encountered. Control is applied in targeted zones (typically 10 km ×10 km) and, mirroring trapping practice, can occur from 1 April to 30 September

(183 days), which is split into three 61 day (2 month) control periods. Trapping is applied in a responsive way to grid squares in which grey squirrels are present and in grid squares in a 2 km buffer zone in each of the three control periods. The model was run for three levels of trap intensity (TD = 0.3 – low; 0.5 – medium; 0.75 – high). This equates to 0.3 × 183 = 55 trap days per year (in a 1 km ×1 km grid square) in the low intensity scenario, 92 trap days per year (medium) and 137 trap days per year per (high), respectively.

In the low intensity scenario, trapping represents a kind of harvesting; there are abundant greys to catch and greys persist indefinitely. At medium intensity, control appears to be largely effective at preventing the northwards spread along the Highland Line. The model also highlights key dispersal routes where high intensity trapping is likely to be required (White, et al., 2017). Taking the Tayside Demonstration area (a key dispersal route) as an example the average, annual control effort predicted to be required (regions 7, 8, 9 in White, et al., 2017) is c. 18,000 trap days under the high intensity scenario. Given the modelled control area includes a slightly larger area than the Tayside demonstration area in order to prevent recolonisation, the levels of control suggested by the model are of the same order as control on the ground between 2012 and 2014 (Table 2) suggesting that this level of control effort needs to be maintained (White, et al., 2017).

Having successfully reduced the range, abundance and occupancy of grey squirrel populations in NE Scotland (Tonkin, et al., 2013; Shirkhorshidi & Tonkin, 2018), eradication of this isolated population now seems like a realistic prospect. However, some of the locations remaining untrapped are more challenging (smaller, fragmented and increasingly urban habitats). In 2014, SSRS set up an additional layer of monitoring to establish grey squirrel occupancy across the entire wooded network in the region. Feeder-box squirrel hair traps (n=223) have been distributed through all the suitable grey squirrel habitat patches in urban Aberdeen and the surrounding area. These data will allow analysis of grey squirrel occupancy (MacKenzie, et al., 2006) and better projections for the time and effort required to eradicate this isolated population. The monitoring will be complemented by rapid-response grey squirrel control.

SSRS's approach in South Scotland has adapted following the continued spread of squirrelpox virus and the model outcomes reported in White & Lurz (2014). The modelling indicates that co-ordinated grey squirrel control can help to protect red squirrel populations from the threat of squirrelpox virus in conifer dominated landscapes, where red squirrels typically occur at low densities, but importantly higher than those of grey squirrels. SSRS's control efforts have now shifted from the 'frontline' of squirrelpox detection to protecting identified priority areas for red squirrel conservation in South Scotland.

Table 2 Combined grey squirrel control effort (annual trap days) achieved by control officers and landowners supported by SRDP funding in the four demonstration areas 2009–2016.

	NE Scotland	Central Scotland		South Scotland
		Tayside	Argyll & Trossachs	
2009	2,465	NA	NA	4,987
2010	5,946	3,389	48	14,678
2011	7,878	8,201	360	17,912
2012	10,554	14,677	6,803	16,934
2013	6,178	16,158	6,721	20,079
2014	6,614	15,004	6,482	15,206

Sustaining the action

SSRS was initially funded for three years and eight months (2008–12), which was then extended by a further four years. The lead partner, SWT, secured a mixture of public and charitable funds to meet a project budget of just over £3 million covering the period 2008–16. In 2016, SWT secured a Heritage Lottery Fund Award of £2.46 million for the next 5 years (until 2022) towards a total project cost of £4.4 million. Hence, the costs have been roughly £0.5 million per annum to date. The piecemeal nature of project funding creates a challenge for sustaining co-ordinated grey squirrel control. Under the new SSRS phase, costs are anticipated to rise to c. £0.88 million per annum reflecting the additional activities aimed at ensuring the long-term sustainability of the control network and with a view to substantially reducing costs thereafter.

By September 2013, 197 landowners were in receipt of five-year SRDP funding at a cost of £4.5 million over the five-year period covered by the contracts. Although trapping by control officers is on average nearly four times more efficient (more captures per 100 trap days, Table 1) than SRDP-supported landowner grey squirrel control, landowner control provides five times more trapping effort than is provided by control officers (Table 1). Hence, being able to access public funding support has been hugely important. However, public funding is not without its challenges including: ease of access to the scheme for applicants; and ensuring trapping data are available to SSRS. Added to this there are uncertainties about the future of support upon leaving the European Union.

Quantifying the control effort needed to deliver SSRS's objectives has been challenging. However, SSRS's monitoring and associated modelling has supported that the levels achieved seem 'about right'. However, this equates to a substantial network of grey squirrel control that needs to be sustained.

Reflecting the successes to date and the challenges ahead, the next five-year phase is called Saving Scotland's Red Squirrels – Developing Community Action. This project's actions are geared towards long-term sustainability and how SSRS's work can be embedded in routine land management and community action, with a move away from reliance on project staff. Project funding at this level of investment is increasingly hard to find, hence there is an expectation that red squirrel conservation will increasingly rely on public delivery.

SSRS – Developing Community Action now aims to eradicate grey squirrels from NE Scotland within 10 years. In South Scotland the aims have been refined and focus on building the skills and resources available to local people and land managers working to control grey squirrels in identified priority areas. As part of this, a Community Hub information management system is being developed for staff and volunteers, which will better capture and integrate data from all sources and will allow improved feedback. For each priority area, an annual trapping programme is being developed that is capable of continuing to protect the red squirrel population. As yet it remains to be determined if the necessary levels of control can be sustained by these means. However, there is a shift in the focus of SSRS work from demonstrating the efficacy of control on to how can it be delivered.

Largely based on the evaluation of work co-ordinated by SSRS, the national policy position now recognises coordinated grey squirrel control as an integral part of the long-term approach to achieving the strategy aims (Scottish Squirrel Group, 2015).

The challenge of protecting Scotland's red squirrels remains significant given the scale and the ongoing nature of the work. However, the prospects for alternative/ or complementary approaches are also improving. Immuno-contraceptives and squirrelpox vaccines are actively being explored with the support of parallel initiatives under the 'UK Squirrel Accord' but are likely to be some years in development. New research into the role of pine marten on the dynamics of red and grey squirrels also offers promising insights in that as pine marten populations recover their range and densities, grey squirrel populations appear to be suppressed in the presence of this novel (to them) native predator, thereby reducing the levels of management control required to promote red squirrel persistence (Sheehy, et al., 2018).

ACKNOWLEDGEMENTS

The Saving Scotland's Red Squirrels partnership includes the Scottish Wildlife Trust, Scottish Natural Heritage, Forestry Commission Scotland, Royal Society for the Protection of Birds (Scotland), Scottish Land & Estates and the Red Squirrel Survival Trust. The partnership is grateful to all organisations and individuals that have made funding contributions. We are particularly grateful to all the landowners and managers, gamekeepers, rangers, researchers and volunteers who have so willingly assisted the project.

Testing auto-dispensing lure pumps for incursion control of rats with reduced effort on a small, re-invadable island in New Zealand

A. Carter[1], R. van Dam[2], S. Barr[2] and D. Peters[3]

[1]Department of Ecology, Evolution & Organismal Biology, Iowa State University, 2200 Osborne Dr., Ames, Iowa 50011, USA. [2]Goodnature Limited, 8 Horner St., Wellington 6021, New Zealand. [3]Department of Conservation Te Papa Atawhai, 18–32 Manners St., Wellington 6011, New Zealand. <dpeters@doc.govt.nz>.

Abstract In locations with a high potential for re-invasion, such as inshore islands, sustained control of invasive species is as important as the initial knock-down for the long-term recovery of native populations. However, ongoing trap maintenance and lure replenishment are barriers to minimising the time and financial costs of long-term suppression, even when automatic traps are used. Control of invasive mammal species is a high priority for the more than 200 islands within Rakiura National Park in southern New Zealand, many of which support nationally and internationally threatened endemic species and ecosystems. We previously used automatic, toxicant-free traps to control rats on Native Island, a 62 ha inshore island within the National Park, where tracking indices were 73% in mid-2013. After 18 months, tracking indices remained below 10%, and site visits were reduced to twice per year, following introduction of novel auto-lure pumps. Tracking indices for rats remained low after six months, then increased to 37% in May 2017. That increase, as well as small fluctuations in measured activity levels throughout the study, could indicate continued incursion from the mainland, highlighting the importance of continued suppression. Additional work is needed to determine the limitations of the automatic lure dispensers and optimise their use for long-term suppression of pest mammals in ecosystems that are highly vulnerable to re-invasion.

INTRODUCTION

Introduced mammals are one of the most significant threats to island ecosystems (Towns, et al., 2006; Bellingham, et al., 2010; Harper & Bunbury, 2015). In particular, rats (*Rattus* spp.) and other rodents have become major predators of endemic island species, causing several local extinctions (Courchamp, et al., 2003; Towns, et al., 2006; Bellingham, et al., 2010). Thus, they are a main target of eradication operations (Howald, et al., 2007; Glen, et al., 2013; Holmes, et al., 2015). However, while numerous offshore rat eradications have been undertaken successfully since the 1980s, eradication is more difficult in locations that are close enough to a non-controlled pest population to facilitate rapid, and inevitable, re-invasion (Russell, et al., 2008; Nathan, et al., 2015). At highly re-invadable sites, such as near-shore islands, a single operation can theoretically eliminate a population of invasive rats. However, that 'eradication' is only temporary. Sustained control is required in order to prevent re-establishment (Simberloff, 2011), which can occur rapidly and with only a few invaders (Russell, et al., 2008; Nathan, et al., 2015).

Most successful eradication operations on New Zealand islands – both of rats and of other pest mammals – have been undertaken using site-wide toxicant applications (Blackie, et al., 2013; Keitt, et al., 2015). However, toxicant-based methods are not as effective for sustained control in highly re-invadable sites as they are on relatively isolated, offshore islands. Importantly, a re-invading population of mammals has to achieve a minimum density in order for repeated toxicant use to be considered a cost-effective means of control (Warburton & Thomson, 2002), but that density threshold is higher than the maximum density under which many native species can successfully recover (Gillies, et al., 2003; Norbury, et al., 2015). Thus, conservation-motivated, long-term mammal suppression in re-invadable sites requires the availability of sustained-use, cost-effective methods. Throughout this paper, we use the terms 'suppression' and 'maintenance control' interchangeably to refer to any control method used to prevent the re-establishment of a population of pest mammals in an island due to incursion. However, the same principles can be applied within any controlled area that is at risk of being invaded, or re-invaded, from an adjacent, un-controlled population.

Unlike mammal control operations that rely on site-wide application of toxicants, traps can be left in situ and used for incursion control. However, current best-practice methods of trapping require continual re-baiting and, if a trap is triggered, re-setting of the trapping mechanism to remain effective (DOC, 2006). In addition, traps may be less effective at controlling low-density populations than they are at eradication of established, high-density populations (Thorsen, et al., 2000; Chappell, 2004). As a result, effective island biosecurity still requires regular surveillance and the availability of funding to undertake contingency response in the event of an incursion (Russell, et al., 2008). A relatively new technique for long-term control of invasive mammal populations is the use of automatic, or self-resetting, trapping and toxicant application mechanisms (reviewed in Campbell, et al., 2015). Like single-use trapping methods, self-resetting mechanisms – both traps and toxicant-delivery devices – can be designed with relatively high specificity, reducing the rate of non-target kills, relative to that realised following site-wide toxicant applications (Campbell, et al., 2015). Unlike single-use traps, automatic mechanisms can remove multiple pests before requiring maintenance and/or re-baiting (Blackie, et al., 2011; Blackie, et al., 2013; Murphy, et al., 2014; Carter, et al., 2016).

Automatic toxicant-delivery devices have been designed for stoats (*Mustela ermina*), possums (*Trichosurus vulpecula*) (Blackie, et al., 2016) and rats (Blackie, et al., 2013; Murphy, et al., 2014). Automatic, toxicant-free traps and corresponding long-life lures have been developed by Goodnature® Ltd for possums, rats, and stoats (Carter, et al., 2016; Carter & Peters, 2016), with the advantage that devices that do not rely on poisons may be more acceptable for control of invasive mammals in locations that support populations of native mammals (Campbell, et al., 2015). Self-resetting traps have been used to control sympatric populations of Norway rats (*Rattus norvegicus*), ship rats (*R. rattus*), and Australian brushtail possums

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 187–190. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

on a single, near-shore island (Carter, et al., 2016) and to control ship rats and mice (*Mus musculus*) within an unprotected mainland site (Carter & Peters, 2016) in New Zealand. One pest control operation in Hawaii also found that automatic traps were more beneficial for decreasing predation of native species by rats than single-action snap-traps (Franklin, 2013).

The long-term financial costs of using automatic traps for control of invasive mammal populations are comparable to those of using basic Victor® snap-traps, especially when work is undertaken primarily by contractors, and slightly lower than the costs of using DOC-200 traps, heavy-duty, single-action tunnel traps commonly used for maintenance control (Carter, et al., 2016; Carter & Peters, 2016). The use of self-resetting traps greatly reduces the frequency at which site visits must be undertaken, relative to traditional methods of trapping that require regular rebaiting and resetting to maintain effectiveness (e.g., Franklin, 2013). However, the rate at which even long-life lures must be replenished in self-resetting traps – approximately monthly – is still higher than the rate at which pests are killed, following initial suppression of the population (Carter, et al., 2016). As a result, the costs of long-term suppression of pest mammals – in terms of both equipment and person-hours – are increased significantly by the investment in on-the-ground trap maintenance, even when self-resetting traps are used (Franklin, 2013; Glen, et al., 2013; Carter, et al., 2016; Carter & Peters, 2016).

The continued effectiveness of self-resetting traps relies largely on maintaining attractiveness of the highly viscous lure, which is contained within a plastic bottle housed inside the trap. When a targeted mammal population is relatively dense and the lure is consumed regularly, the force of gravity is sufficient to keep 'fresh' lure available. Once a population of invasive mammals has been knocked down, human intervention is required to ensure that uneaten lure does not become mouldy and unpalatable after being exposed to air. Thus, the mechanism of lure delivery itself remains a barrier to minimising costs of maintenance control. Here, we tested the use of auto-dispensing lure pumps for retaining lure freshness and maintaining low levels of rats on a previously-controlled inshore island, while significantly reducing the person-hours required for undertaking site visits.

MATERIALS AND METHODS

In November 2013, we installed 143 CO_2-powered, automatic rat traps (A24; Goodnature® Ltd, Wellington, New Zealand; https://www.goodnature.co.nz) on a 100 m × 50 m grid on Native Island (46°54'54″ E 168°09'25″ S) (Carter, et al., 2016), a mostly forested, 62 ha Scenic Reserve within Rakiura National Park in southern New Zealand (DOC, 2012). Because Native Island sits approximately 100 m from the coast of the main island of Stewart Island (also known as Rakiura), incursion by multiple species of pest mammals from the mainland following a control operation is inevitable (Atkinson, 1986). The presence of Norway rats, ship rats and brushtail possums has been confirmed on Native Island (DOC, 2012), and all three species were observed during establishment of the trapping network. In addition, Pacific rats (kiore, *Rattus exulans*) are present on the nearby mainland and may pose an additional incursion risk.

Each trap was initially baited with a bottle of non-toxic, peanut-based lure and checked approximately monthly, with lure bottles and CO_2 cartridges replenished every six months (Carter, et al., 2016). Due to lack of resources, the traps were not maintained for the eight months between September 2015 and May 2016. In May 2016, we replaced all CO_2 cartridges and replaced the standard lure bottles with novel auto-lure pumps. The auto-lure pump is a soft-sided lure bottle that uses hydrogen gas expansion to deliver 55 g of non-toxic lure over a period of six months (Fig. 1). The CO_2 cartridges and auto-lure pumps were replaced every six months.

During the initial control operation only, we used tracking tunnels (Pest Control Research [PCR] Ltd., Christchurch, New Zealand) with inked tracking cards (Black Trakka®, Gotcha Traps, Auckland, New Zealand) to monitor mammal activity within the trapping grid on Native Island and at a control site, located 3.5 km away on Stewart Island (Gillies & Williams, 2013). We estimated rat activity using tracking indices, with detection corrected for interference with the tracking cards by possums, where required (Gillies & Williams, 2013). Tracking tunnels were installed at 50 m intervals on Native Island in six lines of five tunnels each, and at the control site in three lines of five tunnels and two lines of ten tunnels. During each monitoring period, tracking tunnels were baited with peanut butter and tracking cards retrieved after 24 hours (Carter, et al., 2016). Following installation of the auto-lure pumps, rat activity was monitored at two subsequent intervals of approximately six months, at the Native Island site only.

RESULTS

During the initial control operation, tracking indices for rats on Native Island decreased from 73% to 7% within nine months of initiation of trapping and remained perpetually at or below 10% during the monitoring

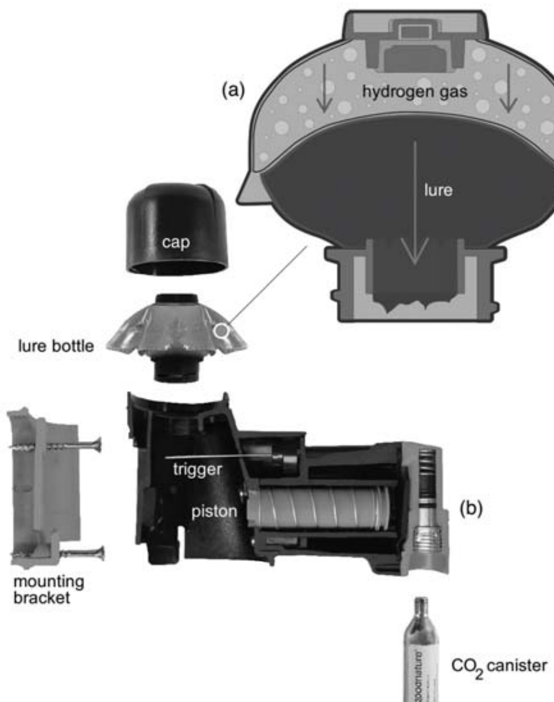

Fig. 1 Diagram of an (a) auto-lure pump and (b) deconstructed interior of an A24 self-resetting rat trap. Activation of the trigger by a rat as it accesses the lure causes rapid deployment of the CO2-powered piston, which strikes the skull and results in near-instantaneous death. The trap automatically resets after each strike, up to 24 times. Gradual expansion of hydrogen gas inside the soft-sided, auto-lure pump slowly delivers lure through the bottle opening over a period of six months. Image courtesy of Goodnature® Ltd (Wellington, New Zealand).

period, while tracking indices at the control site remained comparatively high (Fig. 2; see Carter, et al., 2016 for complete results). On the first monitoring visit following installation of the auto-lure pumps, tracking indices on Native Island were 7% but increased to 37% during the most recent site visit in May 2017 (Fig. 2). Rat activity was not monitored at the control site after the initial trapping operation. However, tracking indices within a separate, un-trapped area on Stewart Island were 40% in March 2017 (SIRCET, 2017). Between the first and second monitoring visits, air temperatures were between -1.5°C and 0.5°C of monthly regional (Southland) averages, varying between 8°C and14°C during the study months (Macara, 2013), and rainfall levels were at or below normal levels (Fig. 2).

DISCUSSION

This project was the first *in situ* test of auto-dispensing lure bottle technology, following a previous knockdown. One of the primary motivations for developing time-saving technologies for invasive mammal control – lack of sufficient available person-hours for maintaining traps and monitoring for incursions – was both the impetus for and the main limitation of this study. Because rat activity levels were not monitored for the year prior to installation of the auto-lure pumps, nor when they were installed, we cannot say definitively that they were as effective as standard lure bottles at maintaining low levels of rats. That is, the activity levels recorded in October 2016 could be indicative of no incursions, with switching of standard bait bottles for auto-lure pumps having no effect on the consistently low activity levels observed since at least August 2014. However, given the proximity of the study site to uncontrolled populations of multiple rat species, as well as fluctuating activity levels throughout the original control operation and slight increase observed in May 2015, that activity levels were still below 10% a year later is unlikely. More likely is that rat activity levels increased to some extent prior to installation of the auto-lure pumps and that the pumps effectively reduced activity levels during the first five months of their operation.

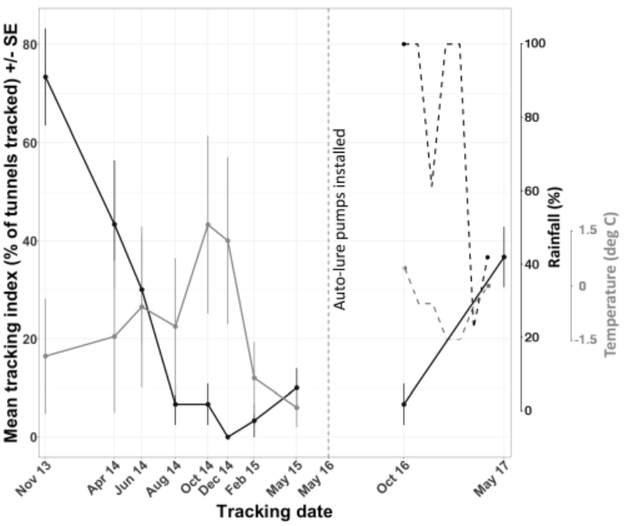

Fig. 2 Summary of monitoring data from tracking tunnels on Native Island (black) and the control site on Stewart Island (grey), with the introduction of auto-lure pumps indicated by the dashed vertical line. Except for the period from May 2015 – May 2016, the spacing of x-axis labels is proportional to the amount of time between monitoring dates. The percentage of tracking cards with interference by possums was high at the control site on Stewart Island throughout the initial trapping operation, so true activity of rats may be higher than indicated by the plot, especially in February and May of 2015. No data are available for the period May 2015 – October 2016, and no monitoring was undertaken at the control site after May 2015. Climate data are shown with dashed lines. The rainfall axis shows the approximate percentage of local rainfall in each month, relative to 'normal' conditions (i.e., a value of 100% is equal to normal). The temperature axis shows the deviation of local air temperatures from average conditions, with a value of 0 equal to the respective monthly mean. Weather information was obtained from NIWA 'Current climate' monthly summaries (https://www.niwa.co.nz/climate/nzcu/). Plot adapted from Carter, et al. (2016).

During the second, but not the first, monitoring visit to Native Island, the lure was noticeably mouldy and may have been less attractive to rats. Mould growth may be related to environmental conditions at the study site, which would suggest that the rate of gas expansion inside the auto-lure pump may be insufficient to keep the lure fresh in certain conditions. Climate has been implicated in the failure of mammal control operations across methods, with stationary bait stations being most similar to trapping. Bait station-based eradication failures have been associated with higher mean annual temperatures and increased variation in inter-annual precipitation in tropical locations, which become more important with increasing island size (Holmes, et al., 2015). High temperatures, in particular, are a significant predictor of failure across toxicant-based methods of rat eradication (Holmes, et al., 2015).

The importance of climate to the success of mammal control has been examined primarily in relation to the timing of toxicant application, particularly in the tropics, where more consistent food availability increases the difficulty of targeting rodents using attractant-based toxicants (Holmes, et al., 2015; Russell & Holmes, 2015). Air temperatures at our study location did not vary much from average monthly conditions, and more months were relatively 'dry' than 'wet,' compared with regional norms (Fig. 2). However, further research should be undertaken to determine whether abiotic environmental conditions constrain the efficacy of auto-lure pumps. If so, either (1) increasing the rate of gas expansion inside the auto-lure bottle or (2) increasing the rate of site visits during particular seasons or in climates normally conducive to mould growth may be required.

Assuming the number of successful control operations in incursion-vulnerable sites increases, so too will the costs of controlling invasive mammals. In highly re-invadable sites, true eradication is an impractical aim (Simberloff, 2011). Indeed, if mammal densities can be maintained at levels low enough to facilitate the recovery of native populations, then eradication becomes less immediately imperative. Thus, cost-effective suppression of pest mammals is a realistic goal for conservation of endemic island biodiversity. Technologies that minimise the time and financial investments required for long-term control will be key to maximising the area within which populations of invasive mammals can be controlled. More work is needed to optimise the use of auto-lure pumps and quantify their limitations. However, effective automatic lure delivery devices would be a transformative addition to the pest-control toolbox and should continue to be rigorously developed and tested.

ACKNOWLEDGEMENTS

Thanks to field volunteers from the East Taranaki Environment Trust; Nick Beckers, Mark Caskey, Joanna Greig, Bob Schumacher and Karen Schumacher; and Dean Caskey from the Taranaki Regional Council. We also thank staff from the New Zealand Department of Conservation *Te Papa Atawhai*, especially Klaartje van Schie, and two landowners for permission to install traps in the privately-owned areas of Native Island. We would also like to acknowledge the contributions of current and former Goodnature staff. Funding for this project was provided by the Department of Conservation.

Abstract Rodent eradications are a key island restoration activity to counteract extinction and endangerment to native species. Despite the widespread use of brodifacoum as a rodenticide for island restoration, there has been little examination of its potential negative effects on native reptiles. Here we examined the survival of two endemic insular lizard populations before, during and after a brodifacoum-based rodent eradication using a mark-recapture study. We found no evidence of an effect from baiting in *Anolis desechensis* and evidence of a change in recapture rates after baiting for *Ameiva desechensis*. Effects of baiting on survival rates were not measurable due to a small sample size. Results suggest that brodifacoum did not result in population-level impacts during the three-week study period after brodifacoum exposure. For invasive species eradications using toxicants, potential risks to non-target species should be assessed against the expected benefits to native biota from the removal of threats posed by invasive mammals. We recommend continued studies that directly examine non-target risk to native reptile populations derived from toxicant baiting programs, particularly on tropical islands that are home for high numbers of endemic reptiles.

INTRODUCTION

Islands represent approximately 5% of the land area of the Earth, yet 61% of extinctions have been insular species, and 37% of species listed by the IUCN as critically endangered are confined to islands (Tershy, et al., 2015). Invasive species are a major driver of species extinctions on islands and remain a significant risk to threatened species (Bellard, et al., 2016; Doherty, et al., 2016). Invasive rats have been introduced to approximately 80% of the archipelagos of the world, and have wide-ranging negative impacts on native flora and fauna (Towns, et al., 2006). Techniques to eradicate invasive rodents from islands are available and the practice is increasing in scope, scale, and application (Howald, et al., 2007; Keitt, et al., 2011), with restoration benefits being accrued when eradication is achieved (Jones, et al., 2016). To date there have been over 650 eradication attempts of rats (*Rattus* spp.) on more than 500 islands worldwide (Russell & Holmes, 2015).

Successful rodent eradication from islands larger than 5 ha primarily relies on the use of anticoagulant rodenticide (Howald, et al., 2007). Second generation anticoagulants are the most commonly used toxicant in invasive rodent eradication programmes (Holmes, et al., 2015). When using toxicants for rodent eradication on islands, the risk to non-target native species is typically assessed. Efforts to reduce this risk during eradication operations commonly include application of bait when susceptible species are absent, temporary captive-holding of species during potential periods of exposure, and alternative delivery methods to reduce bait access (Howald, et al., 2007). While reptiles have been known to consume cereal-based rodent baits (Merton, 1987; Marshall & Jewell, 2007), they have typically been considered at lower risk (Hoare & Hare, 2006), in part because of decreased susceptibility due to differences in blood chemistry and physiology compared to mammals and birds (Merton, 1987; Hoare & Hare, 2006). Although evidence of population level impact to reptiles is sparse, observations from an increasing number of rodenticide-based eradications, plus targeted studies, have suggested the risk is low (Harper, et al., 2011). Nevertheless, additional studies are required to improve general knowledge of the risk of rodenticides to reptiles during rodent eradication operations.

During 2012, an eradication of *Rattus rattus* using rodenticide bait was attempted on Desecheo Island located approximately 21 km off the north-west coast of Puerto Rico. Black rats were introduced in the early 1900s and are considered an important threat on Desecheo, including impacts on native reptiles from direct predation and habitat modification via seed and seedling predation and soil nutrient changes (U.S. Fish and Wildlife Service, 2016). An additional potential threat from rats to native reptiles could include competition for space and food resources, consistent with rat impacts on reptiles elsewhere (Shiels, et al., 2014; Harper & Bunbury, 2015). Two years prior to the eradication operation, exposure of bait to the endemic Desecheo ameiva (*Ameiva desechensis*) and Desecheo anole (*Anolis desechensis*) was assessed through a placebo non-toxic bait biomarker study. The study found no evidence of ameivas (n=18 marked, n=5 recaptured) interacting with bait, but 21% of anoles recaptured were exposed (n=97 marked, n=20 recaptured) (Herrera & Bermúdez-Carambot, 2010). However, because these species occur only on Desecheo, and thus had high conservation value, the fate of both lizard species was followed during the application of toxic bait during the eradication operation. Here we report the results of a mark-recapture study to monitor the short-term survival of the ameivas and the anoles before, during and after the 2012 rodent eradication operation on Desecheo Island.

MATERIALS AND METHODS

Study area

Desecheo Island is a 117 ha hilly island located approximately 21 km off the north-west coast of the Commonwealth of Puerto Rico (18° 23’ N, 67° 29’ W; Fig. 1). It was declared a U.S. National Wildlife Refuge (NWR) in 1976 and is currently administered and managed by the U.S. Fish and Wildlife Service. Sub-tropical dry forest (i.e. woodland) is present primarily on the leeward slopes and valleys, and is dominated by the semi-deciduous almácigo tree (*Bursera simaruba*). The windward slopes and ridges also harbour cacti, shrubs and open grasslands. The annual

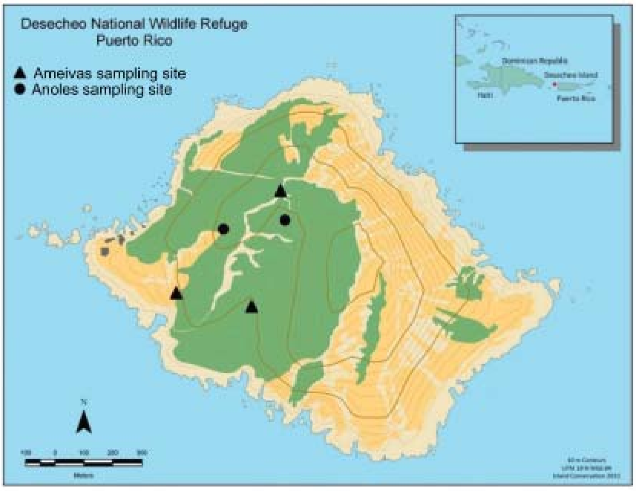

Fig. 1 Location of Desecheo Island and sampling sites for *Anolis desechensis* and *Ameiva desechensis* impact assessment during black rat eradication operations.

rainfall average is 828 mm (range 750–1039 mm; Morrison & Menzel, 1972) with a seasonal dry period between January and March, followed by a rainy season between July and November. The island supports five single-island endemic species (three lizards and two arachnids) as well as one of the three remaining populations of the threatened higo chumbo cactus (*Harrisia portoricensis*). Previous anthropogenic activities on the island included livestock grazing, military operations (e.g. bombing and gunnery range) and the introduction of invasive mammals: black rats (*Rattus rattus*), goats (*Capra hircus*), feral cats (*Felis catus)*, and rhesus macaques (*Macaca mulatta)*. The extirpation of nesting seabirds from Desecheo Island has been linked to the presence of these invasive mammals (U.S. Fish and Wildlife Service, 2016). The island is currently closed to the public due to the existence of unexploded ordnance.

Rat eradication

Aerial bait broadcast for rodent eradication was carried out on Desecheo between March 13 and 23, 2012. The bait used for the eradication was "Brodifacoum Conservation-25D" manufactured by Bell Laboratories in Madison, Wisconsin, USA. The bait was a 2 g extruded pellet, dyed green, and contained 25 ppm of the toxin brodifacoum. The bait broadcast was completed in two aerial applications separated by 10 days and with a ground application rate of 17 kg/ha for the first application and 9.1 kg/ha for the second application. There is no weather station on Desecheo Island and data were obtained from weather stations located in Rincon (13 miles from Desecheo) and Isabela (29 miles) and the Standard Precipitation Index (SPI) produced by Caribbean Regional Climate Center. January and March are usually a dry period but data from two weather stations and comparisons with 2008 and 2010 vegetation cover indicate that in 2012 Desecheo received greater than average rainfall.

Study species

The Desecheo ameiva (Fig. 2a) is a common lizard species found in coastal areas, including shoreline margins, in habitats of maximum solar exposure but frequently near some vegetation cover or shade (Evans, et al., 1991). Adult females tend to be smaller (SVL <90 mm) than males (average SVL 97 mm). Field surveys conducted in 2009 and 2010 estimated the island population at 7,469 individuals (95% CI 1,800–13,137) (McKown, et al., 2010). The Desecheo anole (Fig. 2b) is present throughout the island, but is most common in forested areas (e.g. valleys) and their margins (Evans et al., 1991). Average size for adult males is 57 mm (SVL) and for females 45 mm (SVL). Field surveys in 2009 and 2010 estimated the island population at 52,111 individuals (95% CI 31,464–72,758) (McKown et al., 2010).

Reptile monitoring

During the eradication, we implemented a reptile monitoring program between February and April 2012. We used a standard mark-recapture methodology (Jolly, 1965; Seber, 1965) over three discrete sampling periods of six days each, which coincided with bait application stages during the eradication. The first period began 21 days prior to the first bait application, the second between the first and second bait application, and the third began three days after the second bait application. The sampling sites were randomly located in five different locations within the woodland habitats in the Long and West Valleys (Fig. 1). Ameivas were sampled within one 100 × 10 m plot and

Fig. 2 *Ameiva desechensis* (a) and *Anolis desechensis* (b).

two 50 × 10 m plots. Anoles were sampled within two 100 × 10 m plots. Each plot was surveyed by two observers, each responsible for sampling one side (5 m) of a central transect through the plot. Each sampling day accounted for 8 hours of intensive searches for both species, and included the detection and capture of each observed individual. Individuals were captured using a pole and noose and by hand capture. Each anole was marked on the hind limb with a unique visible alphanumeric implant tag and each ameiva was marked with a unique combination of coloured glass beads sewed to the base of the tail (Fig 2a), and a unique combination of clipped toes (Censky, pers. comm. and modified from Fisher & Muth, 1989). Each individual was released at their capture location.

Statistical analyses

Survival of individuals was estimated using a mark-recapture model based on multiple capture histories within each sampling period (Cooch & White, 2015). We estimated the probability of recapture based on time and apparent survival to assess any potential impacts on either species as a result of the rodent bait application. We used MARK 5.0 (White & Burnham, 1999) to model factors influencing variation in survival. The Cormack-Jolly-Seber (CJS) model based on live animal recaptures in an open population (Lebreton, et al., 1992) was used to estimate the apparent survival (phi or ø). Models were constructed based on the recapture rates (*p*) and apparent survival (ø) remaining constant (.) or changing in time (*t*), and according to the bait dispersal events – before, during, and after (*asp*). The best performing model was selected using the Akaike Information Criteria (AIC) through the proportion test with Akaike weights (AICw; Burnham & Anderson, 2002). The assumptions of the CJS model were tested using TEST 2 and TEST 3 in the U-CARE program version 2.3 M 7.5 (Choquet, et al., 2005). To evaluate the fit of the set of models to the data, a Global TEST was conducted to calculate the variance inflation factor (ĉ).

RESULTS

A total of 452 anoles and 57 ameivas were captured and marked across 18 days of field sampling and 144 person-hours of sampling effort in the five study sites (Table 1). Although ameivas were detected less frequently across the study sites, they had a higher rate of recapture (35 recaptures, 61.4%) than anoles (92 recaptures, 20.4%; Table 1).

The best supported model for anoles explained the probability of recapture according to time and with apparent survival remaining constant (Table 2). For ameivas, the best supported model was the one in which the recapture probability varied across the sampling periods (i.e. bait application) and when apparent survival remained constant (Table 2). Both models indicated no changes in apparent survival along the three periods (asp) of bait applications. TEST 2 and TEST 3 showed no differences in the probability of recaptures and survival for the marked individuals (p>0.61). Global TEST indicated a sub-dispersion in the data (ĉ<1), thus no effect on the variance, therefore this parameter was not modified in the models (Cooch & White, 2015).

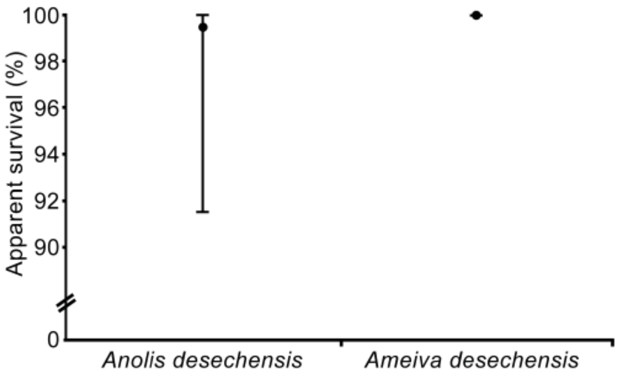

Fig. 3 Apparent survival percentage of *Anolis desechensis* and *Ameiva desechensis* during a black rat eradication on Desecheo Island (Error bars: 95% confidence intervals).

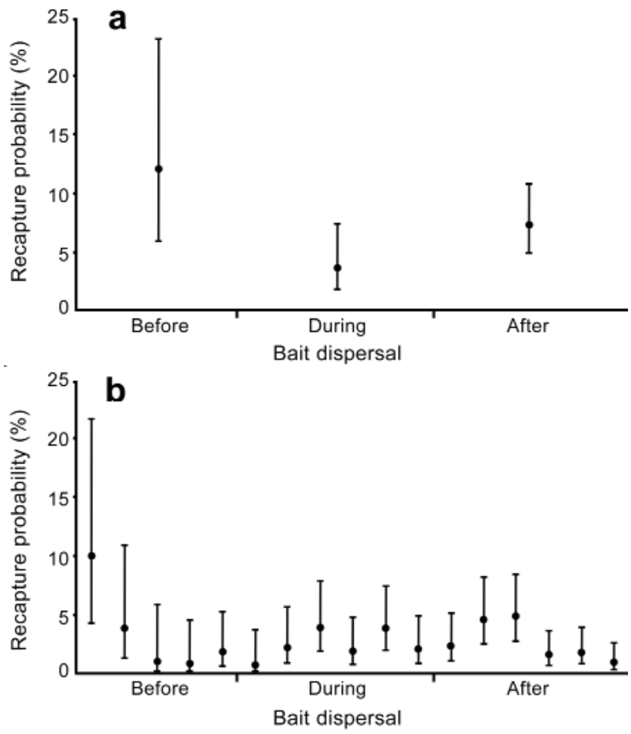

Fig. 4 Recapture probability for (a) *Anolis desechensis* and (b) *Ameiva desechensis* before, during and after bait dispersal for a black rat eradication on Desecheo Island (Error bars: 95% confidence intervals). We retain individual survey events in Figure 3b as these were found to be associated with recapture probability.

Apparent survival for both lizard species during the study period was estimated to be time-invariant and close to 100% (anoles: ø = 0.99, 95% CI = 0.91–0.99; ameivas: ø = 1, 95% CI = 1–1; Fig. 3). However, the precise apparent

survival estimate for ameivas was not realistic due to the small sample size (Fig. 3). An effect of time across bait dispersal over the recapture probability was found in the ameiva, with a tendency to decrease during and after bait dispersal (Fig. 4a). In contrast, for the recapture probability of the anoles there was no pattern associated with bait dispersal, but this variation was related to survey events (Fig. 4b). No mortality was observed for either species.

DISCUSSION

We estimated the survival and recapture rates of two native reptile species during a black rat eradication on Desecheo Island, Puerto Rico. During our study, we found no significant change in apparent survival rates across the sampling periods in anoles or ameivas, indicating that the application of rodenticide bait did not result in any detectable mortality or negative effect on both populations. Furthermore, the recapture probabilities for anoles varied through time (between survey events), but were not dependent on bait application, suggesting that while anoles were exposed to rodent bait (23% of individuals), exposure did not impact survivorship within the sampling period. For ameivas, the placebo-bait biomarker study found no direct or indirect exposure of ameivas to rodent bait. For the current study, the precise apparent survival estimate for ameivas was influenced by the small sample size and was not considered statistically valid. The recapture probability estimate for the species decreased during bait application and then increased following the bait application, which may have been an artefact of increased human activity during the operation affecting movement of these animals.

Behavioural ecology, diet, and foraging habitat of lizards are important considerations in understanding potential pathways of exposure to rodenticides. Although we did not observe anoles or ameivas feeding directly on the placebo biomarker or toxic bait, other studies have shown direct consumption of bait by different reptile species (Merton, 1987; Merton, et al., 2002). Bait availability monitoring showed bait disappeared three days after the second bait application, thus removing a pathway of direct exposure (consumption) for ameivas and anoles. However, we anticipate that anoles were exposed to bait via indirect pathways through consumption of invertebrates feeding on bait. Few anole species are dietary specialists and most species, including the Desecheo anole, consume a wide variety of insects and fruit (Meier & Noble, 1991). The ameiva, a larger species than the anole, primarily forages on the ground where it could be easily exposed to bait through secondary pathways (e.g. ground-foraging beetles and ants that feed on bait).

Delayed response to toxicant impacts on reptiles has been previously reported. Telfair's skinks (*Leiolopisma telfairii*) on Round Island, Mauritius, showed an apparent increased mortality three to six weeks after a brodifacoum bait application (Merton, 1987) and Harper et al. (2011) estimated 4.5% mortality of the Galápagos marine iguana up to two months following rat eradication using brodifacoum. While toxicant as the cause of death was not confirmed during these events, a cautious approach suggests it be considered a risk. While our study was undertaken for approximately three weeks (22 days) after bait was dispersed, the impacts of the rodenticide could not be assessed beyond this timeframe.

This study focused on the survivorship of two reptile species because of the high conservation value of these single-island endemics. Rodenticide application risk assessments should also consider the role of lizards as prey items, and thus as potential toxin pathways to other native species. Food web models that include rodenticide introduction can inform risk assessments, including potential pathways and levels of exposure. Residue analyses can help confirm these assessments. Ultimately, risk assessments for rodent eradication operations using toxicants must evaluate the cost and benefit impacts of these efforts (i.e. negative impacts from using toxicants versus positive impacts from removing rats). Whereas reports of individual reptile mortality during rodenticide-based eradications are evident (Merton, 1987; Harper, et al., 2011) a greater body of evidence suggests that reptile populations benefit following rodent eradication (Jones, et al., 2016). Studies such as ours provide another case study to evaluate the value of island restoration efforts on reptiles. The combination of studies such as these can help managers make informed decisions about the potential negative impacts of rodenticides used during eradication operations versus the expected positive impact to native biota from the permanent removal of threats posed by invasive species.

ACKNOWLEDGEMENTS

This study was supported in part by the United States Fish and Wildlife Service (USFWS), the National Fish and Wildlife Foundation, the David and Lucile Packard Foundation, and private donors to Island Conservation. The views and conclusions contained in this document are those of the authors and should not be interpreted as representing the opinions or policies of the National Fish and Wildlife Foundation. Mention of trade names or commercial products does not constitute their endorsement by the National Fish and Wildlife Foundation. The USFWS Caribbean Islands National Wildlife Refuge Complex provided logistical support and technical assistance during the study period. Thanks to the editor and reviewers for providing insightful comments and suggestions that significantly improved this manuscript. We want to express our deepest gratitude to the field assistants from Island Conservation, USFWS and local biologists for their dedication and commitment that made these conservation efforts on Desecheo possible.

Long term rodent control in Rdum tal-Madonna yelkouan shearwater colony

P. Lago[1], J.S. Santiago Cabello[1] and K. Varnham[2]

1BirdLife Malta,57/28, Marina Court, Abate Rigord Street, Ta' Xbiex (Malta) XBX 1120. <paulolagobarreiro@gmail.com>. 2RSPB. The Lodge, Potton Road, Sandy. Bedfordshire. SG19 2DL, UK.

Abstract Rodent predation on eggs and chicks is one of the main threats to procellariiform species in the Mediterranean, where the black rat (*Rattus rattus*) and brown rat (*R. norvegicus*) have been present on many islands for centuries. The yelkouan shearwater (*Puffinus yelkouan*) is an endemic Mediterranean seabird species classified as vulnerable. Malta holds up to 10% of the global population; the largest colony, Rdum tal-Madonna (RM), protected as a Natura 2000 site, hosts around 500 breeding pairs. This colony has been monitored since its discovery in 1969. A very low reproductive success due to rat predation was noticed in the late 1990s to early 2000s. In 2007 a seasonal rodent control programme was established during the breeding season of yelkouan shearwater to reduce rat predation on eggs and chicks. Rodent control took place between 2007 and 2010 and was reviewed and continued from 2012 to 2017. Breeding success since 2007 has been higher than 80%. In two other colonies with rat presence and where rodent control did not take place, the breeding success in 2016 and 2017 was substantially lower than in the colony with the rodent control programme. The European storm-petrel (*Hydrobates pelagicus melitensis*) only breeds in rat-free areas like remote sea caves or islets around the Maltese islands. In 2014, the first breeding attempt by European storm-petrel was recorded on the Maltese mainland at RM with a chick fledging successfully for the first time in 2016. The ongoing LIFE Arcipelagu Garnija project is assessing rat predation in all Maltese yelkouan shearwater colonies in order to establish predator control in the most important yelkouan shearwater breeding sites in 2018.

Keywords: breeding success, chicks, eggs, littering, rats, seabirds

INTRODUCTION

Malta is a southern European archipelago in the Mediterranean Sea with three main islands: Malta, Gozo and Comino; and other important islets: Filfla, Saint Paul, Fungus Rock and Cominotto. Each island and islet harbours important colonies of seabirds. The archipelago lies 80 km from the south of Sicily (Italy), 284 km from the east of Tunisia and 333 km from the north of Libya. The islands cover over 315 km². Malta hosts internationally important breeding populations of procellariiforms: yelkouan shearwater (*Puffinus yelkouan*) (estimated 1370–2000 pairs, constituting up to 10% of the global population) (Metzger, et al., 2015), Scopoli's shearwater (*Calonectris diomedea*) (estimated 4,500 pairs, up to 5 % of the global population) and European storm-petrel (*Hydrobates pelagicus melitensis)* (estimated 5,000–8,000 pairs, around 50% of the Mediterranean population) (Sultana, et al., 2011).

The invasion of ecosystems by introduced species is one of the most significant sources of ecosystem change (Howald, et al., 2007) and biodiversity loss on islands (Martin, et al., 2000; Courchamp, et al., 2003). Introduction of alien rodents has been shown to have devastating effects on insular ecosystems and some rodent species can be important predators of nesting seabirds (Traveset, et al., 2009), especially procellariiforms (Imber, 1978). Rodent predation on eggs and chicks is one of the main dangers to this group of seabirds across the world (Booth, et al., 1996; Hobson, et al., 1999; Gaze, 2000; Imber, et al., 2000). Rats are associated with extinctions or declines of burrowing seabirds (Seto & Conant, 1996; Towns, et al., 2006). Rats have a severe impact on breeding success and are a major cause of seabird mortality in the world (Jones, et al., 2008; Pascal, et al., 2008).

Rats were introduced into the Mediterranean over 2000 years ago and have been present on many islands for centuries (Atkinson, 1985; Audoin-Rouzeau & Vigne, 1994; Martin, et al., 2000). Black rat (*Rattus rattus*) is the most devastating predator of seabirds in the Mediterranean (Igual, et al., 2006) and the main reason for breeding failure on some islands, for example Corsica (Thibault, 1995). Therefore, the persistence of native long-lived seabirds in the Mediterranean basin, despite the long-standing introduction of black rat on most islands, constitutes an amazing conservation paradox (Ruffino, et al., 2009).

Yelkouan shearwater is an endemic Mediterranean seabird belonging to the family Procellariidae. It is a long-lived species that lays a single egg each season in deep burrows. It has been classified as vulnerable since 2012 according to the IUCN (BirdLife International, 2016). The Maltese population of yelkouan shearwater has declined in recent years, mainly due to predation by rats, loss of breeding habitat, illegal hunting, fishing bycatch, disturbance and light and sound pollution (Sultana, et al., 2011).

The main colony in Malta situated in Rdum tal-Madonna (RM) holds around 500 breeding pairs (2 or 3% of the global population). It is a Natura 2000 site – part of the European network of protected areas. This colony is situated along 1 km of coralline limestone sea cliff. It has been monitored since its discovery in 1969 and it was noticed that the breeding success in the late 1990s to early 2000s was very low, largely due to rat predation, with very few chicks fledging (Sultana, et al., 2011). The best response to such a situation is almost always to control the alien population, either by frequently reducing their numbers, or better still, by eradicating the whole population (Courchamp, et al., 2003).

As the colony is located on the Maltese main island, eradication of rats was not feasible because it is not possible to isolate the area from rat populations found across the rest of the island. The population of rats benefits from the persistent availability of food close to the colony. Litter from recreational users in the area making barbecues and camping is compounded by the inefficient and inadequate waste disposal and collection system. Actions to increase awareness about littering between site users and authorities were carried out but no substantial improvement in the situation was observed.

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 196–199. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

In 2007, a seasonal rodent control programme was established at the site to reduce rat predation. The control programme has now been active for 11 years from 2007 to 2017. In this paper we present the results of the rodent control programme on the breeding success of the yelkouan shearwater colony. We discuss the results and lessons learnt and their applicability to other locations.

MATERIALS AND METHODS

The colony site is surrounded by the ocean on three sides, making it an ideal site for rodent control. The methodology chosen for rodent control was seasonal control using rodenticide. The most frequent rodenticide distribution method used on small islands around the world is bait stations (Howald, et al., 2007) and other projects have shown that using a permanent bait-station system is an efficient methodology to control rats (Orueta, et al., 2005; Pascal, et al., 2008). Around 90 bait stations (PROTEXX TM) were distributed over 25 ha of RM on the top of the cliff plateau and the lower part of the cliffs where yelkouan shearwaters breed (Fig.1). The bait stations on top of the cliffs create a buffer to prevent rats accessing the colony. Bait stations were placed around areas of high rat presence, for example those areas subject to littering from campers. Rodent control took place around nesting sites between February and July during the yelkouan shearwater breeding season, when eggs and chicks are most vulnerable. The bait stations were baited one to three times per month, depending on rodent activity. Each bait station contained two blocks of anticoagulant rodenticide. Between 2007 and 2015 the rodenticide used was brodifacoum 0.005% and from 2016 it was bromadiolone 0.005% to reduce the risk of secondary poisoning. The bait blocks were threaded on to metal skewers that were clipped in place, to prevent them falling out of the stations even if they were shaken violently.

Every time the bait stations were checked, data were collected on the amount of rat sign (droppings and rat teeth marks in the wax bait blocks), non-target species sign like mice, shrews and insects taking the bait, and the number of bait blocks replaced. The area baited was checked for signs of dead rats and primary or secondary poisoning of non-target species. Rat presence was calculated as the number of bait stations with rat teeth marks on the bait divided by the total number of bait stations.

Table 1 Breeding success (% of chicks fledged per eggs laid) of yelkouan shearwater at Rdum tal-Madonna between 2007 and 2017.

Year	No. of nests	Breeding success
2007	6	83%
2008	12	92%
2009	11	91%
2012	16	94%
2013	32	88%
2014	25	88%
2016	24	88%
2017	38	84%

Table 2 Breeding success (% of chicks fledged per eggs laid) of yelkouan shearwater in 2016 and 2017 in Rdum tal-Madonna (rodent control) and St. Paul's Island and Majjistral (no rodent control).

Colony	Year	No. of nests	Breeding success
RM	2016	24	88%
St. Paul's Is	2016	9	67%
Majjistral	2016	12	33%
RM	2017	38	84%
St. Paul's Is	2017	9	11%
Majjistral	2017	11	55%

RESULTS

Rodent control took place between 2007 and 2010, after which it was reviewed and then continued from 2012 to 2017. After the first season of rodent control in 2007, the occurrence of eggs and chicks depredated by rats dropped dramatically and there have been few recorded signs of rat predation during the subsequent 11 years. Breeding success has been very high since rodent control started (Table 1), with a mean of 88 % (averaged over the eight years for which data are available).

In 2016 and 2017, the breeding success (chicks fledged per eggs laid) in RM (88% and 84%, respectively) was much higher than in two other colonies where rats were known to be present but no rat control took place, St. Paul's Island (67% and 11%, respectively) and Majjistral Park (33% and 55%, respectively) (Table 2).

In RM, rat activity varies throughout the yelkouan shearwater breeding season. Rats are regularly present from February until July. Rat activity is reduced after the first month of rat control in February, the peak of activity is in May and then a small upturn in June (Fig. 3). Rodent activity over the period 2012–2017 (data available for four years) shows a decrease in rat presence in recent years. No signs of secondary poisoning have been found in the study period.

After the first season of rat control in 2007, European storm-petrels were regularly seen in RM (Borg, et al., 2010). In 2014 the first breeding attempt was recorded and in 2016 and 2017 chicks fledged successfully. The data collected during 2014–2017 suggest European Storm-petrel is establishing a breeding colony in RM.

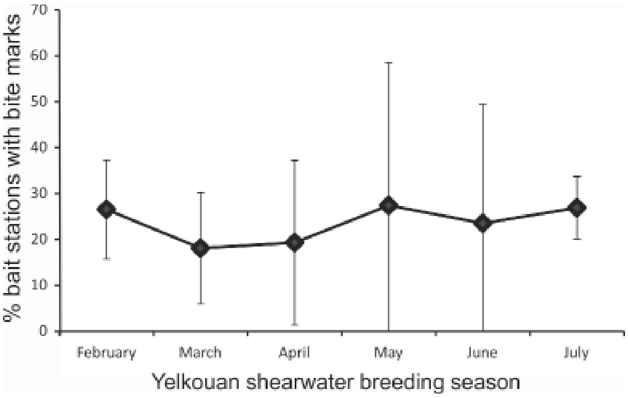

Fig. 2 Proportion (%; with mean and standard deviation) of bait stations with rodent bite marks throughout the yelkouan shearwater breeding season from February to July (for years 2012, 2015, 2016, 2017 combined).

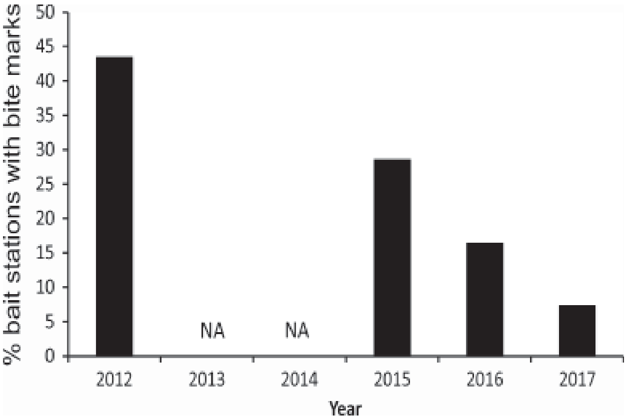

Fig.3 The percentage of bait stations with rodent bite marks by year; 2012, 2015, 2016 and 2017.

DISCUSSION

Seasonal rat control in seabird colonies where eradication is not feasible is an effective way to reduce rat predation and increase reproductive success (Imber, et al., 2000; Martin, et al., 2000; Jouventin, et al., 2003; Orueta, et al., 2005; Igual, et al., 2006; Pascal, et al., 2008). In many cases, the removal of the alien invasive species is followed by a fast and often great recovery of the damaged local populations (Courchamp, et al., 2003), even allowing new colonies of other species to become established, as has been seen at RM (Malta). However, only intensive and constant long-term poisoning will control rats satisfactorily (Jouventin, et al., 2003).

The increase in the reproductive success observed during recent years in the yelkouan shearwater colony in RM is correlated with the lower rat activity as a result of rodent control programme. Rat activity varies throughout the yelkouan shearwater breeding season. The peak of activity in May is related to the increase in ambient temperature and also to the start of camping activity in the area. The presence of campers increases littering (i.e. supplying food for rodents) which is the likely reason for the increase in the rat population around the colony. The general decrease of rat presence in 2016 and 2017 may be related to the very dry weather in these two years, but possibly also to increased public awareness about littering. On 30 April 2017, an intensive clean-up by more than 100 volunteers was organised in the area.

The rodent control programme showed its effectiveness at increasing the breeding success of yelkouan shearwater and allowed the establishment of a new European storm-petrel population. The main yelkouan shearwater colony locations are situated on the main islands of Malta and Gozo making the eradication of rats not possible. Rat eradication could only be feasible in the islands of Comino, Cominotto and Saint Paul that hold smaller colonies. Ongoing rodent control programmes are therefore needed in the main colonies to secure yelkouan shearwater populations in the archipelago and to improve their situation. Building on the lessons learnt and the success of the rodent control programme in RM, the current EU-Life Arċipelagu Garnija project LIFE14 NAT/MT/991 is assessing predation by rats in all Maltese yelkouan shearwater colonies in order to establish predator control in the most important sites in 2018 and secure the main colonies across Malta. During the study period, no evidence of secondary poisoning was found but, in any case, from 2016 the bait was changed from brodifacoum to bromadiolone that has less risk of secondary poisoning. Less toxic bait, such as first generation anticoagulants, are not available in Malta. In order to reduce the amount of anticoagulant used in the new rat control programmes, the current project is testing methodologies to replace or combine anticoagulant baiting with auto-reset mechanical traps and carrying out activities to increase awareness about littering among site users.

ACKNOWLEDGEMENTS

We thank B. Metzger, N. Barbara, J. J. Borg, A. Raine, H. Raine, G. Meier, and all staff and volunteers working on rat control over the last 11 years. The rodent control programme was funded throughout the years by the EU-Life Yelkouan Shearwater Project LIFE06 NAT/MT/000097 from 2007 till 2010, MEPA and HSBC. It is currently part of the EU-Life funded Arċipelagu Garnija project LIFE14 NAT/MT/991, co-funded by the Maltese Ministry for the Environment, Sustainable Development and Climate Change (MESDC). All the activities were carried out under MEPA/ERA permits.

Seasonal variation in movements and survival of invasive Pacific rats on sub-tropical Henderson Island: implications for eradication

Abstract Invasive rodents are successful colonists of many ecosystems around the world, and can have very flexible foraging behaviours that lead to differences in spatial ranges and seasonal demography among individuals and islands. Understanding such spatial and temporal information is critical to plan rodent eradication operations, and a detailed examination of an island's rat population can expand our knowledge about possible variation in behaviour and demography of invasive rats in general. Here we investigated the movements and survival of Pacific rats (*Rattus exulans*) over five months on sub-tropical Henderson Island in the South Pacific Ocean four years after a failed eradication operation. We estimated movement distances, home range sizes and monthly survival using a spatially-explicit Cormack-Jolly-Seber model and examined how movement and survival varied over time. We captured and marked 810 rats and found a median maximum distance between capture locations of 39 ± 25 m (0–107 m) in a coastal coconut grove and 61 ± 127 m (0–1,023 m) on the inland coral plateau. Estimated home range radii of Pacific rats on the coral plateau varied between 'territorial' (median: 134 m; 95% credible interval 106–165 m) and 'roaming' rats (median: 778 m; 290–1,633 m). The proportion of rats belonging to the 'roaming' movement type varied from 1% in early June to 23% in October. There was no evidence to suggest that rats on Henderson in 2015 had home ranges that would limit their ability to encounter bait, making it unlikely that limited movement contributed to the eradication failure if the pattern we found in 2015 is consistent across years. We found a temporal pattern in monthly survival probability, with monthly survival probabilities of 0.352 (0.081–0.737) in late July and 0.950 (0.846–0.987) in late August. If seasonal variation in survival probability is indicative of resource limitations and consistent across years, an eradication operation in late July would likely have the greatest probability of success.

INTRODUCTION

Eradications are a powerful and frequently used management option to counter the native biodiversity loss caused by invasive species on islands (Jones, et al., 2016). Planning for an eradication requires a fundamental understanding of the ecology and movement characteristics of the target invasive species (Zavaleta, 2002; Keitt, et al., 2015). Among the most widespread invasive species on islands are three species of rat (*Rattus rattus*, *R. norvegicus*, *R. exulans*), which now occur on >80% of the world's island groups (Atkinson, 1985; Jones, 2010). Rat eradications have been successfully completed on hundreds of islands (Howald, et al., 2007), but eradications on tropical islands, where a lack of seasonal fluctuation in resource abundance allows rodents to reproduce throughout the year, still have a lower success probability than eradications on temperate islands (Holmes, et al., 2015; Keitt, et al., 2015). Detailed information on rat movements and demography from tropical islands should therefore benefit eradication planning on tropical islands (Keitt, et al., 2015).

Rodent eradications on islands larger than 100 ha are generally conducted by aerially distributing cereal-based toxic bait pellets across the island, and are only successful if every individual rodent has access to sufficient bait within its home range to consume a lethal dose of toxin (Cromarty, et al., 2002; Howald, et al., 2007; Broome, et al., 2014; Holmes, et al., 2015). Hence, a better understanding of the size of home ranges can inform the density at which bait pellets need to be dispersed on the ground. Movements of invasive rodents on islands vary by habitat, population density, food availability, individuals' age and sex (Bramley, 2014a; Ringler, et al., 2014; Harper, et al., 2015), but more information on the size of movements and their variation over time of year could contribute to eradication planning on islands.

Besides ensuring each individual has access to a sufficient quantity of bait, rodent eradications are also more likely to succeed if they are timed to coincide with a predictable period of rodent stress (e.g. mortality). On temperate islands, mortality occurs during a predictable seasonal shortage in resource availability during autumn or winter, and therefore provides a natural time window for an eradication operation when rodents are more likely to switch to palatable poison baits (Howald, et al., 2007; Russell & Ruffino, 2012). On tropical islands, with less-defined seasonality and irregular periods of resource limitation, there is still very little information on how the survival of rodents varies within a year (but see Tamarin & Malecha, 1971). Additional information on seasonal variation in survival of rodents on tropical islands can inform when an eradication operation would have the highest probability of success and therefore aid the planning of an eradication operation (Howald, et al., 2007; Holmes, et al., 2015; Keitt, et al., 2015).

Here we use data from a large spatial capture-recapture programme and conventional radio-tracking to investigate the movements of invasive Pacific rats (*R. exulans*) on an uninhabited sub-tropical island (Henderson) in the South Pacific. An eradication operation on this island in 2011 failed to kill all individuals. Among the reasons that can cause eradication failure, insufficient bait toxicity could be excluded due to follow-up experiments (Amos, et al., 2016). However, two further potential causes, namely that not all rats had access to bait and that the eradication was poorly timed and coincided with high survival, have not been investigated so far. Our study was designed to provide knowledge to better understand the 2011 eradication failure and improve the probability of success of a future eradication attempt. We estimate movement distances and home range sizes using mark-recapture and radio-tracking

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 200–208. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

data and evaluate if the smallest rodent home ranges would contain a sufficient quantity of bait pellets based on bait distribution rates used during the eradication attempt in 2011. We further estimate survival of rats over a five-month period, examine temporal variation in their monthly survival probability, and assess whether the timing of the failed operation in 2011 was appropriate.

METHODS

Study area

Henderson Island (24º22′ S, 128º20′ W) is a flat, raised coral atoll of 4,309 ha in the sub-tropical Pacific Ocean with two distinct habitats – a central plateau roughly 25 m above sea level (4,290 ha), and a sandy beach area with a vegetated margin (hereafter referred to as 'embayment forest', 14 ha). Henderson Island has a sub-tropical climate with erratic rainfall patterns, and there are no permanent freshwater bodies on the island (Spencer, 1995; Weigelt, et al., 2013). The plateau substrate is fossilised coral with uniform, dense native vegetation consisting mostly of *Pandanus tectorius*, *Xylosma suaveolens* and *Psydrax odorata* (Waldren, et al., 1995). The beach and embayment forest areas have a sandy substrate with a mixed shrubby vegetation and small stands of introduced coconut (*Cocos nucifera*) (Paulay & Spencer, 1989; Waldren, et al., 1995).

Pacific rats were introduced to Henderson Island by Polynesians several hundred years ago (Steadman & Olson, 1985), and currently have adverse effects on native biodiversity on Henderson Island (Brooke, et al., 2010; Dawson, et al., 2015). In late August 2011, an operation using the aerial distribution of cereal-based pellets containing 20 µg/g of the toxin brodifacoum was carried out to eradicate all Pacific rats from Henderson Island. Although the baiting operation met best practice standards, had no spatial gaps in bait distribution, used bait pellets containing a sufficient amount of toxin (Torr & Brown, 2012), and used bait application densities well beyond those needed to overcome estimated hermit-crab consumption (Cuthbert, et al., 2012), the eradication operation was unsuccessful and 60-80 individual rats were predicted to have survived (Amos, et al., 2016). Rat populations recovered within 2–4 years (Bond, et al., 2019) and were at an unknown stage of expansion or fluctuation during 2013 and 2015.

Rat live trapping

To obtain a robust estimate of rat survival probability, and to document rat movements over five months, we implemented a spatial capture-mark-recapture programme in 2015. Rats were live-trapped on the plateau from 28 May to 16 October 2015 during seven primary sessions of 10 trapping nights each, with a window of 8–15 days with no trapping between primary sessions. This time frame was chosen because food availability for rats was assumed to be lower during the 'winter' months on Henderson than at other times of the year (Spencer, 1995; Brooke & Towns, 2008). In the embayment forest, rats were live-trapped between 1 August and 19 September 2015 during three primary sessions of 6–10 trapping nights each.

On the plateau we established a trap network placed along 3 km of cleared path (Fig. 1). Traps were arranged at distances from 3–20 m at 343 locations, with a different subset of trap locations used during each primary session due to gradual progression of trail clearance. In the embayment forest, we established a grid of 63 traps arranged in an oblique rectangular configuration (Fig. 1) with traps spaced 10 m apart. Traps were placed on the ground, marked with a unique number, and locations were recorded to within 5 m using a hand-held GPS device.

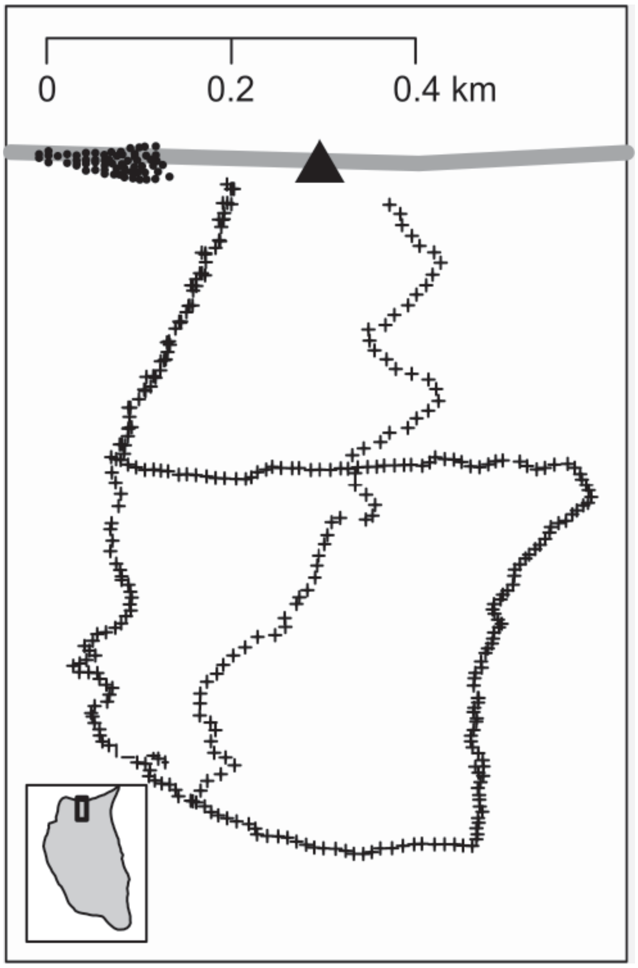

Fig. 1 Map of the trapping network used on Henderson Island in 2015. Black triangle is the research camp, the grey line is the upper margin of the beach, + indicate trap locations on the coral plateau, and black dots indicate trap locations in the embayment forest.

We used two different live trap types, a small metal box (7.6 × 8.9 × 22.9 cm, LFA Folding Trap, H. B. Sherman Traps Inc., Tallahassee, Florida, USA), and a metal cage (13 × 16 × 27 cm, Metal Rat Cage Trap, Key Industries, Auckland, New Zealand). Before the first primary session in each habitat, traps were deployed, but not opened, for approximately five days to allow rats to overcome neophobia (Yackel Adams, et al., 2011; Russell, et al., 2015). For each night in each ten-day trapping period, traps were baited with a small (1 × 1 cm) cube of fresh coconut between 1600–1800 h local time (UTC-8), and checked the following morning between 0800–1000 h.

Each captured rat was fitted with a uniquely numbered ear tag (size 1005-1; National Band & Tag Company, Newport, Kentucky, USA), and the rat was released next to the trap. We recorded the trap location for each capture, whether female rats showed signs of lactation or pregnancy, and whether traps were available to capture rats or had been de-activated (e.g., by crabs). Upon their first capture, rats were sexed by examination of external genitalia, weighed using a spring balance (± 1 g; Pesola AG, Schindellegi, Switzerland), and their body and tail lengths were measured to the nearest 1 mm using a metal ruler (Cunningham & Moors, 1996).

In November 2015, after the mark-recapture effort, we also conducted lethal snap-trapping along a subset of the locations of the live-trap locations on the plateau. This lethal trapping was designed to provide definitive age and sex classifications and body measurements for as many tagged rats as possible.

Radio-tracking

To provide an alternative estimate of movement range not dependent on the recapture of a rat, we radio-tracked rats that were captured on the plateau in July 2013 using the same small metal box traps as mentioned above. We fitted radio-collars (pipAg393, 2.6 g, Biotrack, Wareham, UK) attached to plastic collars with rubber tubing to each rat. After fitting the collar, rats were placed back in the trap and monitored for five minutes; adjustments were made to the collar if necessary before the rat was released at the site of capture. The capture location, sex, reproductive status (males with or without descended testes; females with or without a perforated vagina) and mass were recorded for all radio-tracked rats as described above.

After release, rats were located at least twice daily during daylight hours using a three-element Yagi antenna and Telonics TR-4 receivers with each radio-collar separated by frequency. Locations were either recorded by homing using a hand-held GPS device with an accuracy of <5 m or estimated through bisection by using distance and bearing from two observation points with an accuracy of ca. 25 m (Kenward, 2001).

Calculation of movement distances

We first calculated the straight-line distance between trap locations for subsequent captures of individual rats. These distances are a conservative estimate of rats' movement distances, because they assume an unrealistic direct line of travel from one trap to the next. We summed all distances between subsequent captures and divided the total travel distance calculated for each individual by the number of captures to provide an overall estimate of mean distance moved between two capture events that is not dependent on the number of captures (Püttker, et al., 2012). We also calculated the observed range length, defined as the maximum distance between any two capture locations for a given individual (Stickel, 1954; Lindsey, et al., 1973). We present results as median ± standard deviation and range.

Analysis of home range size and survival

To estimate rat survival while taking movements into account, we used a spatially-explicit Cormack-Jolly-Seber (CJS) model adapted from similar models (Gardner, et al., 2010; Raabe, et al., 2013; Royle, et al., 2016). We considered each primary session as a capture occasion and reduced binomial capture data from trapping nights to counts of each individual at each trap location during a given primary session because robust-design formulations of the spatial CJS model (Ergon & Gardner, 2014) did not converge. We removed all rats that were captured only once from the analysis, because these transients do not provide any information on movement or survival probability (Pradel, et al., 1997), and we draw no inferences from estimated capture probabilities. We also implemented a non-spatial CJS survival model following Russell & Ruffino (2012), to compare to the spatial model. This model yielded similar mean estimates and temporal variation in survival, suggesting the spatial model results are valid, but with much greater precision by not incorporating the large variance in rat movements (ESM Fig. S1). Understanding and incorporating rat movements is critical for distinguishing survival from movement in apparent survival models (Gilroy, et al., 2012; Schaub & Royle, 2014), especially for inferring potential factors in eradication failure, and we therefore present only the results of the spatial CJS model.

Our spatial CJS model assumed that rat home ranges were circular, but that the estimated centre of a rat's home range could vary spatially based on an individual-specific correlated random walk parameter (Royle, et al., 2016), which effectively allowed rats to shift their activity centre over time. We also assumed that capture probability of rats at a given trap followed a negative exponential function based on the distance of the rat's home range centre to the trap (Ergon & Gardner, 2014; Royle, et al., 2016), and that the shape of this capture probability function varied over time and among individuals. Because exploratory analysis of rat movements indicated that neither individual nor environmental covariates could adequately capture the variation in rat movement, we assumed that the shape of the capture probability function originated from two different statistical distributions: one distribution reflected 'territorial' rats and was specified as a normal distribution with a mean of $\sigma = 30$, which corresponds to a typical home range radius for insular rats (Bramley, 2014b; Ringler, et al., 2014; Harper, et al., 2015). The other distribution reflected 'roaming' rats with a uniform distribution between $\sigma = 60$ – 400, allowing a movement radius of 1,000 m, which has been recorded for Pacific rats in other studies (Wirtz, 1972; Lindsey, et al., 1973). For each individual rat, we allowed the model to select the home range radius parameter belonging to either the 'territorial' or 'roaming' movement type, and we report the proportion of males and females that were estimated to belong to each type.

We estimated rats' survival probability between primary sessions and assumed that survival varied over time. Because the interval among primary sessions was not constant, we calculated the interval as the time difference between the mid-point of subsequent primary sessions (range: 17–25 days) and converted survival probabilities to monthly survival probabilities to allow a direct comparison among different primary sessions. In a CJS model the probabilities of capture and survival are confounded for the last trapping occasion; to allow inference on survival probability up to our last live-trapping occasion in October 2015, we included data from a final additional session of kill trapping in November 2015 in the model (sensu Nathan, et al., 2015), and allowed for a different capture probability for that trapping period. Because rat survival may vary by sex and may depend on food availability (Russell & Ruffino, 2012; Ringler, et al., 2014), we included individual sex and the Normalised Difference Vegetation Index (NDVI) as covariates affecting survival probability. NDVI is a measure of vegetation 'greenness' derived from remote sensing imagery and can serve as a useful proxy for rat food availability (Pettorelli, et al., 2011; Pettorelli, et al., 2014). We downloaded NDVI for Henderson Island at a 250 m resolution from NASA Earth Data (https://daacmodis.ornl.gov/cgi-bin/MODIS/GLBVIZ_1_Glb/modis_subset_order_global_col5.pl), and averaged NDVI over 32 days centred on the mid-point of each survival period to reflect the food availability for rats during the period over which survival was estimated. We used diffuse priors for covariate effects on survival, but used informative priors for daily survival probabilities that were based on previous studies (Tamarin & Malecha, 1971; Moller & Craig, 1987; Roberts & Craig, 1990). Time-specific priors for daily survival probability were drawn from a random uniform distribution between 0.9 and 1.

We fitted the robust design CJS model in JAGS v 3.4.0 (Plummer, 2012) using the 'jagsUI' package (Kellner, 2016) called from R 3.2.5 (R Core Team, 2016). We ran three Markov chains each with 30,000 iterations, discarded the first 7,000 iterations as adaptation and burn-in, and tested for convergence using the Gelman-Rubin diagnostic (Brooks & Gelman, 1998) as well as visual representations of all parameters of interest. We report posterior mean estimates and 95% credible intervals for survival probability and the spatial shift of home range centres among primary capture sessions. Code to repeat the analysis can be downloaded from: https://github.com/steffenoppel/henderson/blob/master/Oppel_etal_SECR_ANALYSIS_and_DATA.zip.

To estimate a 'home range radius' from the shape of the spatial detection function, we assumed a circular exponential distribution for individual home ranges, and calculated an approximation of the home range radius that would encompass 95% of an individual's territory using the function 'circular.r' in R package secr 2.10.2 (Efford, 2016). We converted this estimate of home range radius to an estimate of home range size using standard geometry ($A = \pi r^2$). This estimate of space use, although not equivalent to a home range estimate obtained from telemetry, allowed us to compare the space use inferred from our spatial trapping approach to a similar metric estimated from radio-tracking to compare the conclusions from each approach.

To provide a comparable estimate of home range size from radio-tracking data, we first calculated the minimum convex polygon (MCP) for each tracked animal and then calculated the 95% kernel utilization distribution using the 'kernelUD' function of the 'adehabitatHR' package in R (Calenge, 2006) for all rats with >10 position fixes after capture. We parameterized our kernel density estimation model using a grid size of 1000, and a smoothing parameter of h = 10 m to avoid overestimation of home ranges due to large kernels around single locations.

Adequacy of cereal bait distribution during eradication attempt

To assess how many bait pellets would have been available to rats, we calculated the approximate number of bait pellets that would have been available in minimum home range sizes of rats during the eradication operation in 2011 based on mean bait application rates. In 2011, bait was distributed at 40–60 kg/ha in the embayment forest and 10 kg/ha on the plateau during the first of two bait applications. Given that a bait pellet weighs ca. 1.8 g, there were between 22,000 and 33,000 pellets/ha available in the embayment forest, and 5,500 pellets/ha on the plateau. For each of the home range estimates from radio-tracking and spatial re-capture, we multiplied the estimated size of the minimum home range area by the density of pellets to infer how many bait pellets would have been accessible to individual rats.

RESULTS

Rat movement

We captured and marked a total of 810 rats, of which 580 were recaptured at least once, yielding a total of 4,920 capture events at 396 unique trap locations. On the plateau, we captured 727 individuals of which 524 were recaptured at least once; in the embayment forest we captured 86 individuals of which 56 were recaptured at least once; only three individuals were captured in both habitats.

The median movement distance between subsequent captures was 17 ± 19 m (range: 0–153 m) in the embayment forest and 23 ± 70 m (0–970 m) on the plateau (Table 1). The median maximum distance between subsequent capture locations averaged across all individuals was 31 ± 23 m in the embayment forest and 54 ± 105 m on the plateau. The observed range length was 39 ± 25 m (0–107 m) in the embayment forest and 61 ± 127 m (0–1,023 m) on the plateau. The total minimum movement distance of individuals summed across all their capture events was 83 ± 100 m (range: 0–387 m) in the embayment forest and 140 ± 617 m (0–8,022 m) on the plateau; however, due to the unequal trapping effort in both time and space these basic movement distances are not directly comparable between the two habitats. Males showed generally longer and more variable movements than females in both habitats, but this effect was more pronounced on the plateau where much longer movements could be recorded by the larger trap network (Table 1). There was very little difference among females that were recorded with or without signs of current reproduction (Table 1). Of the rats recaptured at least once, 8.4% were only captured in one trap location. With the exception of one lactating female which was captured nine times in the same trap location, all rats that were captured >5 times moved between at least two different trap locations.

Table 1 Median and standard deviation (sd) straight-line movement distances (m) and observed range lengths of Pacific rats between live capture events during a spatial mark–recapture study on Henderson Island in May–October 2015. Note that the trapping effort in the two habitats had a different spatial and temporal extent (see Fig. 1 for spatial extent of trap locations). 'breed' females were classified if they had obvious signs of lactation or pregnancy.

Seasonal variation in survival and space use

Based on the capture and recapture of 540 individual rats on the plateau (including recapture in snap traps in November), we found seasonal variation in monthly survival probability (Fig. 2), but no evidence that survival was influenced by sex (β = -0.15; 95% credible interval -0.43–0.12) or NDVI (β = 0.44; -0.87–1.73). In June and early July, the median monthly survival probabilities of Pacific rats on the plateau were 0.794 (0.306–0.967) and 0.781 (0.471–0.933), respectively, but dropped to 0.353 (0.081–0.737) and 0.636 (0.488–0.763) in late July and early August, respectively (Fig. 2). Remaining survivors had very high survival in late August (0.950; 0.846–0.986) and September (Fig. 2), despite persisting low NDVI (Fig. S2). Similar estimates were obtained from 60 individual rats in the embayment forest, with median monthly survival probabilities of 0.361 (0.054–0.907) in early August and 0.864 (0.466–0.995) in September.

The survival estimates had very low precision due to the potential for confounding emigration, because during the times of lower mean survival probability, a larger number of rats appeared to exhibit longer movements. Rat movements were captured by two frequency distributions (Fig. 3), with the majority of rats (79.1%) belonging to a ‘territorial’ type that exhibited home range radii between 100 and 200 m, and a smaller proportion (19.9% of males, 22.0% of females) belonging to a ‘roaming’ type with highly variable and occasionally very long-distance movements (Fig. 3). The proportion of captured rats belonging to the roaming type increased from 0.8% in June to 13.8% in late July (Table 2). In the embayment forest, we estimated only marginally smaller home range radii as on the plateau in early August (Table 2).

Besides large movements around a central point in their territory, our model also indicated that, for rats that were captured in two subsequent primary sessions, the central point of their activity shifted by a median of 50 m (5–290 m) between early and late August, and by a median of 92 m (4–378 m) between September and October (Fig. 4).

Home range sizes estimated from telemetry

In 2013, we successfully tracked 19 rats (9 females, 10 males) between 1 July and 24 August with body mass ranging from 29 to 107 g (median: 71 g, SD: 32 g). The median 50% utilization distribution (the core home range) was 0.095 ± 0.08 ha (range 0.05–0.30 ha), and the 95% utilization distribution (UD) was 0.55 ± 0.37 ha (range 0.21–1.58 ha). The minimum convex polygon home range was more variable with a median of 0.36 ± 0.86 ha (range 0.003–2.99 ha). Rats used vegetation in the canopy or sub-canopy during less than 20% of re-locations. There was no relationship between the number of days a rat was tracked (range: 7–54 days) and the size of its home range (MCP: p = 0.11; 95% UD: p = 0.31). Thus, the estimates derived from radio-tracking suggested much smaller rat home range areas than those derived from spatially-explicit mark-recapture models, which ranged from 2.88 to 931.6 ha for territorial rats on the plateau, and from 0.11 to 53.6 ha in the embayment forest, assuming that these rats used a circular home range.

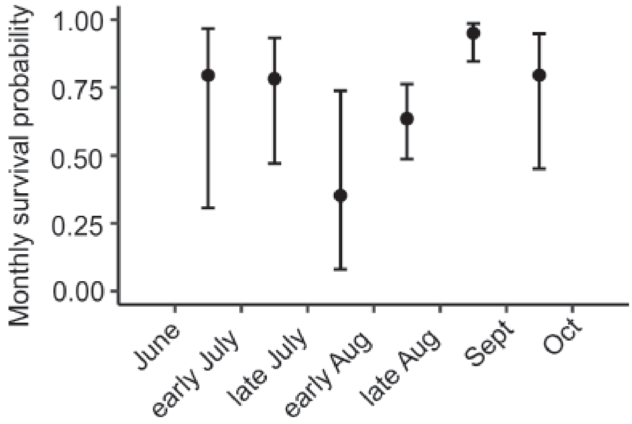

Fig. 2 Mean (95% credible interval) monthly survival probability of Pacific rats on Henderson Island between seven primary trapping sessions over five months in 2015 estimated from a spatial Cormack-Jolly-Seber model. Note that survival probability is scaled over a 30-day period due to unequal time intervals between primary trapping sessions.

Adequacy of cereal bait distribution during the 2011 eradication attempt

The lowest confidence limit for an estimated home range for any season based on our spatial capture data was 2.88 ha on the plateau and 0.11 ha in the embayment forest.

Table 2 Home range radius (m) of two different behavioural types of Pacific rats on the coral plateau and in the embayment forest of Henderson Island between June and October 2015, estimated from a spatial mark–recapture model. Median estimated home range radius and lower (lcl) and upper (ucl) 95% credible limits are given in m. ‘prop’ indicates the proportion of captured rats in a 10-day trapping session that belonged to one of the behavioural types. Roaming rats could not be detected in the embayment forest.

		Residential rats				Roaming rats			
		prop	median	lcl	ucl	prop	median	lcl	ucl
Plateau	June	0.99	135	107	162	0.01	399	290	584
	early July	0.91	132	103	161	0.09	776	223	1,659
	late July	0.86	133	104	162	0.14	866	279	1,725
	early Aug	0.89	135	107	165	0.11	1,038	307	1,767
	late Aug	0.93	138	110	167	0.07	1,229	619	1,774
	Sept	0.88	137	110	171	0.12	688	150	1,579
	Oct	0.77	132	102	171	0.23	724	293	1,568
Embayment forest	early Aug		96	37	228				
	late Aug		137	36	377				
	Sept		142	34	382				

Home ranges of this size would result in 15,988 toxic bait pellets being available within a rat's home range on the plateau, and 2,456 in the embayment forest. Based on radio-tracking, where the smallest 95% UD was 0.21 ha, 1,175 pellets would have been available in a rat's home range on the plateau, and 4,700 pellets in the embayment forest.

DISCUSSION

We demonstrated that invasive Pacific rats on Henderson Island exhibited substantial individual and temporal variation in their movement and survival over a five-month period. We found no evidence to suggest that rats had home ranges that would have limited their ability to encounter bait if bait was distributed with a density similar to the 2011 eradication attempt. Indeed, the movements and home range estimates that we obtained were considerably higher than those of any other published study on the same species (Table 3), including populations that have been eradicated (Bramley, 2014b). The timing of the failed eradication operation in mid/late August 2011 also appears to have been at a time of the year where we recorded naturally low survival in 2015, and the seasonal timing of the operation was likely appropriate if conditions in 2011 followed a similar phenology as in 2015 (Fig. S2).

Monthly survival probability of Pacific rats varies between 0.40 and 0.72 (Tamarin & Malecha, 1971; Moller & Craig, 1987; Bunn & Craig, 1989), with an expected life span around 8–10 months (Harrison, 1956;

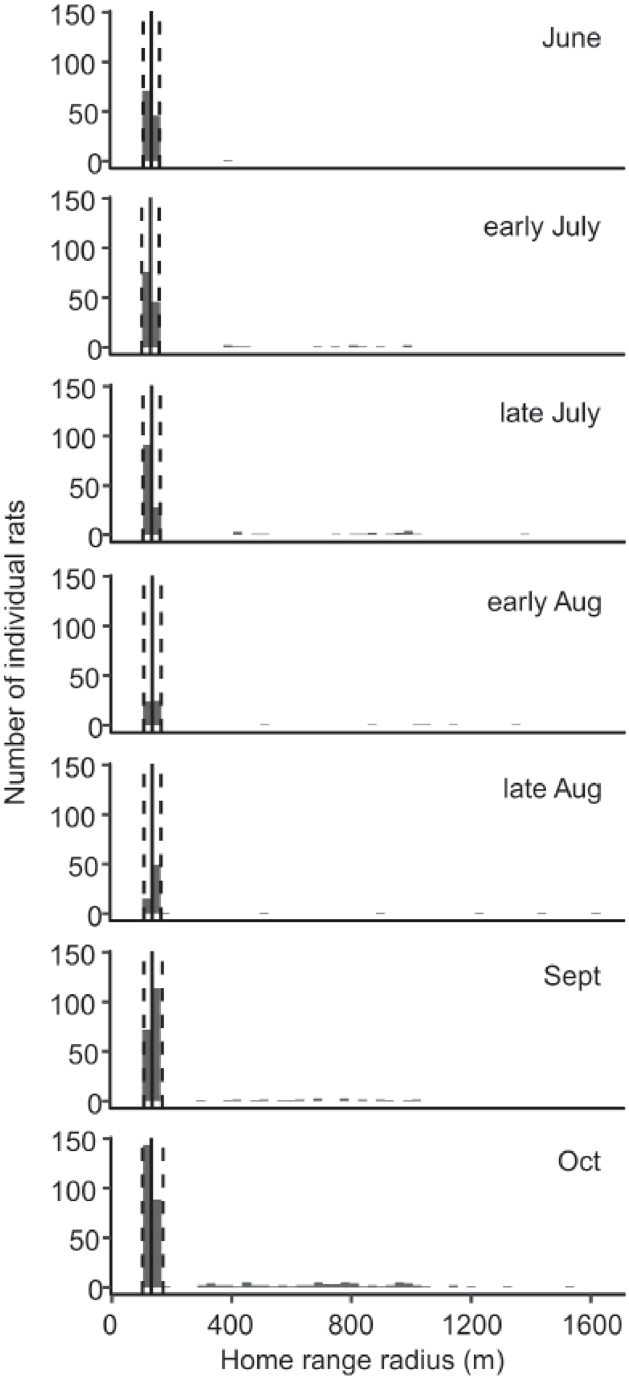

Fig. 3 Histogram of the number of individual Pacific rats having a home range of a radius estimated from a spatial Cormack-Jolly-Seber based on mark–recapture data from the coral plateau on Henderson Island during seven primary trapping sessions in 2015. Vertical lines indicate the population mean (solid) and 95% credible interval (dashed) home range radius.

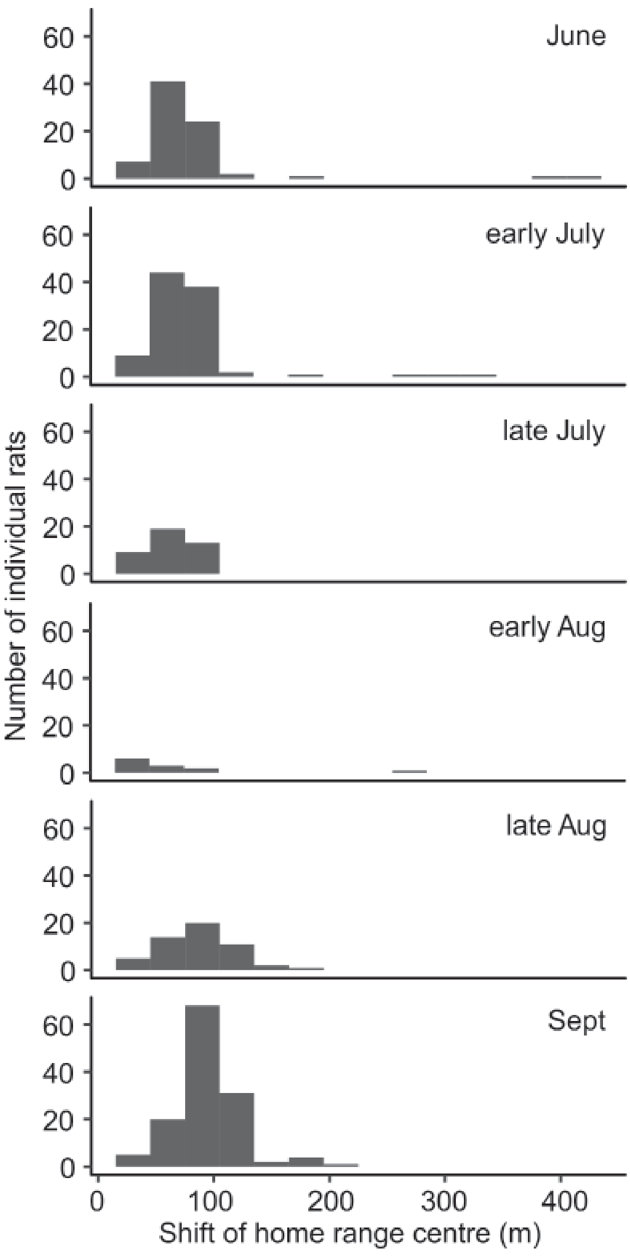

Fig. 4 Frequency of displacement distances of activity centres of male and female Pacific rats on the interior coral plateau of Henderson Island between seven primary trapping sessions over five months in 2015 estimated from a spatial Cormack-Jolly-Seber model.

Bourliere, 1959). We estimated broadly similar median monthly survival probabilities of 0.36–0.90 on Henderson Island. However, previous estimates were mostly based on raw recapture rates and did not account for recapture probabilities, and our slightly higher estimates of survival in June, early July, and late August may be due to our model accounting for low recapture probability. A higher survival probability of Pacific rats on Henderson Island might also be expected given the absence of larger competitors (*R. rattus* or *R. norvegicus*).

There was temporal fluctuation in survival probability of Pacific rats in other tropical (Tamarin & Malecha, 1971) and temperate island populations (Moller & Craig, 1987; Bunn & Craig, 1989), and we found similar short-term variability in survival on Henderson Island. We currently do not understand what may have caused the temporal decline in survival probabilities in July and August, and whether such a reduction occurs predictably every year in response to regular environmental events. As a sub-tropical island, Henderson Island experiences only moderate fluctuations in temperature and day length, which are unlikely to lead to the same predictable population fluctuations as observed on temperate islands (Russell & Holmes, 2015). The changes in both survival and movement within our five-month study period on Henderson may have reflected a period of resource shortage from late July to September that may have induced higher mortality and emigration as a larger proportion of rats belonged to the 'roaming' movement type. Assuming that the reduced survival that we observed in 2015 was caused by resource limitation (e.g. Russell & Ruffino, 2012), and that fluctuations in resource availability and survival are similar among years (Fig. S2), an operational timing in July or early August may maximise the chances of eradication success.

Our spatial mark-recapture data on the plateau, where traps were up to 1.5 km apart, revealed many long movements by rats. These movements matched or exceeded the previously estimated maximum travel distance of 1,097 m or home range estimate of 3 ha for Pacific rats (Lindsey, et al., 1973; Nass, 1977; Lindsey, et al., 1999; Clapperton, 2006; Scheffler, et al., 2012), and were similar to movements typically found in the much larger Norway rat (*R. norvegicus*) (Clapperton, 2006; Bramley, 2014b). Despite some long movements that we recorded, the extrapolated 'home range areas' from our spatial capture data are possibly biased high, because these extrapolations are based on the assumption that rats occupy a circular home range, which may not be the case (Nass, 1977; Lindsey, et al., 1999; Clapperton, 2006). In particular, our trails may have affected rat movement by providing highly nutritious and palatable coconut bait in traps that is otherwise not available on the plateau. However, our trails were characterised by an absence of vegetation between 30 to 250 cm above ground, and probably did not materially affect the movement ability of rats on the ground. Nonetheless, the maximum estimates of home range area that we provide must be considered with caution, as the areas actually exploited by rats may be significantly smaller than the assumed circular radius range.

Based on our estimates of movement behaviour from radio-tracking in 2013 and spatial mark-recapture in 2015, individual rats would have theoretically encountered hundreds to thousands of bait pellets in their typical home range, which would likely be sufficient for them to ingest a lethal dose even if crab consumption gradually reduced bait density over time (Cuthbert, et al., 2012). We therefore consider it unlikely that the eradication failed because individual rats did not have access to a sufficient quantity of toxic bait, but uncertainty remains with respect to certain life stages (e.g. nursing female rats and freshly weaned pups): the number of rats surviving the 2011 operation was very small, constituting <0.2% of the estimated rat population (Amos, et al., 2016). An eradication operation may fail if only a very small number of rats exhibit no movement and would therefore not encounter a sufficient quantity of bait. Of the 810 rats that we captured in 2015, 28% were never recaptured, and of those that were

Table 3 Summary of home range size (ha) estimates of Pacific rats (*Rattus exulans*) on subtropical and tropical islands derived from either radio tracking (TR) or spatial capture–mark–recapture (CMR); type of estimate refers to minimum convex polygon (MCP) or spatially-explicit capture recapture (SECR) and indicates what measure of uncertainty (standard deviation, SD; range) is provided with the estimate.

recaptured at least once, 8% were only captured in a single location. Because we did not record any movement for a greater proportion of rats than the estimated surviving population in 2011, it is theoretically possible that there are some individuals that move very little or move very little for a short period of time during which bait is available on the ground. Unfortunately, the probability of detecting a non-moving phenotype that exists with a prevalence of <0.2% in the population is virtually zero for any practically feasible sample size.

In summary, the rat eradication attempt on Henderson Island in 2011 failed to kill all individuals, and our work provides new knowledge to evaluate the potential causes of this failure. An eradication failure can occur if (i) not all individuals had access to sufficient bait; (ii) not all individuals died despite consuming bait; or (iii) not all individuals consumed a lethal dose of bait despite having access (Holmes, et al., 2015). We have shown that the timing of the operation was appropriate and that it is unlikely that rats did not have access to sufficient bait. Previous work confirmed that rats remain susceptible to brodifacoum, suggesting that toxicological resistance is an unlikely cause of the 2011 eradication failure (Amos, et al., 2016). A combination of factors leading to high alternative food availability and a small number of rats preferring natural food sources and disregarding bait may have resulted in the failure of the eradication attempt in 2011, and further research is required to examine whether that risk can be reduced for a new eradication attempt.

ACKNOWLEDGEMENTS

We thank the Government of the Pitcairn Islands for permission to work on Henderson Island; M. de L. Brooke, L. MacKinnon, A. Forrest, A. Skinner, N. Torr, S. O'Keefe, and P. Warren for assistance in the field; and J. Vickery, J. Hall, A. Schofield, and C. Stringer for general support. The crews of the *Braveheart*, *Claymore II*, *Teba,* and *Xplore,* provided transportation to and from Henderson Island. We thank A. Hughes for performing the triangulation of rat telemetry relocations. The David and Lucile Packard Foundation, Darwin Plus: Overseas Territories Environment and Climate Fund, British Birds, generous donors, and the RSPB, the UK partner in Birdlife International, helped to fund our research. Scientific and ethical approval was granted by the Government of the Pitcairn Islands, and the RSPB Council (paper 2/13/62 and protocol EAC 2015/01). Comments from M. de L. Brooke, and two anonymous reviewers improved this manuscript.

Abstract Invasive rodent eradications are one of the most effective conservation interventions to restore island ecosystems. However, achievements in the tropics are lagging behind those in temperate regions. Land crab interference in bait uptake has been identified as one of the main causes of rodent eradication failure on tropical islands, but the issue of effective mitigation of bait loss due to land crab consumption is poorly understood. For example, there are over 100 species of land crab and each may behave differently. We reviewed the available literature to answer: (1) which crab species are the most problematic? (2) what mitigation measures have been effective? and (3) how do invasive rodents impact land crab communities? We analysed a systematic dataset from six tropical islands to test two hypotheses: (a) bait uptake is highest when burrowing (Brachyura) land crabs are present; and (b) small land crabs (including juveniles of the larger species) are highly vulnerable to rodent predation. We found that large species (e.g. genera *Cardisoma, Johngarthia* and *Birgus*) are the most problematic during rodent eradications. Effective mitigation measures to prevent bait loss include using higher bait application rates and conducting eradications during the driest months. Land crab communities tend to go through significant changes after rodent removal. From our analyses, we confirmed pre-eradication data are valuable for eradication planning, as seasonality and type of crab can influence outcomes. Post-eradication data confirmed small crab species (<60 mm) are highly vulnerable to rodent predation. More effort should be invested into monitoring land crabs in tropical latitudes, particularly to determine any biogeographic or taxon trends in land crab interference. Land crabs are key for the restoration of the islands, as they shape ecosystems through their role as ecosystem engineers, hence they are excellent indicators of ecosystem recovery. Our results will contribute to the better planning of future rodent eradications on tropical islands where land crabs are significant bait competitors.

INTRODUCTION

Islands are some of the most important repositories for biodiversity, with 15–20% of terrestrial biodiversity held on only 5.3% of the world's land area (Weigelt, et al., 2013). Tropical islands are particularly important due to their high levels of endemism (Myers, et al., 2000). Island species are also highly vulnerable to anthropogenic impacts, of which invasive alien species (IAS) introductions are often the most severe (Russell, et al., 2017), causing 86% of island endemic species extinctions (Bellard, et al., 2016). Moreover, IAS also interrupt ecosystem functioning through predation of, and competition with, other biotic components (Athens, et al., 2002; Towns, et al., 2006; Hilton & Cuthbert, 2010).

Over the past 50 years, eradication of IAS has been increasing (Towns, et al., 2013; Jones, et al., 2016), with the removal of invasive rodents proving highly effective in targeted species recovery and island ecosystem restoration (Le Corre, et al., 2015; Croll, et al., 2016). Over 90% of rat eradication attempts have been successful, with increasingly larger islands being effectively targeted (Holmes, et al., 2015). However, the rate of eradication failure on tropical islands has been 2–2.5 times higher than on temperate islands (Russell & Holmes, 2015). This discrepancy is due to several contributing factors (Holmes, et al., 2015). Probably the most significant are the benign climate facilitating rodent reproduction (Harper & Bunbury, 2015), and bait competition from abundant land crabs (Wegmann, 2008; Griffiths, et al., 2011).

Land crabs comprise over a hundred species in three broad groups, burrowing crabs, hermit crabs and coconut crabs, although the latter single species (*Birgus latro*) is technically a hermit crab. As the largest invertebrates on islands, particularly coral atolls, land crabs are often the apex land predator (Burggren & McMahon, 1988), and can attain high population densities and occupy the niches of vertebrates on small oceanic islands. As such, they act as allogenic ecosystem engineers (Green, et al., 2008; Paulay & Starmer, 2011) through their significant influence on forest structure, plant species composition, soil formation and nutrient transfer and cycling (Green, et al., 1999; Sherman, 2002; Gutiérrez & Jones, 2006; Gutiérrez, et al., 2006; Sherman, 2006; Green, et al., 2008; Lindquist, et al., 2009). As keystone consumers (Paine, 1966), the removal of or reduction in crab abundance through the introduction of IAS can trigger a trophic cascade of effects, leading to 'meltdown' in island ecosystems in the worst cases (O'Dowd, et al., 2003; Pitman, et al., 2005; Nigro, et al., 2017). Moreover, as smaller crab species in particular are vulnerable to predation by rodents (St Clair, 2011; Samaniego-Herrera & Bedolla-Guzmán, 2012) and invasive rodents are found on >80% of island groups (Atkinson, 1985), an improved understanding of the interaction between rodents and land crabs is urgently required. However, land crabs have rarely been monitored before and after rodent eradications (but see Nigro, et al., 2017), and basic tools such as inventories are lacking for most tropical islands where rodent eradications are being planned.

The Pacific Invasives Initiative (PII) commissioned the first review on land crab interference in rodent eradications about 10 years ago (Wegmann, 2008) and many lessons have been learnt since. To improve the justification and implementation of rodent eradications on tropical islands, we conducted literature reviews on two main topics: the role of land crabs in invasive rodent eradications and the vulnerability of land crabs to rodent invasion. A case study from six tropical islands is presented, demonstrating the utility of monitoring land crabs both pre- and post-rodent eradications. Based on our previous observations of land crabs across islands, we expected (a) bait uptake to be highest on the islands where large burrowing species were abundant, and (b) population abundance of small burrowing species to increase over time after rodent eradications.

METHODS

Land crabs and rodent eradications

Following Burggren & McMahon (1988), we consider land crabs to be crabs that show significant behavioural, morphological, physiological, or biochemical adaptations permitting extended activity out of water. This includes a few families of the diverse infraorders Anomura (hermit crabs) and Brachyura (burrowing crabs), yet there are over a hundred species that can be considered land crabs. Land crab distribution ranges from tropical to subtropical areas, hence the scope of this paper focuses on islands located between ~25° north and south of the equator. We also focus on the two most common rodent eradication methods: aerial and hand broadcast of bait directly onto the ground (Howald, et al., 2007; DIISE, 2016).

The islands included in the review are a subset from the Database of Island Invasive Species Eradications (DIISE, 2016). These were selected based on the following criteria: 1) location: between latitudes ~25° north and south of the equator, 2) target IAS taxa: Muridae, 3) whole island eradications, 4) toxicant used: 2nd generation anticoagulant, 5) main bait delivery method: hand or aerial broadcast, 6) quality of data: good or satisfactory, the latter were updated to good, and 7) eradication status: known or 'to be confirmed', the latter were updated to failed or successful. Islands without land crabs such as the Galapagos Islands and Western Australia islands were excluded.

For each island, we collated the following additional data: bait rates used during the rodent eradications, island type (savanna, tropical seasonal forest or tropical rainforest), presence/absence status and abundance for each land crab group (hermit, coconut, burrowing), land crab group identified as the main bait competitor and timing of the eradication (dry or wet season). This information was collated through review of project documents (i.e. feasibility studies, operational plans, post-operation reports and scientific papers). We also sought inputs from project managers when we required further clarification/confirmation or information was missing from the documents available. Given the scarcity of scholarly information on land crabs, and the lack of a single source with the basic biology and current taxonomy for all land crabs (as most crab species are marine), we conducted an additional literature review to compile such information.

A 2-way ANOVA test for unbalanced designs was used to evaluate the variations in bait rates in relation to island type and main bait competitors. Data were log-transformed to achieve normality. All analyses were performed in R 3.4.

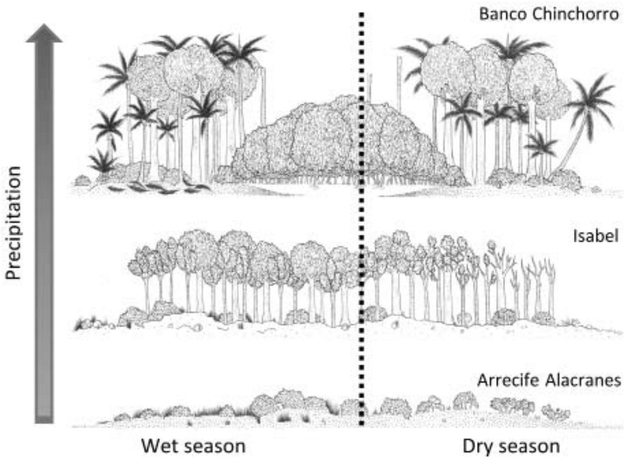

Fig. 1 Dominant vegetation on the islands where the case study took place.

Rodent impacts on land crabs

Some of the information on the impacts of rodents on land crabs was collated from the project documents mentioned above. In addition, we also searched the Web of Science, Scopus and Google Scholar for published literature using keywords: [island OR atoll OR cay OR archipelago] AND [rodent OR rat OR rattus OR mus] AND ["land crab" OR invertebrate]. We collated information on impacts through review of the resulting publications and relevant references listed in these.

Case study: Mexican tropical islands

Study sites

As part of a wider restoration programme led by Grupo de Ecología y Conservación de Islas (GECI) (Samaniego-Herrera, et al., 2011), bait uptake and land crab monitoring was conducted on six Mexican tropical islands. The islands, three in the Gulf of Mexico, one in the Mexican Pacific, and two in the Caribbean Sea fall into the three categories of tropical island ecosystems described by Russell and Holmes (2015): savanna, tropical seasonal forest and tropical rainforest, respectively (Table 1; Fig. 1). The aims of the monitoring were to inform the specific rodent eradication plans by assessing the potential interference of each land crab community, and to compare such communities before and after the removal of the invasive rodents. Invasive rodents (Table 1) were successfully eradicated from all islands either by hand or aerial broadcast of bait (Samaniego-Herrera, et al., 2014; Samaniego-Herrera, et al., 2018), following international best practices (Keitt, et al., 2015).

Bait uptake

Two types of bait were used: placebo bait for pre-eradication assessments and toxic bait for the actual rodent eradications. The toxic bait consisted of 2 g cereal bait pellets containing 25 ppm brodifacoum (second generation anticoagulant), manufactured by Bell Labs. The placebo bait, also from Bell Labs, was identical but non-toxic. Total bait uptake (i.e. by the target and non-target species) was measured before and during each eradication operation. Pre-eradication, bait uptake was monitored to help decide application rates for the eradication. During eradications, the monitoring took place to (a) validate the intended bait rate, by estimating bait density on the ground immediately after the bait drops, (b) assess the daily uptake rate, by repeating measurements every 24 hours, and (c) investigate the relationship of bait uptake rate, rodent abundance, and land crab diversity and abundance, by combining results from different islands.

In all cases, bait uptake was measured daily for 6–10 consecutive days in a systematic way, starting on the same day of bait broadcast. For all pre-eradication studies bait was broadcast by hand, whereas for the eradications either aerial or hand broadcast was used (Table 1). Bait uptake was measured in fixed circular plots as described by Pott, et al. (2015). A subset of the resulting dataset was included in the meta-analysis by Pott, et al. (2015), which showed the utility of bait availability studies. However, there are three major differences with the present study. Firstly, Pott and colleagues only used a subset of the Mexican dataset due to the limited data available for the other islands (e.g. data from only two of the 6–10 days available were analysed). Secondly, the results presented here derived from standardised monitoring methodologies. Lastly, our focus is to investigate the role of land crabs in the overall bait uptake in more detail, distinguishing for crab type (hermit and burrowing).

Table 1 General description of the six Mexican islands where land crabs were monitored before and after the successful rodent eradications.

Archipelago Island	Area (ha)	Ecosystem type	Dominant vegetation[1]	Species eradicated (year)[2]	Eradication method and bait rate (total kg/ha)	Main bait competitors (seasonal fluctuation)
Arrecife Alacranes						
Pájaros	3	Savanna	Shrubs and grasses	*Mus musculus* (2011)	Hand broadcast 17 kg/ha	Hermit crabs (low fluctuation)
Pérez	13	Savanna	Shrubs	*Rattus rattus* (2011)	Hand broadcast 17 kg/ha	Hermit crabs (low fluctuation)
Muertos	15	Savanna	Shrubs	*Mus musculus* (2011)	Hand broadcast 17 kg/ha	Small burrowing crabs (low fluctuation)
Isabel	82	Tropical seasonal forest	Deciduous forest	*Rattus rattus* (2009)	Aerial broadcast 20 kg/ha	Large burrowing crabs[3] (high fluctuation)
Banco Chinchorro						
Cayo Norte Mayor	30	Tropical rainforest	Mangroves & evergreen forest	*Rattus rattus* (2012)	Aerial broadcast 42 kg/ha	Large burrowing crabs (moderate fluctuation)
Cayo Centro	539	Tropical rainforest	Mangroves & evergreen forest	*Rattus rattus* (2015)	Aerial broadcast 60 kg/ha	Large burrowing crabs (moderate fluctuation)

[1]See Fig. 1.
[2]Always end of dry season.
[3]There was virtually no crab interference during the rat eradication; bait lasted for weeks.
Sources: Samaniego-Herrera, et al., 2013; Samaniego-Herrera, et al., 2014; Samaniego-Herrera, et al., 2018.

Land crab recovery

On all islands, land crab activity was monitored twice a year, at the end of each dry and wet season, both before (2–3 years) and after (1–5 years) each rodent eradication. Every season, several (6–18) fixed plots (25 m × 2 m) were used to estimate crab density; the exception was on Isabel Island, where two 300 m × 6 m plots were used. Plots were walked for 3–5 consecutive nights. One person with a headlamp walked in the middle of the plot, starting one hour after sunset. In order to walk all plots within 90 minutes (i.e. the peak activity period), several observers participated each night on some islands. The number of land crabs, by species, was recorded. Minimum training is required to carry out this task given the morphological differences of the species present.

Data analysis

Bait uptake trends (always measured in the dry season) were investigated using a linear mixed model (R software package nlme) for bait availability, where the density of bait (kg/ha), using the difference of target density minus measured density as the response variable (i.e. comparing rates of decline rather than actual densities), was dependent on time (days) and interactions of time with fixed effect covariates (i.e. covariates which would affect bait availability). These fixed effects included whether the study was conducted prior to or during the eradication (distinguishing between first and second bait application), whether rats or mice were the target species and how abundant they were (according to local mark-recapture studies by Samaniego-Herrera (2014)), and the abundance of both types of land crabs: hermit and burrowing (low – high, based on the monitoring in this study, therefore standardised). Although each island used different bait application rates, we were specifically interested in the rates of decline in bait availability. Inter-island differences were accounted for by including island as a random effect in our model. Diagnostic plots were visually checked for violations of model assumptions.

For land crab activity, an index of density was estimated as the number of nocturnal surface-active crabs per hectare. First, we used 2-way ANOVA to test the difference in density between seasons (dry and wet) and islands only for the pre-eradication periods (i.e. avoiding potential confounding effects caused by the eradications), as obvious fluctuations were occurring at least on some islands. In order to compare trends during favourable periods (hence closer to real density, as inactive crabs typically bury themselves), and given that the lower land crab activity during the dry season was confirmed for some islands, further analysis comparing pre- and post-eradication density used data from wet seasons only. Differences in density among island types (savanna, seasonal, rainforest) and periods (pre- and post-eradication) were tested with linear models. Data were log-transformed to achieve normality. All analyses were performed in R 3.4.

RESULTS

Land crabs and rodent eradications

The resulting database contains 108 eradication attempts spread over 101 tropical islands (Appendix 1; detailed spreadsheet: www.pacificinvasivesinitiative.org/). On some islands, there were two eradication attempts targeting a single rodent species or there were two rodent species being targeted by a single eradication attempt. Island sizes range from 0.1 ha to 4,310 ha (median = 10 ha). Most attempts (86.1%) targeted only rats (*Rattus exulans*, *R. norvegicus, R. rattus* or *R. tanezumi*), 2.8% only mice (*Mus musculus*) and 11.1% targeted both rats and mice.

Eighty-nine (82.4%) of the eradication attempts were successful and 19 (17.6%) failed (Table 2). Land crab interference was reported as important in 56.2% of the successful attempts and in 100% of the failed ones. However, for the latter, in addition to land crab interference other potential factors that may have contributed to the failure were also reported. Examples of such factors are gaps in bait coverage, which in turn can increase in area as land crabs take bait at the edges.

Over 82% of the eradication attempts used higher bait rates ($\bar{x} = 25.7$ kg/ha, range: 3–163 kg/ha) compared to those typically used on temperate islands (12 kg/ha; Broome, et al., 2014). In all cases, the justification for using higher bait rates was high rodent abundances (either estimated or assumed) and land crab presence, although abundance of either was rarely quantified. On some islands, additional factors such as high abundance of small invertebrates (e.g. ants and cockroaches, also bait consumers) were also mentioned.

Land crab abundances were reported as having been estimated either through measurements (21.5%) or observations (55.9%) during the planning phase; the rest (22.6%) of the cases did not try to estimate land crab abundance. On most islands, land crabs have been identified to the genus level. Through our research on current taxonomy, we identified 165 species of land crabs in 52 genera and 15 families, of which seven genera have been reported as important bait consumers (Table 3). For most islands (90.7%), only three or fewer land crab species were reported to be present.

Considering all islands, the 2-way ANOVA test revealed significant differences in total bait rates used depending on which type of land crab was the main source of interference (F = 11.33, $p<0.001$) and on the interaction between crab type and island type (F = 3.65, $p<0.001$), whereas island type was marginally significant (F = 3.02, $p = 0.05$). Higher bait rates (17–163 kg/ha) were used when burrowing crabs were the main bait competitors (n= 8), followed by hermit crabs (3–83.3 kg/ha; n= 55) and cases with 'no interference' (8–33.2 kg/ha; n= 39), i.e. low crab abundance (Fig. 2). When considering only successful attempts, the patterns remained the same.

Rodents impacts on land crabs

Accounts of insular land crab populations being negatively impacted by invasive rodents included 15 populations of ten species across nine countries and overseas territories (Table 4). These impacts are mainly in the form of population suppression and ecological extirpation. Pascal, et al. (2004) first suggested possible rat predation on *Gecarcinus ruricola* on Hardy Islet, after they found numerous crab carapaces in rat middens and the index of crab abundance increased after the rat eradication. Samaniego-Herrera & Bedolla-Guzmán (2012) and Samaniego-Herrera (2014) confirmed invasive rats can indeed cause ecological extirpations of land crabs; they documented how *G. quadratus*, a small burrowing crab, shifted from being extremely rare before the *R. rattus* eradication to being the most abundant species four years post-eradication. Evidence of rodent predation on land crabs as well as the dramatic recovery responses following rat eradication is growing (Harper & Bunbury, 2015; Samaniego-Herrera, et al., 2017). For example, Nigro, et al. (2017) showed that the recovery of two carnivorous species (*Geograpsus* spp.), the smallest of the Palmyra atoll crabs, led to a dramatic widening of the crab trophic niche following the rat eradication on Palmyra atoll, which is altering the ecology of the atoll presumably towards a more natural state. Likewise, Russell, et al. (2015) showed land crab trophic position differed depending on what invasive rat species is present.

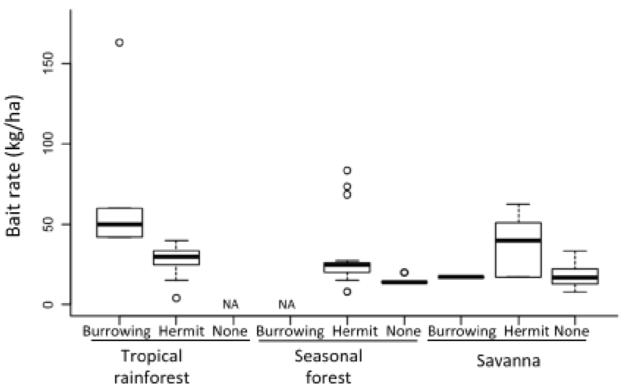

Fig. 2 Total bait used (median, IQR, range and outliers) in successful rodent eradications on tropical islands with land crabs, by type of dominant land crab and type of island. None = land crabs were present at low densities therefore interference was minimum.

Table 2 Success rate of hand and aerial rodent eradication projects, per target species, on tropical islands with land crabs.

Target species	Failed		Successful	
	%	n	%	n

Rattus rattus	18.5	5	81.5	22
Rattus tanezumi	0	0	100	2
TOTAL	17.6	19	82.4	89

Case study: Mexican tropical islands

Bait uptake

Linear mixed models were constructed, including period (trials or during eradication), rodent species (*R. rattus* or *M. musculus*), rodent abundance (high or low) and land crab abundance (high or low) per crab type (hermit or burrowing) as covariates. The model with the greatest support (49.8%) revealed a complex relationship between the difference in bait density from target density (response variable) and all variables tested and some interactions (Table 5). Essentially, the rate of decline of bait density depends on (a) days since broadcast, declining over time, (b) the type of crab, declining faster with burrowing crabs, (c) the density of burrowing crabs, declining with high density, (d) the density of hermit crabs, declining with high density, (e) study type, declining faster during trials, (f) the broadcast, declining faster after first broadcast, (g) the density of rats, declining with high density, and (h) the density of mice, declining with high density. Fig. 3 illustrates the variability in bait density among plots and islands after the rodent eradications, although in all cases (trials and eradications) bait was still readily available after the recommended four nights (Keitt, et al., 2015). The faster decline in available bait when burrowing crabs are abundant is a novel result.

Land crab recovery

For the pre-eradication period, the 2-way ANOVA revealed significant differences in land crab density depending on island type (highest on rainforest islands)

[1]Referred to as *Gecarcinus planatus* before 2008.

($F = 28.01$, $p < 0.001$) and season (higher in wet season) ($F = 15.05$, $p < 0.001$). However, Tukey comparisons confirmed that the increase during wet seasons was significant only on two islands (Isabel and Muertos).

Given the differences between seasons on some islands, trends in land crab abundance between pre and post eradication periods was evaluated only for wet seasons. The linear model confirmed that land crab densities (pooling species) are significantly higher ($R^2 = 0.19$, $F = 30.27$, $p < 0.001$) post-eradication (1–5 years later) on all islands, except on Cayo Norte and Pérez where the increase was not significant. On Isabel Island, the smallest burrowing crab (*G. quadratus*) showed a substantial trend of increase over a period of five years after the rat eradication (Fig. 4).

DISCUSSION

Land crabs and rodent eradications

Interference by land crabs remains poorly understood, documented and managed, despite its significant impact on rodent eradication operations on tropical islands. It appears that inconsistent application of recommended practices (Wegmann, 2008; PII, 2011; Keitt, et al., 2015) continues across projects (Broome, 2011), e.g. a lack of estimating land crab densities and undertaking consumption trials to inform baiting rates. Without determining how significant the land crab problem is on an island and how it fluctuates with seasons, managers tend to automatically apply a mitigation strategy of high bait application rates.

However, the use of high bait rates increases the cost of operations, adds logistical complexity and, if unnecessarily high, potentially increases the risk to non-target vertebrates (Pitt, et al., 2015) (as invertebrates are not susceptible to anticoagulants (Broome, et al., 2012)). The highest total bait rate used in a rodent eradication to date was 186 kg/ha on Palmyra Atoll (Wegmann, et al., 2012). This high bait rate (spread over two applications) was determined and approved on the basis of sound field studies (Wegmann, et al., 2008; Wegmann, et al., 2011) as it had been demonstrated that the diverse and abundant land crab community represented a significant bait 'sink', warranting drastic mitigation measures. Importantly, Palmyra has an exceptionally wet climate and this eradication case is an outlier, as the second highest bait rate used to date is 94.2 kg/ha for the eradication of *R. exulans* on two Gambier

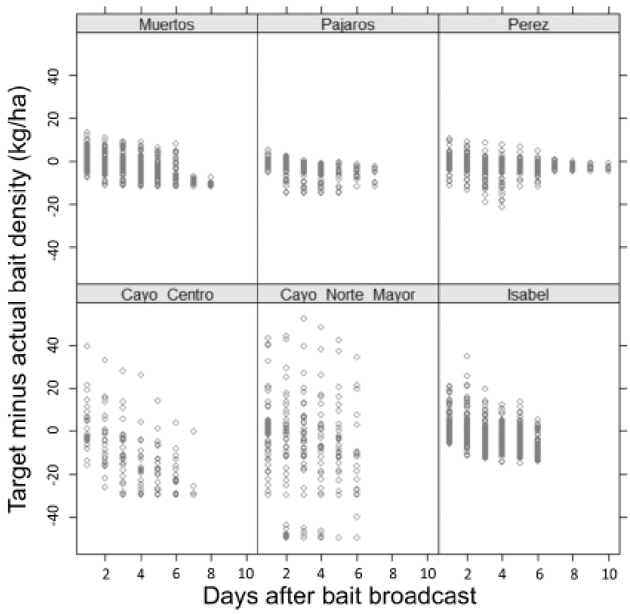

Fig. 3 Bait availability days after hand or aerial broadcast during six rodent eradications on Mexican islands.

islets (Kamaka and Makaroa)(Appendix 1). In addition, the largest rat eradication on a rainforest island (539 ha Cayo Centro, Banco Chinchorro), where large land crabs are abundant, was successful using 60 kg/ha over two applications (Samaniego-Herrera, et al., 2018). Moreover, there have been several instances where managers reported that the bait rates used were higher than required based on their observations of bait availability 5–15 days post bait application, which also coincided with 'fewer land crabs than expected' (Steve Cranwell, Araceli Samaniego, Elenoa Seniloli, pers. comm.). Studies (Samaniego-Herrera, et al., 2014; Samaniego-Herrera, et al., 2018) have shown that temporal land crab interference can vary substantially even on rainforest islands, the lowest peaks of activity being over the driest months. Thus, timing the eradication operation to coincide with the driest conditions of the year is recommended, particularly on islands with high abundance of burrowing crabs. Unquestionably, land crab activity is only one of the many factors that must be taken into account while planning an eradication (PII, 2011), so this has to be done in tandem with the other components, for example, minimising operational risks and the potential lethality to non-target species. Land crab interference with bait stations was outside the scope of this paper, but it is certainly a problem (Wegmann, 2008).

In addition to land crab abundance, land crab species composition also affects bait uptake. Burrowing land crabs, in particular large species (e.g. genera *Cardisoma*, *Johngarthia* and *Discoplax*), are generally the most problematic, although coconut crabs (*B. latro*) can be as troublesome even though they are usually in low to medium abundances. This has been reflected in the tendency to use higher bait rates on islands with abundant burrowing crabs, and confirmed by our case study where bait availability was quantified. Hermit crabs appear to be more widespread globally, so they may cause less interference on individual islands but affect more islands overall. Note that burrowing crabs, although larger, are more elusive than hermits due to their propensity to burrow or seek shelter under rocks or leaf litter during the day (Bliss, et al., 1978). Species richness of land crabs per island is likely to be generally underestimated. On the few islands for which comprehensive inventories exist (e.g. Christmas Island, Seychelles or French Polynesia), a list of 5–12 species of land crabs is common (Orchard, 2012), which is higher when compared to the three or fewer species usually recorded by eradication managers.

At present, bait uptake trials (e.g. Pott, et al., 2015) are the best way to predict bait rates required for rodent eradication. However, if climatic conditions are not very similar during implementation, the 'land crab scenario' could be very different and significantly affect the bait consumption rate. In order to better predict the potential variability of bait uptake in the presence of certain land crab communities, future monitoring of climatic conditions and land crab communities on a suite of islands is required. Note that carnivorous and intertidal crabs may also consume bait (confirmed for ghost crabs, A. Barnaud pers. comm.), but due to their generally low abundance (probably due to vulnerability to rats) and/or limited distribution (coastal), they tend to be neglected. The implications for failed eradication attempts are important. Estimations of bait uptake rates may no longer be true if a second eradication attempt occurs within a few years of the first one, i.e. when crab populations are more abundant because rats haven't had the time to fully recover and therefore haven't again supressed the land crabs.

Behaviours as well as consumption capabilities vary widely among groups and species, hence the importance of identifying species or at least type of crab (hermit, coconut, burrowing; Fig. 5). Hermit crabs are small and slow eaters and walkers compared to the average burrowing crab. They can take only one piece of bait at a time and they do not cache food. In contrast, most burrowing crabs are able to take up to three pieces of bait at a time (depending on crab size/species) and walk quickly to their burrow where they cache the bait (G. Harper & A. Samaniego pers. obs.). How much bait they can accumulate, how fast, and how long it takes for it to be eaten has not been determined.

Land crab activity is regulated by a combination of air and soil surface temperature, relative humidity, the intensity of insolation (solar radiation) and the availability of protective cover, be it leaf litter, suitable cavities, or soil for burrowing, which is further influenced by the soil compaction (Bliss, et al., 1978; Green, 1997; Brook, et al., 2009). The optimum temperature for land crab activity appears to be about 30°C, with virtually no activity below 18°C (Bliss, et al., 1978). Hence, in order to mitigate the desiccating effects of the high temperatures that crabs require to be active, their activity is largely restricted to periods and locations with high humidity. To reduce interference by land crabs, on 'wet' subtropical islands cooler months should be targeted for eradications.

The thermoregulatory abilities of hermit crabs (*Coenobita* spp.) are low, which is less of a problem where there is little temperature variation, as often occurs on wet tropical islands, but on arid islands they are essentially nocturnal (Achituv & Ziskind, 1985). Wind strength will also affect activity through increasing desiccation (Barnes, 1997). For burrowing crabs (e.g. *Gecarcinus* spp.) on seasonally arid islands, activity is dictated by relative humidity, with little or no activity below 77% RH, through to high activity above 95% RH (Bliss, et al., 1978; Green, 1997; Capistrán-Barradas, et al., 2003). Burrowing crabs probably occupy burrows to reduce their water loss. Often, unseasonal rain or even showers will initiate short periods of activity, but if conditions are very dry land crabs can remain underground for several months (Bliss, et al., 1978).

The effects of humidity and insolation on land crab activity strongly suggest nocturnal land crab monitoring will detect the highest crab activity and species diversity, particularly if all habitats are sampled and the season is taken into account. Land crabs are long-lived species, so monitoring tends to indicate how many land crabs are active at that time, not how many are actually present.

Table 5 Significant parameters in relation to bait availability after rodent eradications, according to linear mixed models for six rodent eradications on Mexican tropical islands.

	Value	Std Error	DF	t-value	p-value
Day	-1.456	0.275	2768	-5.287	> 0.001
Period	4.204	1.014	2768	4.142	> 0.001

Day × Burrowing × Bait application	1.672	0.431	2768	3.875	> 0.001

Rodent impacts on land crabs

Except for New Zealand, little has been documented regarding impacts of invasive rodents on island invertebrates in general (St Clair, 2011). Furthermore, few land crab accounts exist, due to the limited research conducted in the tropics (Brook, et al., 2009) and the low proportion of rodent eradications carried out in this region (Howald, et al., 2007; Holmes, et al., 2015). Our list of land crab species impacted by rodents is most likely to be severely under-reported as Rodentia comprise over a quarter of terrestrial mammal species known to forage on intertidal food sources. Burrowing crabs make up a substantial proportion of this and the number of species is highly likely to be an underestimation (Carlton & Hodder, 2003).

Adding to the impacts of invasive rodent predation on a wide range of plants and animals (Carlton & Hodder, 2003; St Clair, 2011; Sunde, 2012; Harper & Bunbury, 2015), the suppression of native ecosystem engineers, such as land crabs, by rats and other invasive species such as ants, cats and dogs, could have significant and enduring consequences on relatively simple island ecosystems (Carlton & Hodder, 2003; O'Dowd, et al., 2003). Land crabs are often the largest invertebrates on tropical islands, and particularly atolls, and will occupy the niches of vertebrates on small oceanic islands (Burggren & McMahon, 1988). They are highly integrated in the ecosystem energetics of tropical islands, as they control recruitment and species composition of seedlings on the forest floor (Green, et al., 1999; Lindquist & Carroll, 2004). They also regulate nutrient dynamics through substantial leaf litter consumption (Kellman & Delfosse, 1993; Capistrán-Barradas, et al., 2003; Gutiérrez & Jones, 2006; Gutiérrez, et al., 2006). Hence, they may govern the growth and productivity of tropical forests (Lindquist, et al., 2009) and sustain diversity at large scales (Young, et al., 2013; Nigro, et al., 2017). Moreover, plant composition will be influenced by soil structure, which is affected by land crab activity through inland transfer of marine debris and shells, removal of algae from rock surfaces subsequently deposited as faeces, and by increasing leaf litter breakdown through deposition underground in burrows. Given the critical role land crabs play in island ecosystems, it is recommended that these are included as outcome indicators and monitored post-eradication.

CONCLUSION

Land crabs are a diverse group. For management purposes, it is useful to distinguish three groups: hermit crabs, coconut crabs and burrowing crabs, noting the latter vary widely in size. The ecology and climatic tolerances of each group is different, as is their capacity as bait consumers. Assessing species richness and abundance of land crabs should be a priority in the planning phase of rodent eradication projects in the tropics, so that their interference can be efficiently managed during eradications. Similarly, changes to the land crab community should be measured

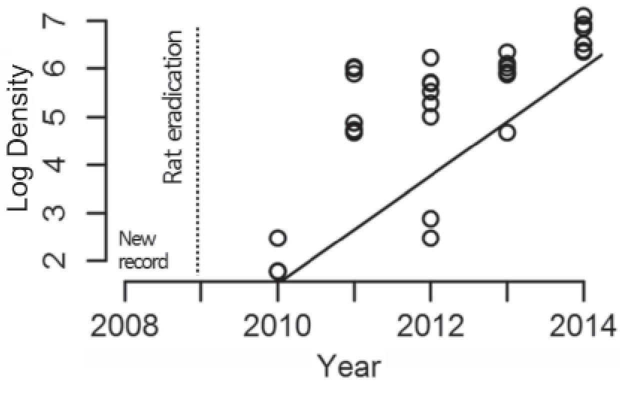

Fig. 4 Population increase of *Gecarcinus quadratus* on Isabel Island, Mexico after the ship rat eradication in 2009. The single record in 2008 was a new record for the island.

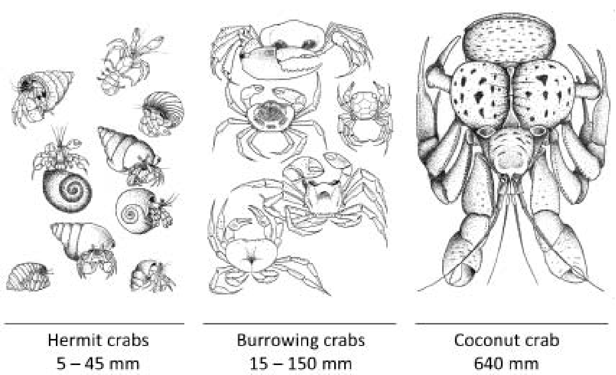

Fig. 5 Types of land crabs in relation to potential interference with rodent eradications on tropical islands. Sizes refer to the range of mean size across species.

post-eradication as indicators of ecosystem recovery. Once enough data are gathered regarding bait consumption in a standardised manner, we will improve our ability to predict appropriate bait rates for the eradication of invasive rodents on different types of tropical islands, as is currently done for temperate islands. Where compatible with other factors (e.g. non-target species and human activities), rodent eradications on tropical islands should be timed for the driest conditions or alternatively on 'wet' subtropical islands, the coolest months.

ACKNOWLEDGEMENTS

We would like to thank the following colleagues for providing unpublished data, project documents and valuable comments: Ray Pierce, Derek Brown, Graham Wragg, Thomas Ghestemme, Mike Bell, Elenoa Seniloli, Richard Griffiths, Sia Rasalato and Gerard Rocamora.

Data from the Mexican islands were collated by A. Samaniego thanks to the support of GECI. Thanks to Rigel Sansores for kindly drawing the illustrations and to Anny Peralta for helping with data collection. Thanks also to Andy Cox, Dick Veitch and two anonymous reviewers for the valuable feedback on the manuscript.

Trail cameras are a key monitoring tool for determining target and non-target bait-take during rodent removal operations: evidence from Desecheo Island rat eradication

Abstract Efforts to remove invasive rodents (e.g. *Rattus* spp. and *Mus musculus*) from islands often use toxicant-laced baits containing the anticoagulants brodifacoum or diphacinone. Rodenticide baits are generally delivered through aerial- or hand-broadcast, or in bait stations. These baits are not rodent-specific and are subject to non-target consumption or secondary exposure (e.g. an individual preying upon another individual that has consumed bait). During rodenticide applications, it is generally unknown which animals are visiting and consuming bait; and to quantify this, we recommend using trail cameras (e.g. Reconyx™ motion-activated infra-red) positioned to monitor individual bait pellets. To demonstrate the importance and effectiveness of using trail cameras during such operations, we report results of target (*Rattus rattus*, black rat) and non-target (native land crab, lizard, insect) bait-interactions after an aerial-broadcast of Brodifacoum-25D Conservation to eradicate rats from Desecheo Island, Puerto Rico. During the first five days following bait application, trail cameras (n = 15) revealed that there were 40 incidences of animals contacting bait pellets: 50% rat, 32% hermit crab, 13% *Ameiva* lizard, and 5% insect. Trail cameras provide temporal and spatial information regarding the effectiveness of rodent removal, and the last rat pictured by trail cameras on Desecheo was six days after bait application began. Trail cameras revealed 30 incidences of animals contacting bait pellets 6–20 days after bait application began: 47% hermit crab, 37% *Ameiva* lizard, 13% insect, and 3% black crab. Despite viewing ~69,000 images from trail cameras, lizards were never pictured consuming bait on Desecheo; therefore, any brodifacoum exposure to Desecheo lizards likely occurred via secondary pathways (e.g. consumption of contaminated insects). Scaling up, we estimate that > 75% of the total bait distributed on Desecheo was not consumed by rats. Trail cameras help inform the hazards of rodenticide use and can be easily incorporated into rodent removal operations.

INTRODUCTION

Invasive species, particularly rodents, are among the greatest threats to native biodiversity on islands. The breadth of flora and fauna that have been extirpated, or are currently threatened, by invasive rats (*Rattus* spp.) and house mice (*Mus musculus*) is extensive (*see* Towns, et al., 2006; St Clair, 2011; Shiels, et al., 2014). The most common method to suppress invasive rodent populations, or eradicate them from islands, is by using toxicant-laced baits such as those containing the anticoagulants brodifacoum, bromadiolone, or diphacinone (Howald, et al., 2007; Duron, et al., 2017). These rodenticide baits are not rodent-specific and are subject to non-target exposure through their direct consumption of the bait (i.e. primary exposure) or by an individual preying upon another individual that has consumed bait directly (i.e. secondary exposure). Until there is a rodent-specific toxicant developed that can be effectively delivered to target rodent species, non-target species that co-habit treatment areas where rodenticides are used may be at risk to exposure and possibly death. Therefore, there is a level of risk involved when using anticoagulant rodenticides that is relevant to livestock managers and pet owners in domestic settings, and to conservationists attempting to protect native species from the negative effects of rodents in natural areas (Hoare & Hare, 2006).

Existing methods for rodenticide risk assessments suggest implementation of non-toxic bait-uptake trials with biomarker-laced bait, and rodenticide residue analysis of native fauna, both of which can be expensive and may require harvesting individuals including those that are threatened or rare (Pott, et al, 2015). Bait uptake trials with biomarkers are important to determine the level of non-target exposure to bait, and subsequently help determine the bait application rates needed at the site. However, such trials are not always used for island-wide rodent eradication attempts (Pott, et al, 2015) and rarely used for rodent suppression projects (Duron, et al., 2017), perhaps in part because such trials are not a requirement for use of the rodenticide product, and they necessitate considerable effort associated with the capture and sampling of the target and non-target animal community. Although expensive and requiring the harvest of native animals, rodenticide residue studies revealed that residues of the used toxicant establish throughout most of the biological food web and often result in some non-target animal mortalities (e.g. Pitt, et al., 2015). The general acceptance of risk associated with rodenticide use is based on the premise that benefits to native wildlife outweigh the costs (i.e. native wildlife populations increase despite losing a few native individuals from toxicant exposure). A recent example in Alaska reviewed by Croll, et al. (2016) demonstrates that the short-term loss of some individuals of native birds following a rat eradication using brodifacoum has been overwhelmed by large increases in types and abundances of native seabirds over the long term.

The use of trail cameras (i.e. motion-triggered infra-red cameras) is an underutilised method to assess risk to non-target animals associated with rodenticide use. Trail cameras are a means of continuously monitoring rodenticide bait for animal interactions without having to be physically present for such observations. Human observations of animals visiting the bait during rodenticide applications are rare, due to the inability to watch more than a few bait pellets at once and the great likelihood of missing certain animals because of their unique behaviours during foraging (e.g. being secretive, nocturnal, or confined

to particular habitats). Trail cameras can be placed across a variety of habitats, installed to monitor bait for long periods (days to months), and reliably record diurnal and nocturnal visitation while not substantially altering behaviours (some animals can hear or see cameras/functions; Meek, et al., 2014) or harming resident animals (Swan, et al., 2004). When monitoring bait exposure to wildlife, trail cameras may be less expensive than other methods that require capturing or harvesting animals, and do not require animal use permits or animal sampling. Furthermore, the nearly real-time evidence of bait consumption by target and non-target species documented by trail cameras provides the operational staff confidence that the target rodents are consuming the bait, and allows for adjustments to any subsequent rodenticide bait applications or non-target mitigation strategies, if needed.

We propose that trail cameras provide critical information regarding target bait acceptance, effectiveness, and primary non-target bait exposure during rodent removal campaigns, and therefore future rodent removal campaigns should consider employing this tool. To demonstrate how trail cameras can be used effectively to meet such goals, we report the results of a field study associated with a rat eradication project on Desecheo Island, Puerto Rico, where bait take by target (*R. rattus*) and non-target animals (native crab, lizard, insect) were assessed after the aerial-broadcast of Brodifacoum-25D Conservation bait (3 g pellets, 0.0025% brodifacoum). We used trail cameras to assess the proportion of bait that rats and non-target species interacted with, including how much they removed or consumed, during each of the bait applications. We were also interested in documenting the spatial and temporal changes in bait interactions, including when rats were no longer observed visiting baits. We expected rats to be early primary consumers of the bait, and their observation would quickly decline one to two weeks after the first bait application. Because of the high densities of hermit crabs (*Coenobita clypeatus*) on many parts of the island, we expected that their role in bait consumption and removal would be formidable and consistent between applications; yet, we expected much less bait removal and consumption from other non-targets, such as the three endemic lizard species that have mostly insectivorous life-histories, and the few forest birds and seabirds on the island.

METHODS

Study site and animals

Desecheo (18°23′14″N, 67°28′19″W) is a small (1.2 km^2 or 117 ha) island approximately 21 km from the western shore of the main island of Puerto Rico. The terrain is rugged with karst limestone as parent material, and the peak elevation is 218 m. Vegetation is *Bursera simaruba*-dominated forest, shrubland, and grassland. Annual rainfall averages 1020 mm (Seiders, et al., 1972). The island is a U.S. Fish and Wildlife Service (USFWS) National Wildlife Refuge. *Rattus rattus* is abundant on Desecheo, and was first reported in 1912 (Wetmore, 1918). The negative impacts of *R. rattus* to natural areas and native species on tropical islands are well known (Towns, et al., 2006; St Clair, 2011; Shiels & Drake, 2011; Pender, et al., 2013; Shiels, et al., 2013; Shiels, et al., 2014); rats on Desecheo have been observed eating juvenile lizards and suspected of consuming other native species (Draft EA, 2015). Desecheo has three endemic lizards (anole: *Anolis desechensis*, gecko: *Sphaerodactylus levinsi*, ameiva ground lizard: *Ameiva desechensis*) that may be vulnerable to rats. Although non-native goats (*Capra hircus*) and non-native rhesus monkeys (*Macaca mulatta*) were once common to the island, they have been functionally eradicated (Hanson, et al., 2019). Prior to military actions and rhesus monkeys being introduced to the island, Desecheo had one of the largest nesting colonies of brown boobies (*Sula leucogaster*) in Puerto Rico.

Bait application

In March/April 2016 (the dry season), USFWS and Island Conservation (IC) conducted the bait application operation on Desecheo using Brodifacoum-25D Conservation (25 ppm brodifacoum in ~3 g pellets), under a supplemental label specific to the 2016 eradication effort (Will, et al., 2019). Bait was applied aerially at 30–45 kg/ha (depending upon habitat; see Fig. 1) for each of two applications (18 March and 9 April) in 2016. The 2016 rat eradication attempt used application rates two to three times greater of Brodifacoum 25-D Conservation than those used in the unsuccessful 2012 eradication attempt.

Experimental design

There were 11 sites on Desecheo established for monitoring (Table 1; Fig. 1). These sites were chosen to occupy the different habitats and bait application regions (e.g. deflector, coastal overlap, valleys, cliff; Fig. 1) in areas accessible (often near established trails) on the western half of the island; the steeply sloped terrain and cliffs were avoided for safety and logistical concerns. In total, we established four sites in the 'interior' on ridges or slopes, two sites in 'valley floor/bottoms', one 'cliff' site, two sites in the 'deflector' zone, which was immediately inland of the water's edge and high tide line, and two sites in the 'coastal overlap', which was the most inland portion of the deflector zone and the adjacent inland zone (i.e. interior or valley floor/bottom). To consistently describe the habitat at each site, slope and vegetation were described by a single person (A. Shiels) measuring three variables at each of the 11 sites (Table 1).

At each of the 11 sites, we established a single 150 m transect that had flags marking each 10 m along the transect. Transects were established with meter tapes in a straight line that roughly paralleled walking trails. Once within at least 150 m of a targeted habitat (i.e. interior, valley floor/

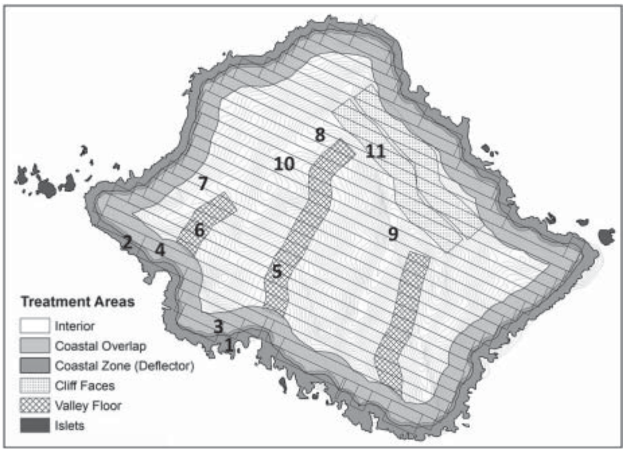

Fig. 1 Map of Desecheo Island, Puerto Rico, outlining the different treatment zones for bait application. The entire island received two applications of Brodifacoum 25D: Conservation rodenticide bait in 2016 (18 March and 9 April). Bait application rates were 30 kg/ha for both applications for all parts of the island except the coastal overlap (#3, #4), cliff faces (#11), and valley floors (#5, #6), which each received a total of 45 kg/ha during both applications. For orientation, there are three main valleys on the island, where (left to right, or west to east) West Valley (containing #6) is the smallest and most western (also where camp was set up at the base), Long Valley is the middle valley (containing #5), and East Valley is the eastern valley. See Table 1 for details of each site.

Table 1 Bait application rates (mean +/- SE bait pellets per m²) and ground cover vegetation (0–1 m height) measured on the ground in 1 m² plots (n = 15 for each site) along 150 m transects on Desecheo Island, Puerto Rico. Target application rates were either 30 kg/ha (equivalent to 1 bait pellet per m²), or 45 kg/ha (equivalent to 1.5 bait pellets per m², and listed in bold), as each pellet weighed 3.06 ± 0.09 g (n = 49).

Site No (see Fig. 1)	Site	Habitat description	Average & (Maximum) Canopy Height (m)	Slope (%)	Application 1 (Pellets/m²) (March 18, 2016)	Application 2 (Pellets/m²) (April 9, 2016)

bottoms, cliff, deflector, coastal overlap), the start of a transect was randomly established by blindly throwing an object over one's shoulder while standing on the walking trail and then beginning the transect from where the object landed. The 10 m interval flagging marked the location of the 1 m² plots for which we monitored bait pellets (15 1 m² plots per transect; 165 total plots for each application at all 11 sites).

A total of 15 trail cameras (12 Reconyx HyperFire models HC500 and HC600, and three Browning Model No: BTC-6HD) were placed to monitor bait pellets to help identify animals visiting and consuming the pellets. Each of the 11 sites always had at least one plot with a trail camera monitoring baits, and some sites had up to three cameras positioned at randomly assigned plots. Only one camera was placed per plot, and each camera was secured to the lower 30–70 cm of a tree or rock. Within 15–120 minutes of the helicopter applying bait to the site, two bait pellets were gathered from the surrounding 2 m² of a respective plot and the trail camera was aimed at the two bait pellets that were placed side-by-side, 40–90 cm away from the camera. A pin-flag was placed next to the two bait pellets in each plot so their presence could be monitored with subsequent visits. All other bait pellets in a 1 m diameter around the pin flag that marked the two target pellets were removed from the area so as not to confuse the observer monitoring pellets. The cameras were set to be triggered by motion, but also were programmed to take a picture each hour (on the hour), and sometimes more frequently (15 or 30 min) at set intervals to help account for periods where bait disappeared or was visited without an animal triggering the camera (e.g. insects rarely trigger these cameras). Once a Reconyx camera was triggered by motion, it would take 10 consecutive pictures over 20 seconds; Browning cameras would take one picture each time triggered.

Cameras were serviced (batteries and SD cards changed, checked for functioning) as needed, and if both bait pellets were removed from a plot with a motion-camera, the camera would be moved to another plot within the site, where bait pellets were still present. Upon activating the cameras on the day of each bait application, the baits and cameras were checked daily for at least seven consecutive days, which was the duration that field staff was on the island; the bait pellets and cameras were also checked at day 20 after the first application because that day preceded the second (and final) application and field staff had returned to the island.

For our analysis, we scored the number of incidences where an animal was observed contacting the bait (i.e. touching, eating, removing). An incidence ended when the animal left the camera's field of view, or when a series of pictures produced by one triggering event ended. The trail cameras monitored for 27 continuous days, which began the first day of application one and ended seven days after application two. Results were presented in three time-periods: 1) application one until the date rats were last observed contacting bait (i.e. day five), 2) days 6–20 post-application one, and 3) the first seven days following application two.

RESULTS

From the 15 cameras deployed, ~38,000 pictures were taken between application one and two (i.e. 20 days of continuous monitoring). We reviewed each picture from all 11 sites, and found 2,686 pictures where an animal was present. Most of the pictures that captured animals showed that they were not in contact with the bait, but instead they were passing by the bait (e.g. ameiva in Fig. 2), or perhaps searching or foraging nearby the bait. Seventy pictures from application one showed an animal in contact with a bait pellet. The first five days following application one was the only time period that rats were observed in contact with the bait (18–22 March), and of the 40 pictures involving animals during this period, 20 were of individual rats (Fig. 3). Although rats dominated bait contact (Fig. 4) during the first five days following bait application (especially so during the first two days), hermit crabs (Fig. 5) comprised 32% of bait contact events (Fig. 3). Most rats and hermit crabs contacting bait either removed it or consumed it in place. Ameivas, which contacted the bait in 13% of the pictures during the first five days, usually had a part of their body (e.g. leg, tail) contacting the bait, or they occasionally touched it with their snout, or on one occasion licked the bait and moved out of the frame. Thus, other than a single lick of the bait, ameivas were never seen consuming (biting, chewing, swallowing) or removing the bait. Finally, there were two insects (one appeared to be a grasshopper) seen in contact with a bait pellet during the first five days following bait application one (Fig. 3).

Fig. 2 An adult ameiva (*Ameiva desechensis*) triggers a trail camera positioned to monitor brodifacoum bait pellets on Desecheo Island, March 2016. Notice the two green bait pellets at the base of a pin-flag at the lower central position of the photo. Ameivas rarely were pictured in contact with the bait and were never documented consuming or removing the bait pellets.

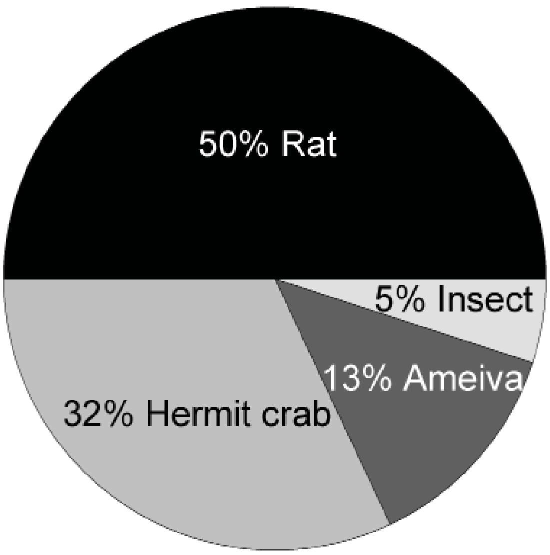

Fig. 3 Percentage of all trail camera results when an animal was in contact with a bait pellet (e.g. touching, eating, removing) during the first five days (18–22 March) after bait application one, on Desecheo Island, Puerto Rico. There was a total of 40 animals in contact with bait during this period (20 rats, 13 hermit crabs, five ameivas, and two insects), and these pictures were taken on the following five sites (Cliff, Overlap #2, Deflector #1, Ridge #4, and Long Valley #1; see Table 1 for site descriptions).

The last day when a rat was captured by motion-cameras on Desecheo was 23 March, which was the sixth day following application one. On this day, there was one rat pictured at Coastal Overlap #2 (grass/shrubland), and one at Ridge #2 (forest). Neither rat came into contact with the bait, but instead passed within 12 cm and 1 m of the bait pellets. These were the last two rats pictured by trail cameras on Desecheo despite the cameras being active and bait present in their field of view through to 15 April 2016.

There were 30 pictures from days 6–20 (23 March–7 April) following application one that showed an animal

Fig. 4 A black rat (*Rattus rattus*) triggers a trail camera positioned to monitor brodifacoum bait pellets on Desecheo Island, March 2016. Notice the bait pellet the rat is nearly touching with its nose. Black rats, being the target species, were pictured consuming and removing the bait pellets for the first five days following the first bait application (18 March 2016).

Fig. 5 A hermit crab (*Coenobita clypeatus*) triggers a trail camera while approaching a bait pellet on Desecheo Island. Hermit crabs were the primary visitors and consumers of bait pellets after the first week following application one.

in contact with a bait pellet. Because rats were no longer present or otherwise not pictured by the trail cameras, the proportion of animals documented contacting the bait shifted (compare Fig. 3 and Fig. 6), such that hermit crabs comprised nearly half (i.e. 14 of 30) of the pictures, and ameivas were pictured contacting the bait in 37% of the pictures during this period (Fig. 6). Insects, primarily grasshoppers, were contacting the bait in four pictures, and there was one picture of a black land crab (*Gecarcinus ruricola*) consuming a bait pellet during this period (Figs 6 & 7).

Sites tended to differ in the types of animals, and their relative abundances, captured on camera contacting bait pellets. In total, there were only five sites following application one that had pictures of animals contacting bait, even though all 11 sites had one to three cameras monitoring bait pellets and all 11 sites had pictures of some animals in the view. For example, the Cliff site only had pictures of hermit crabs contacting bait, whereas the Deflector #1 site only had pictures of insects (primarily grasshoppers) contacting bait (Fig. 8). Coastal overlap #2 and Deflector #1 were the only sites that had rats pictured contacting bait, and Long Valley #1 (valley bottom) and Coastal Overlap #2 were the only sites that had ameivas pictured contacting the bait pellets following application one (Fig. 8). It should be noted here that trail cameras were only monitoring, although continuously, a small subset of the total bait applied to Desecheo (i.e. only about 30 baits; 15 cameras monitoring two baits each).

Bait pellets were monitored during the first seven days following bait application two (Day 21–27), which occurred on 9 April 2016. There were approximately 31,000 pictures taken and reviewed during this period, and 176 pictures contained an animal. Similar to our findings after the first application, most of the pictures that captured animals showed that they were not in contact with the bait. There were 16 incidences where animals were in contact with bait pellets during the week following application two. There tended to be few proportional changes in animal-bait interactions that occurred from the 6–20 days of monitoring after bait application one and the first seven days of bait application two (Day 21–27). Hermit crabs continued to dominate bait interactions, and insect consumption of the bait had risen to the highest proportional levels of all previous measurements (Fig. 9). Ameiva interactions tended to decrease after application two relative to the 6–20 days following application one (Fig. 9). There were five incidences of animals contacting bait pellets during days six and seven: two hermit crabs, two insects, and one ameiva; thus, the first five days of bait interaction would have been similar to the first seven days of bait interaction. Furthermore, the pictures that captured animals interacting with bait occurred at five of the 11 sites (Cliff, Overlap #1, Ridge #1, Ridge #4, and Long Valley #1) during the week following bait application two. As

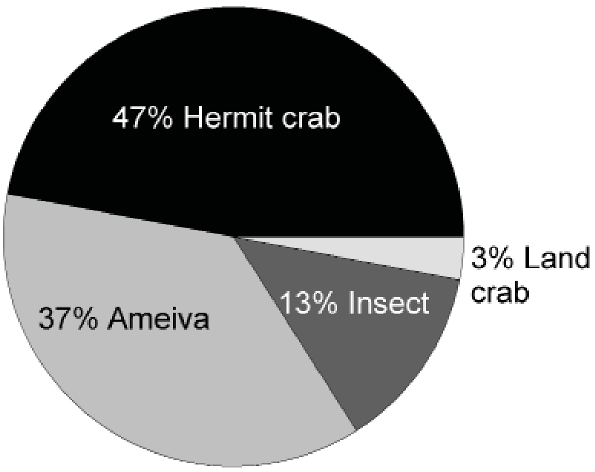

Fig. 6 Percentage of all trail camera results when an animal was in contact with a bait pellet (e.g. touching, eating, removing) during days 6–20 (23 March-7 April) following bait application one, on Desecheo Island, Puerto Rico. There was a total of 30 animals in contact with bait during this period (14 hermit crabs, 11 ameivas, four insects, and one black land crab), and these pictures were taken on the following five sites (Cliff, Overlap #2, Deflector #1, Ridge #4, and Long Valley #1; *see Table 1 for site descriptions*). Note that there were no rats pictured interacting with bait after five days, and rats were not pictured at all after six days following bait application one.

Fig. 7 A black land crab (*Gecarcinus ruricola*) triggers a trail camera while consuming a bait pellet on Desecheo Island. Black land crabs were rarely observed, and only active at night, on Desecheo Island.

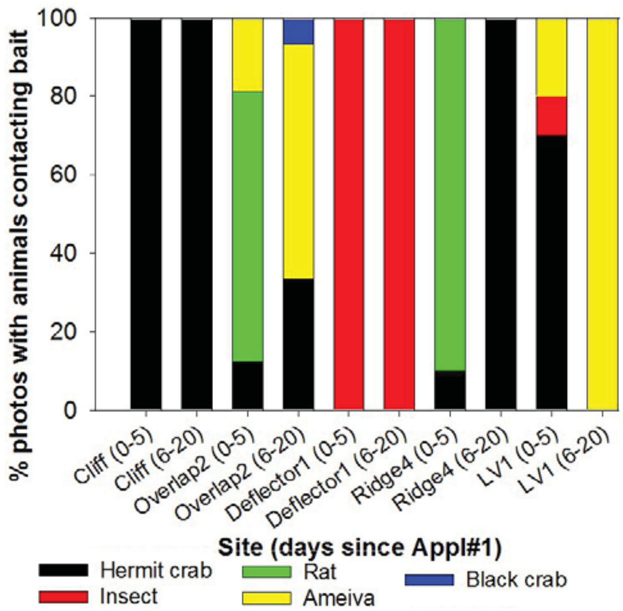

Fig. 8 Percentage of all trail camera results, separated by site, depicting when an animal was in contact with a bait pellet (e.g. touching, eating, removing) during the initial five days (18–22 March), and days 6-20 (23 March-7 April), following bait application one, on Desecheo Island, Puerto Rico. There was a total of 70 animals in contact with bait during this period (i.e. 40 during the initial five days, 30 from 6–20 days), and these pictures were taken at the following five sites (Cliff, Overlap #2, Deflector #1, Ridge #4, and Long Valley #1; *see Table 1 for site descriptions*). Note that there were no rats pictured interacting with bait after five days, and rats were not pictured at all after six days following bait application one.

with all previous pictures, hermit crabs and insects were observed consuming bait pellets, yet ameivas were not seen consuming bait.

DISCUSSION

Trail camera usage during the 2016 rat eradication on Desecheo Island allowed us to quantify, in near "real-time" fashion, the proportional visitation, removal, and consumption of bait pellets, and the timing of such visitation, by target rats and non-target species. Such quantification of bait interactions allows for upscaling to whole habitats and an island-wide understanding of the risks to non-target native species and the potential effectiveness of the eradication campaign at various timescales following initial bait application. Initially, most bait interactions involved rats, and the last rat documented by cameras was on the sixth day after initial bait application. Non-targets that consumed, removed, or otherwise contacted the bait pellets were numerous during the continuous 27 days of cameras monitoring bait pellets on Desecheo, and hermit crabs, ameiva lizards, and insects were the main non-target visitors to the bait pellets. Trail camera usage can therefore better inform rodent removal campaigns of potential animal exposure pathways and confirm target bait acceptance as they are occurring, and therefore should be considered for future rodent control and eradication operations.

Trail cameras revealed that bait was readily consumed by invasive rats on Desecheo during the 2016 rat eradication campaign. Results during the first five days following bait application, when averaged across all monitored habitats, revealed half of the bait that animals on Desecheo interacted (i.e. made contact) with was by rats, and these were most-likely bait consumption events. Without implementing trail cameras to monitor bait pellets, our sole indication that rats were consuming the bait would have not occurred until four days post-application when the first rats turned up dead (Shiels, et al., 2017a). Live rats were rarely observed during the day prior to and following bait application, and bait was never observed being visited by rats without the aid of trail cameras (Shiels, et al., 2017a). Furthermore, carcasses of rats may not always be found because of the expense to keep monitoring crews on the island for extended periods following bait application, rodents suffering from toxicosis often die belowground, and dead rats are quickly scavenged on many islands with a substantial land crab population (Pitt, et al., 2015). Although non-toxic bait uptake trials using biomarkers were performed prior to the 2012 rat eradication attempt on Desecheo (USFWS, 2011), trail cameras provided evidence during the 2016 rat eradication that rats were indeed consuming the bait.

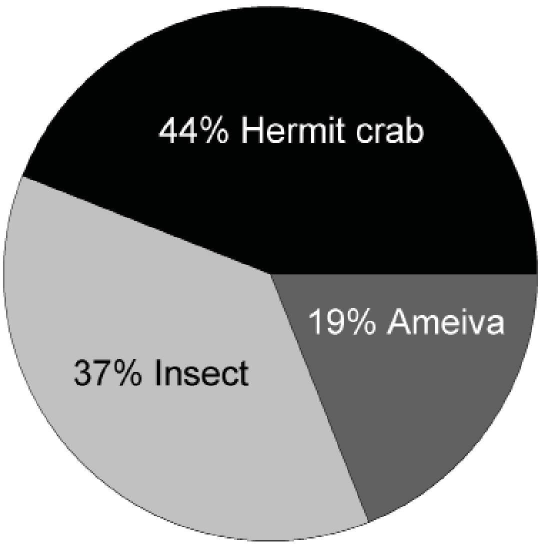

Fig. 9 Percentage of all trail camera results when an animal was in contact with a bait pellet (e.g. touching, eating, removing) during days 0–7 (9–16 April) following bait application two, on Desecheo Island, Puerto Rico. There was a total of 16 animals in contact with bait during this period (seven hermit crabs, three ameiva, six insects), and these pictures were taken at the following five sites (Cliff, Overlap #1, Ridge #1, Ridge #4, and Long Valley #1; *see Table 1 for site descriptions*).

If we use the trail camera findings to scale-up to the whole island, and assume that all pictures with rats contacting the bait resulted in the bait pellet being consumed by the rat, over half of the 5,325 kg of bait that was distributed across Desecheo in application one, and most (or all) of the 5,325 kg of bait in application two, was not consumed by rats. Furthermore, > 75% of the bait applied to Desecheo was consumed by non-target species or did not result in animal consumption (i.e. the bait disintegrated into the soil or was consumed by the microbial community). Clearly, accounting for non-target bait consumption is a critical part of the best practices associated with initial determination of bait application rates for island-wide rat eradications (Pott, et al., 2015). For example, six- to eight-times as much bait as the Brodifacoum 25W: Conservation parent label includes was applied to Palmyra Atoll, in the tropical Pacific, to account for the high density of land crab populations (Pitt, et al., 2015). Land crabs are a well-known non-target species that, like all other invertebrates, are not affected by the brodifacoum toxicant when they consume the bait, but they render the bait unavailable to target rodents (Cuthbert, et al., 2012). Our evidence from trail cameras during the Desecheo rat eradication demonstrates how common non-target bait interactions can be when rodenticides, such as brodifacoum bait pellets, are used for rodent removal. Furthermore, trail cameras revealed the importance of applying additional bait to Desecheo to account for non-targets, primarily hermit crabs, rendering the bait pellets unavailable to rats.

Substantial spatial variation of rat and non-target bait pellet interactions was present during the period following bait application on Desecheo, as bait interactions involving particular animal species tended to differ by habitat (Fig. 8). We must remind the reader that only a very small subset of the bait pellets applied to Desecheo were monitored with trail cameras, and there were far more appearances of animals in the camera view than there were animals that contacted the bait pellets. Additionally, several of the sites that had trail cameras continuously monitoring bait pellets did not have any rats that contacted the bait pellets. The spatial heterogeneity of rat and non-target events in various habitats also highlights the need for trail camera replication, and we feel that our sample size of 15 cameras is modest, and that substantially fewer cameras would be insufficient for an island of size and habitat heterogeneity like Desecheo. Additionally, we benefited from programmed interval-triggering for the cameras that supplemented motion-triggering because this helped capture insects and other small or slow-moving animals that would not trigger the cameras (Newey, et al., 2015). However, the trade-off of programmed interval-triggering, and 10 pictures per triggering, is the added human labour needed to view and analyse the large number of pictures.

Temporal variation of target rodent visitors to bait pellets can inform operational use of the rodenticide, and the trail cameras revealing an absence of rats after six days on Desecheo may suggest modifications to the operation plan to shorten the length of bait availability on the island. However, adjustments to operational plans are generally made to be more conservative (i.e. more bait for longer periods) rather than less conservative.

Our concerns of primary brodifacoum bait exposure to the Desecheo endemic lizard community were abated by the trail camera results, as there was an absence of pictures where lizards were observed consuming bait despite their interactions with the pellets. Additionally, there were no population level impacts to the lizard community as observed by the mark-and-recapture work completed in 2012 (Herrera Giraldo, et al., 2019). Ameivas were the only lizard species that were pictured in contact with the bait pellets during our monitoring, and there was no evidence of bait consumption aside from a single lick of the bait pellet by one individual. Most events where ameivas contacted the bait were by brushing the tail or legs on the pellet when passing by. Ameivas, and the other lizard species on Desecheo, are primarily insectivorous, and are commonly seen foraging in the leaf litter for insects (Shiels, et al., 2017a). Based on brodifacoum residue analysis following bait application, all three endemic lizard species had detectable levels of brodifacoum in their livers or bodies (Shiels, et al., 2017a), and the trail cameras and general diets of these lizards support consumption of contaminated insects as the most-likely pathway for such brodifacoum exposure. Although we could not definitively conclude that insects pictured on the bait pellets were consuming them, at minimum they would have gained exposure to the bait through direct contact, which probably facilitated exposure to higher trophic level predators. We were surprised that birds, particularly pearly-eyed thrashers (*Margarops fuscatus*), were not pictured consuming bait pellets as the few birds collected for residue analysis had evidence of brodifacoum exposure (Shiels, et al., 2017a); however, their omnivorous diet that includes invertebrates and vertebrates (Wetmore, 1916) favours brodifacoum exposure through this secondary pathway.

Trail cameras are a cheaper method than residue analysis to document primary exposure of target and non-target species during rodenticide campaigns. The USDA NWRC Chemistry Unit commonly charges between US$150–US$250 per sample for brodifacoum residue analysis, and this is a comparable fee to other laboratories. Additionally, brodifacoum residue analysis generally takes several weeks to complete. There is a wide price range in trail cameras, but some of the least expensive trail cameras can be purchased for <US$100 per camera (e.g. see https://www.amazon.com/). Inexpensive trail cameras are often adequate for most rodent removal campaigns because these cameras produce an image that is identifiable as a rat or a non-target (e.g. Bushnell brand from 2005 used in Shiels & Drake (2011)); the reliability, quality of the image, and flexibility of the cameras in customising image quality, triggering frequency, and sensitivity are all factors that are generally better in the Reconyx Hyperfire cameras (US$450–US$550 for those used in our study; http://www.reconyx.com/product/Outdoor_Series) than the less expensive alternatives (see Newey, et al. (2015) for a review). An important component that trail cameras cannot easily produce is evidence of secondary exposure of non-target species. One could, however, position rodent carcasses (or non-target carcasses of interest) on the ground such that trail cameras could document the scavengers of those carcasses. The potential brodifacoum exposure of local raptors is worrisome (e.g. Rueda, et al., 2006), and on Desecheo there are only a few resident kestrels, and several non-resident raptor visitors (several species of hawks), that would not be easily observable in their consumption of carcasses or any mortalities that may occur from rodenticide exposure on Desecheo.

Prior to rodenticide use, trail cameras can also help in surveying the potential target and non-target species at a site. Either singly or in combination with non-toxic bait uptake trials (Pott, et al., 2015), trail cameras can inexpensively help identify the potential animals without catching or harming them. Because rodenticide bait pellets are a mostly cereal-grain matrix, setting out 'home-made' mixtures or placing local fruits and seeds on the ground with monitoring cameras (*see* Shiels & Drake, 2011) may be a first step in determining some of the potential animal species that may visit rodenticide baits. This may be applicable for planning purposes, especially on isolated islands where visits to the island may be short or infrequent. Additionally, advanced trail camera technology now allows pictures to be checked remotely, via cellular transmission of the pictures to a cell phone or email account (Eason, et al., 2017).

Additional benefits of using trail cameras include assistance in the confirmation that the target rodent species is indeed the only rodent species on the island. Trail cameras producing high quality pictures, and multiple shots that can reveal multiple angles of the animal, allow for distinguishing features (e.g. tail length, ear size, body size) to be revealed and assessed. Furthermore, there are some occasions where rat-eradications have resulted in surprises such as house mouse populations 'suddenly present', or an explosion in their abundance, due to the mice being masked by the dominance of rats prior to rat eradication (Witmer, et al., 2007); trail cameras would be a viable method to document and act upon such surprises. Trail cameras may also be implemented to assess the particular prey (e.g. fruit and seed) that are most attractive or vulnerable to rodent predation (e.g. Shiels & Drake, 2011), and to document biological change after rodent removal by quantifying before and after native prey survival (e.g. Pender, et al., 2013). On Desecheo, there was a major caterpillar outbreak coinciding with rat removal (Shiels, et al., 2017b), and trail cameras could have been used to better document the development of the outbreak.

The use of trail cameras is an underutilised method of risk assessment for rodenticide use, particularly assessing primary rodenticide exposure that could be a substitute for, or an improvement upon, more expensive methods that require animal handling or sacrifice. Trail cameras can be placed across a variety of habitats, installed to monitor bait for extensive periods (days to months), and reliably record diurnal and nocturnal visitation of target and non-target animals while not substantially altering behaviours or harming resident animals. Trail cameras provide temporal and spatial information regarding the effectiveness of rodent removal, help inform the hazards of rodenticide use, and can be easily incorporated into rodent removal operations.

ACKNOWLEDGEMENTS

We are grateful for the multi-agency partnership (USFWS, IC, USDA, DNER, NZ pilot, AK mechanic) involved in the Desecheo rat eradication project of 2016. Field assistance was provided by Erick Bermúdez, Juan Carlos Alejandro, Ricardo Colón, Juan García-Cancel, Jorge Gutiérrez, Armando Feliciano, Claudia Lombard, Ricardo Albarracín, and José Luis Herrera-Giraldo.

Abstract Montecristo and Pianosa islands, although approximately equal in surface area (c. 1,000 ha), differ greatly in substrate, human presence, vegetation and altitude (650 m vs. 30 m asl, respectively). The former island hosts one of the largest yelkouan shearwater (*Puffinus yelkouan*) populations in Italy, the latter a depleted remnant of once numerous Scopoli's shearwaters (*Calonectris diomedea*). Two consecutive EU-funded LIFE projects have been designed to protect these seabird populations. On Montecristo, rough and inaccessible, aerial delivery of toxic baits in January-February 2012 eradicated black rats (*Rattus rattus*) and feral rabbits (*Oryctolagus cuniculus*) (originally a non-target species), with no permanent consequences on a local, ancient population of wild goats (*Capra hircus*). Eradication on Pianosa, currently underway (started January 2017), is being performed by ground baiting, delivered by 4,750 dispensers placed on a 50 m × 50 m grid throughout the island. The latter operation is included in a multi-species eradication aimed at several other target species, among which was the brown hare (*Lepus europaeus*), apparently introduced around 1840. Genetic analyses on the first trapped hares showed that this was the last uncontaminated and viable population of *L. europaeus* subsp. *meridiei* in existence. Whether of natural origin or introduced, the commencement of eradication of this population has instead created the awareness of a taxon otherwise unavailable for conservation elsewhere. While both projects address the same conservation issues (protection of shearwater colonies and restoration of natural communities), they differ greatly regarding economic cost, public perception, effort needed to maintain results in the long term and effects on non-target species. In the present paper, specific attention has been paid to the comparison between bait delivering techniques, results obtained, the array of problems originating from the complex regulatory framework and reactions by the general public.

Keywords *Capra hircus, Lepus europaeus meridiei*, Montecristo, *Oryctolagus cuniculus,* Pianosa, *Rattus rattus,* Tuscan Archipelago

INTRODUCTION

We present here two eradications of invasive mammals carried out on Mediterranean islands, directly concerning black rat (*Rattus rattus*), but also affecting two species of lagomorphs (feral rabbit (*Oryctolagus cuniculus*) and brown hare (*Lepus europaeus*)) and the wild goat (*Capra hircus*) (Table 1). These actions are part of a comprehensive recovery programme of nesting areas of seabirds in the Italian islands (Capizzi, et al., 2016). The two islands concerned, Montecristo and Pianosa, belong to the Tuscan Archipelago National Park and are almost equal in size but very different in morphology, vegetation, fauna and human presence. These differences influenced the eradication approaches.

Montecristo is a 1,080 ha island located in the central northern Mediterranean Sea, in an intermediate position between Corsica and the Italian Peninsula (Fig. 1), with a rugged topography and a maximum altitude of 650 m. It is uninhabited, and access is strictly limited. There are very few trails and no roads. As a consequence, the only realistic method to eradicate rats was the aerial distribution of bait. The main conservation target here was the yelkouan shearwater (*Puffinus yelkouan*), with 400–750 breeding pairs whose reproductive success was heavily affected by predation on eggs and chicks by the black rat (Baccetti, et al., 2009). A population of feral rabbits was also present. Given the bait distribution technique chosen, the eradication of this species was considered possible, although unlikely, and was not declared as a project target. The species considered at risk of unwanted mortality (Table 1) by direct consumption of baits (<http://www.montecristo2010.it>) were mainly the yellow-legged gull (*Larus michahellis*) and Montecristo wild goat. The latter was introduced on the island in pre-Roman times from founders that were still at a very early stage of domestication (or just tamed). The species' historical origin, together with its current uniqueness in the western Mediterranean, motivated its role as a flagship species and led to the founding of Montecristo State Nature Reserve in the early 1970s. The cultural/historical value of this peculiar population makes it deserving of appropriate conservation efforts (Gotti, et al., 2014).

Pianosa is a 1,040 ha island, that is entirely flat (< 30 m altitude), 30 km NW of Montecristo (Fig. 1) with a

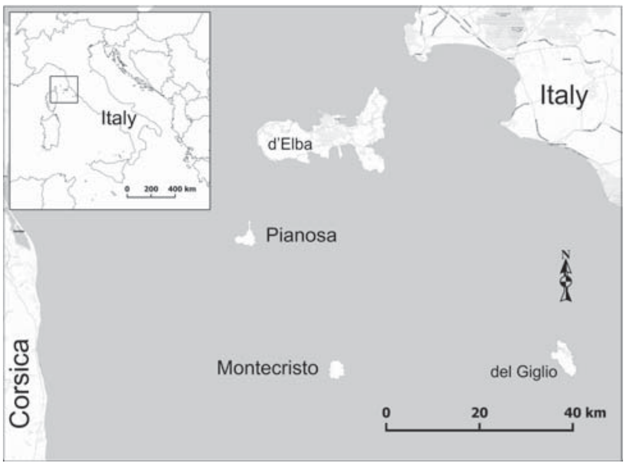

Fig. 1 Location of Montecristo and Pianosa islands.

small village and some scattered (and usually abandoned) settlements. It was occupied as a prison until 1998, making it inaccessible even for researchers during that time. Currently it is permanently inhabited by 20–30 detainees with two–three guards and it is open to guided tours with a daily limitation of 330 visitors. The extensive road network is maintained in reasonably good condition; vegetation is relatively accessible, especially on formerly cultivated areas (roughly half of the island). The main conservation target is Scopoli's shearwater (*Calonectris diomedea*), threatened by black rat predation on eggs and chicks (Table 1), consisting of 30–50 nesting pairs on Pianosa and 150–250 on La Scola, a satellite islet located 240 m to the east of Pianosa (Capizzi, et al., 2016). Rats were removed from La Scola, only 1.6 ha in size, in 2001; however, the short distance from the main island allows periodical rat incursions (three in the period 2001–2011, by single individuals), which till now have been successfully eliminated (Capizzi, et al., 2016) by a set of bait stations permanently installed and refilled when necessary.

Black rat eradication on Pianosa is part of a multi-species eradication programme aimed at the restoration of the native animal community <(http://www.restoconlife.eu/en>), which originally included the removal of the brown hare (*Lepus europaeus*). The house mouse (*Mus musculus*) is widespread on the island and is not an explicit eradication target of the project (Table 1), due to the spacing of the bait stations chosen for an island of the size of Pianosa and for the primary target species. The existence of permanent settlements, the presence of tourists during the summer and the occurrence of several non-target species, together with legal constraints on distribution methods, forced the choice of a ground-based eradication. Diurnal raptors, owls, yellow-legged gulls and hooded crows (*Corvus cornix*) and finally some domestic cats (*Felis catus*) are among the non-target species potentially threatened by the operation (Table 1). For non-domesticated feral cats living in the wild another specific eradication action has been conducted.

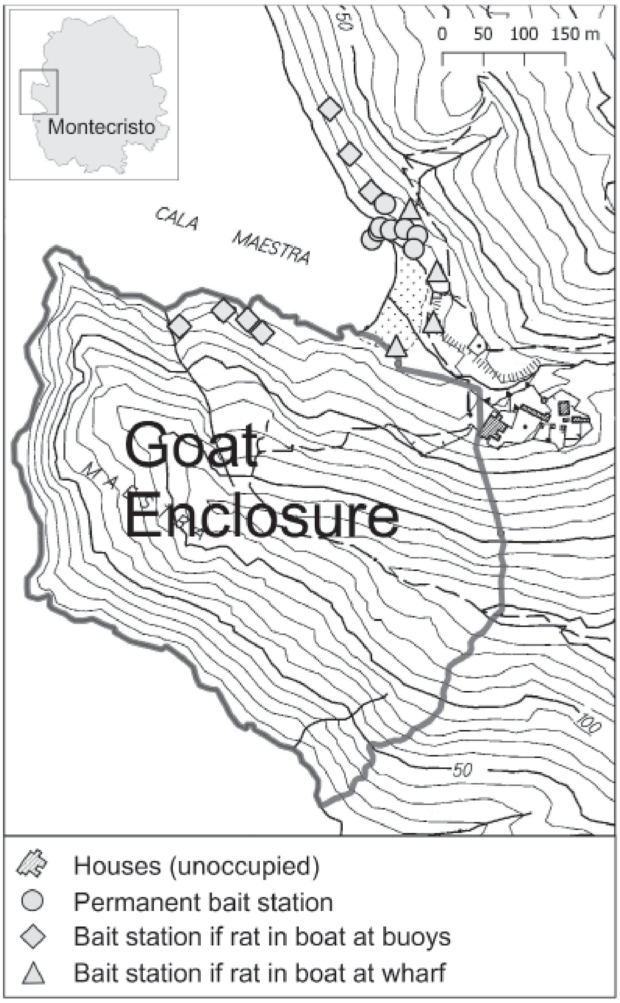

Fig. 2 Location of the goat enclosure, houses, and bait stations involved in the Montecristo biosecurity plan.

METHODS AND RESULTS

Rodent eradications

On Montecristo the first aerial baiting was conducted on 8 and 9 January 2012, with a pellet density of 10 kg/ha on the ground. The baits consisted of 2 g cereal (Brocum®, 0.005% brodifacoum as active ingredient, produced by Colkim Ltd).

A 30 ha area was excluded from the aerial drop (Fig. 2). This included unoccupied human dwellings, and an enclosure of about 25 ha, where 44 wild goats (at least 24% of the population size, assessed through direct counts, the rest having remained free) were kept to ensure survival of the population. This area was treated either by bait stations in the goat enclosure hand-broadcast of pellets outside the goat enclosure. Wax blocks (Solo Blocs®, 0.005% brodifacoum as the active ingredient, produced by Bell Ltd) were installed in the bait-stations.

The aerial distribution was originally planned along parallel transects, 50 m apart, to obtain a roughly complete overlap between parallel transects. However, the pilot had difficulties flying along such predefined routes without veering significantly from the flight line, as the geographic positioning system (GPS) based guidance system malfunctioned and caused frequent interruptions of the baiting. We changed our plans and opted in favour of baiting along two different sets of 100 m wide parallel flight lines, at right angles to each other. This would allow a greater tolerance for the helicopter's distance from the scheduled flight-lines and smaller areas without overlap. We then covered the coast and endeavoured to cover obvious gaps (Fig. 3). The second distribution of baits was initially expected to occur two weeks later, but the exceptionally dry weather that allowed pellets to persist on the ground in good shape and adequate amounts, made it unnecessary for a much longer time. The second baiting was done 45 days after the first delivery, covering 110 ha only, corresponding to the most critical areas: the coastline, a buffer zone around the excluded areas and an area where the first distribution appeared to have been less than optimal. The bait density was lower than in the first

Table 1 Species involved in the Montecristo and Pianosa rat eradication projects. Among non-target species, strong negative impacts on local populations have been recorded on Montecristo for the breeding pair of *Corvus corax* (with permanent reoccupation of the site in 2015–2016) and on Pianosa for *Tyto alba.*

Island	Conservation target species	Invasive species	Invasive non target species	Non target species
Montecristo	*Puffinus yelkouan*	*Rattus rattus*	*Oryctolagus cuniculus*	*Larus michahellis, Capra hircus, Corvus corax*
Pianosa	*Calonectris diomedea*	*Rattus rattus*	*Mus musculus*	*Larus michahellis, Corvus cornix,* owls, diurnal raptors

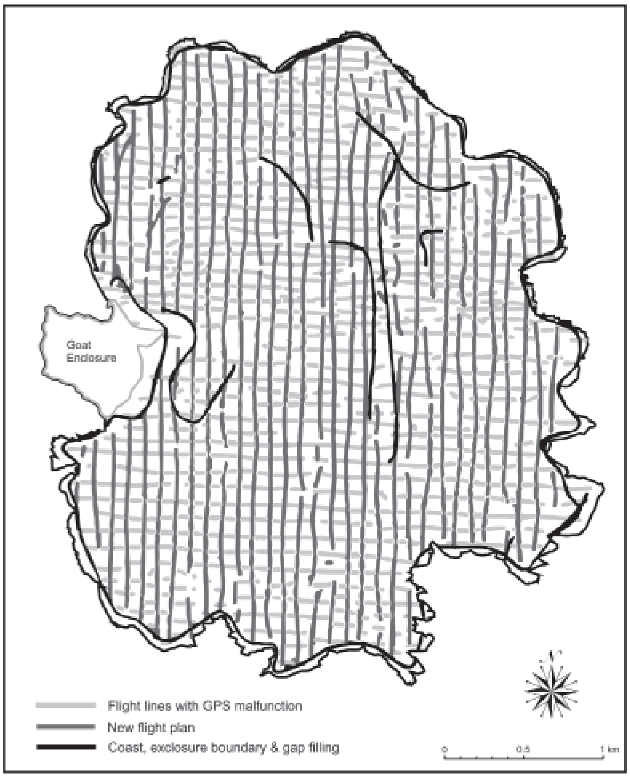

Fig. 3 Helicopter flight lines during the first bait drop.

distribution, i.e. 4 kg/ha on the ground. The eradication was successful, as the last sign of rats was detected 15 days after the first distribution (Sposimo, 2014). The cost of the whole operation, excluding preliminary analyses, planning and devices for protection of goats, was €226,800 (US $280,000).

On Pianosa Island, the eradication took place via ground-baiting with second generation anticoagulants inside bait-stations, placed at the nodes of a 50 m × 50 m grid covering the entire island. Bait density was doubled along the coastline and in urban areas, in consideration of locally higher rat densities. Approximately 4,750 bait-stations were deployed in January 2017, then checked and refilled monthly until May 2017. The percentage of consumed baits and/or any sign of rats were recorded. Bait stations were retrieved in October 2017. The bait consisted of wax-blocs with brodifacoum (Solo Blocs®, 200 or 20 g), except in the area occupied by human settlements where it was replaced by wax-blocks with 0.005% bromadiolone (Notrac Blox®, 225 or 28 g, produced by Bell Ltd) during the first and second baiting events, to reduce the risk of secondary poisoning of domestic animals (Buckle & Smith, 2015).

Rates of bait consumption are detailed in Fig. 4. After the initial and very high rate of bait consumption, the rate decreased by one order of magnitude during each of the two successive sessions; low and steady final values were assumed to be mainly due to house mice and invertebrates. In May, only one credible sign of black rat was found across the entire island, but the success of the eradication has to be confirmed by the implementation of monitoring activities that are still ongoing; the presence of house mouse was detected in nine bait-stations, suggesting that eradication of this species, as expected, is unlikely. This result would be consistent with other evidence of house mice being more difficult to eradicate than *Rattus* species (MacKay, et al., 2007), because of smaller home-range size that allows the survival of some individuals in bait-free areas between 50 m spacing of stations. The cost of the eradication, excluding preliminary analyses and planning, was €477,600 (US $590,351).

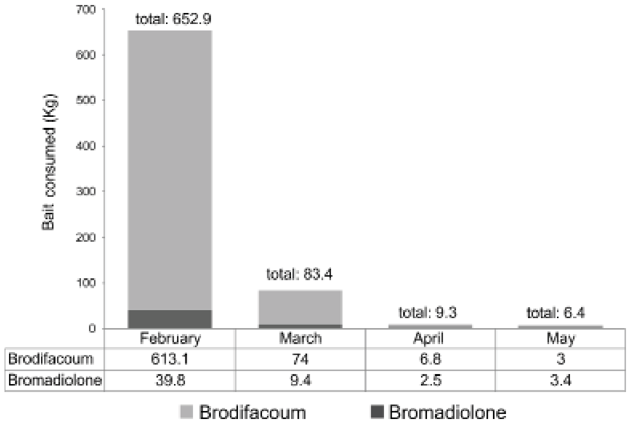

Fig. 4 Bait consumption on Pianosa during the first four sessions.

Lagomorphs

Feral rabbit: the aerial delivery of rat bait took place on Montecristo during mid-winter, when feral rabbits appear to be in the most critical annual phase and when local decreases in the population had been observed. Nevertheless, the presence of a 25 ha fenced area where the bait distribution had been implemented with bait-stations inaccessible to rabbits, and the lack of any specific effort to cull surviving rabbits (Murphy, et al., 2010), made the eradication of this species quite unlikely. Nonetheless, rabbits do seem to have been eradicated, probably due to the rabbit-permeable fencing of the goat enclosure and unusually long duration of pellets outside it, because of the dry weather. After the bait delivery of February 2012 there was just a single observation of rabbits (an adult with young) in April 2014. Traps were immediately set in the observation area without any result. The lack of any further finding of individuals or sign more than three years later makes it unlikely that any survivors might still be present on the island. Despite the lack of any specific monitoring, rabbits would not have escaped detection in the surroundings of the fenced gardens, where full time employed wardens are present, or along the transects regularly covered for goat counts.

Brown hare: the Pianosa multi-species eradication programme originally included netting and shooting brown hares, which had likely been introduced on the island for hunting purposes as early as 1840. Tissue and blood samples obtained from 35 individuals netted at the beginning of the operation, or shot with hunter-dog teams, were collected and genetically analysed, leading to the unpredicted result that the Pianosa brown hare population represented the last uncontaminated and viable population of *Lepus europaeus meridiei*, a subspecies once distributed in central and northern Italy, believed to be extinct due to genotype contamination with exotic hares massively imported in Italy for hunting (Mengoni, et al., 2018). Pianosa's insular status, habitats, and past restricted access due to the prison have resulted in maintaining a viable and representative stock of high conservation value. The number of individuals captured and culled in early 2016 had no consequence on the population size after one to two breeding seasons.

Biosecurity

Reinvasion risk varies greatly between the two islands, because of the different human presence and accessibility (Russell, et al., 2008b). On Montecristo an incoming rat would likely follow a single pathway covering the small area of the wharf and buoys. After the eradication, a biosecurity interception system was set up consisting of 15 bait stations placed all around the entry point at the landing bay. We experimentally tested the effectiveness of this system in December 2016, releasing 14 black rats, all adult males, equipped with VHF transmitters. Animals were released on the pier individually, over 19 hours, simulating a reinvasion event. Each bait station was armed with a lethal snap-trap. Individuals were tracked for 65 hours. Twelve individuals were intercepted by a bait station, the majority (10) within 20 m from the release point, while one disappeared shortly after release (and is suspected of dying from hypothermia after having been observed swimming) and the last one escaped the interception system to hide in a stone wall 100 m inland from the wharf. The average time between release and capture was 3.4 h, which is very short if compared with the results of similar experiments on brown rats (Russell, et al., 2008a). The biosecurity system was modified after these results and organised in three sub-systems (Fig. 2): one permanently active (eight bait-stations), concentrated in the vicinity of the wharf, and two more to be activated in case of potentially rat-infested boats docking at the wharf or buoys. A plan for contingency response has been set-up as well.

Biosecurity measures to be implemented in Pianosa, beginning in October 2017, are directed both towards ferries, to reduce the presence of rodents on board, and towards the implementation of an island-based interception system, roughly following Montecristo's scheme. In the likely case of an unsuccessful mouse eradication, the land system will require a more frequent bait replenishment, together with a permanent mouse-control strategy in the harbour area.

Effects on conservation targets

The effects of the Montecristo eradication on its conservation target species are shown in Table 2, where a dramatic increase in breeding success of yelkouan shearwater has taken place since the year of the bait delivery (2012), whereas breeding performance of Scopoli's shearwater on Pianosa has constantly remained poor. Evidence of new breeding sites, including nest boxes, being occupied by yelkouan shearwaters on Montecristo since 2012 is available, but an increase of nest density or population size remains to be quantified as of yet. A number of benefits were recorded on non-target avian species, such as minor increases of breeding scops owl (*Otus scops*) and European nightjar (*Caprimulgus europaeus*), and an obvious increase of sedentary and alien chukar partridges (*Alectoris chukar*).

Effects on non-target species

Thorough searches for gull and goat corpses were repeatedly carried out on Montecristo from one to four months after bait delivery, where gull casualties were recorded for at least a four month period. On Pianosa, the operators who checked bait-stations every month collected all corpses they found. Standardised counts were performed on both islands to assess any negative effects on non-target populations. Deaths recorded on Montecristo only occurred for two species, the wild goat (n=35) and yellow-legged gull (n=891), while the local pair of common raven (*Corvus corax*) was no longer observed, indicating presumed extirpation. Ravens permanently reoccupied the site only in 2015–16. Annual monitoring of the Montecristo goat population by distance sampling methods showed a temporal decrease of approximately 30–40% in the summer following the aerial treatment, while counts performed in all subsequent years attested to a fast recovery of the population to the pre-eradication level. On the contrary, yellow-legged gulls dropped from 1,036–1,833 breeding pairs in the two years before baits were delivered to 591 in 2012, 292 in 2013, with a steady, slight increase in all following years, up to 499 in 2017.

On Pianosa the impact of rodenticide indirectly consumed by native predators was more diverse, more concentrated in time, but less thoroughly recorded: findings of fresh corpses ceased around mid-March 2017 and included nocturnal raptors of two species (eight individuals), diurnal raptors of three species (seven individuals) and at least three hooded crows; no gulls were affected. Effects on native populations at Pianosa seem to be limited to the expected extirpation of breeding barn owls (*Tyto alba*).

Table 2 Breeding success of the two conservation target species on Montecristo (black rats eradicated 2012) and Pianosa (treated 2017, first rat free season still in progress).

Year	Montecristo target: *Puffinus yelkouan*		Pianosa target: *Calonectris diomedea*

2015	26	0.80	19	0.16
2016	35	0.80	17	0.12

DISCUSSION

Black rats have been successfully eradicated on Montecristo and Pianosa seems to be on a similar trajectory, thanks to two projects performed with radically different techniques.

In order to maintain these achievements – and investments – in the long term, different efforts are needed. Biosecurity measures are relatively simple for Montecristo, as long as the current management of access is allowed. A field test has shown that currently adopted measures are adequate, suggesting minor adjustments enabling a slight reduction of effort needed for their maintenance.

Reinvasion risk is significantly higher for Pianosa, this island being affected by a permanent, yet currently moderate, flow of supplies and visitors, that could strongly increase in the near future due to already planned restoration of many buildings. This, together with the probable survival of the house mouse, results in the need for more complex and costly (due to bait consumption by mice) biosecurity measures. Risks for native species and the insular ecosystem deriving from a house mouse increase following black rat eradication was considered to be low, due to the presence of several species of specialised or generalist predators of rodents (three breeding species of owls and one of snake).

The unexpected disappearance of rabbits from Montecristo can likely be related to timing of the operations, that coincided with seasonal lows of the population, and to random factors such as a very unusual and prolonged drought for the season (January–April rainfall of 34.6 mm in 2012, vs. an average of 112.1 mm in the same period for the previous five years), which allowed longer bait persistence and possibly impacted rabbits more strongly. Similarly, unexpected results for different reasons were obtained in the case of the Pianosa brown hare, representing a taxon believed to be extinct and, thus, deserving appropriate management in future.

Effects on conservation target species were, and are expected to be, very positive. Although this is easily understandable – and already evident for Montecristo yelkouan shearwaters, based on the resulting local population size and productivity – in the case of Pianosa, for Scopoli's shearwaters a full evaluation should include: i) the huge potential for breeding sites, most of them currently unused by the depleted breeding stock; and ii) the effortless maintenance of permanently rat-free conditions on adjacent La Scola islet, where a large Scopoli's shearwater colony is already present. Moreover, since Pianosa is almost devoid of burrowing seabirds at present, but has suitable breeding sites, its value in the future attraction of species that are currently absent (e.g. yelkouan shearwaters from nearby Montecristo and Mediterranean storm petrel [*Hydrobates pelagicus melitensis*]) might even exceed its importance for Scopoli's shearwater.

Consequences on non-target species have varied greatly, depending on bait deployment methods, geo-morphological features and faunal composition of the two islands. Non-target mortality of Montecristo goats did not prevent the recovery of the population to its initial level in a few years and, after the aerial treatments, the widespread presence of goats did not limit the availability of baits for rats. The presence of the large enclosure to protect some goats and prevent population extirpation has to be considered as a prudent measure to ensure the long-term persistence of this valuable population. However, it posed a risk to the success of the rat eradication and demanded an alternative approach (bait delivery inside bait-stations).

The higher mortality of diurnal and nocturnal raptors observed on Pianosa (and probably underestimated) can be attributed to several factors: 1) their greater abundance, 2) the presence of house mice that are preyed upon by small-sized raptors that do not feed ordinarily on rats, and 3) possibly also the delivery of poison through bait stations, that may allow rodents to consume a much higher amount of poison than during an aerial distribution. The most striking difference between the casualties of the two projects was the massive impact of the aerial treatment on the yellow-legged gulls, compared to the absence of any effect on this species in the bait station-based operation. Losses could have been minimised with an aerial delivery planned earlier in the season, when fewer birds are on the breeding sites. Nevertheless, even these losses – of a human-dependent and super-abundant species – are negligible compared to the benefits achieved. A slightly earlier seasonal planning, however, has to be recommended in consideration of possible public reactions to the issue of gull mortality, which was a population decrease lasting more than one year following the operation's conclusion. Losses of barn owls on Pianosa, and their probable (albeit possibly only temporary) extirpation, represent possibly the highest biological cost of the programme.

Both projects triggered negative reactions from the public, particularly harsh towards the Montecristo eradication. Evidently, aerial baiting was perceived as a more threatening method by non-experts. Thus, projects planning to use this technique should employ greater communication efforts at different levels. The strategy for communicating with the public, structured as in many other LIFE projects (e.g. via a dedicated website) was clearly ineffective, despite the projects being on islands lacking human populations which should have restricted the potential audience. People from nearby towns on the coast or from nearby Elba Island were often unresponsive to any outreach efforts and usually exploited debated topics in favour of other agendas, such as anti-Park personal positions, or criticising the 'waste' of money (Baccetti, et al., 2016). Ambiguity of national regulations in force during the Montecristo eradication led to legal actions being taken against project managers, but were finally positively concluded for the defendants. Currently, the EU Biocide Regulation 528/2012 clarifies the situation, but the possibility to carry out aerial baiting remains undefined, depending on specific authorisations issued by nationally competent authorities.

Aerial baiting has allowed the black rat to be eradicated from an island primarily relevant for Mediterranean seabird conservation that could not be otherwise treated with traditional ground-based methods. Tangible drawbacks are not larger than those observed during a comparable operation implemented by a bait station distribution, while the economic cost was certainly lower. Nevertheless, at present, the opportunity to carry out similar operations is extremely uncertain in Italy, as well as across the rest of the EU.

ACKNOWLEDGEMENTS

Both operations described have been realised thanks to EU LIFE programme co-financing, as for the majority of Italian eradications. Project monitors Michele Lischi and Chiara Caccamo were particularly helpful. Many people offered their collaboration in the course of the programmes, starting from Jacopo Primicerio (Institute of Biometeorology of the National Research Council) and Barbara Lastrucci (NEMO Ltd), responsible for the GIS and GPS guidance system during the Montecristo eradication, the permanent staff of the two islands (Montecristo wardens Luciana Andriolo and Giorgio Marsiaj, as well as several Pianosa prison guards and detainees) and many colleagues from the UTB Forestry office of Follonica, Tuscan Archipelago National Park, Penitentiary offices of Porto Azzurro and ISPRA. We are most grateful to the reviewers and editors for their comments and English edits.

Big island feral cat eradication campaigns: an overview and status update of two significant examples

D. Algar[1], M. Johnston[1] and C. Pink[2]

[1]*Science and Conservation Division, Department of Biodiversity, Conservation and Attractions, Locked Bag 104, Bentley Delivery Centre, Western Australia, Australia 6983. <dave.algar@dbca.wa.gov.au>.* [2]*Christmas Island National Park, P.O. Box 867, Christmas Island, Indian Ocean, Australia 6798.*

Abstract Feral cats have been known to drive numerous extinctions of endemic species on islands. Also, predation by feral cats currently threatens many species listed as critically endangered. Island faunas that have evolved in the absence of predators are particularly susceptible to cat predation. Australian islands, such as Dirk Hartog and Christmas, both formerly known to be high biodiversity islands, are no exception. In this paper we outline the techniques being used in the two eradication campaigns currently underway and provide an update on the status of the programmes on these islands that differ significantly in terms of climate, topography and habitation. Poison baiting and trapping are the methods used on both islands but have been managed differently to suit the local conditions.

Keywords: Christmas Island, Dirk Hartog Island, domestic cat, fence, land crab, planning, poison baiting

INTRODUCTION

There is extensive evidence that domestic cats (*Felis catus*) introduced to offshore and oceanic islands around the world have had deleterious impacts on endemic land vertebrates and breeding bird populations (e.g. Van Aarde, 1980; Moors & Atkinson, 1984; King, 1985; Veitch, 1985; Bloomer & Bester, 1992; Bester, et al., 2002; Keitt, et al., 2002; Pontier, et al., 2002; Blackburn, et al., 2004; Martinez-Gomez & Jacobsen, 2004; Nogales, et al., 2004; Ratcliffe, et al., 2009; Bonnaud, et al., 2010). Feral cats have been known to drive numerous extinctions of endemic species on islands and have contributed to at least 14% of all 238 vertebrate extinctions recorded globally by the IUCN (Nogales, et al., 2013). In addition, predation by feral cats currently threatens 8% of the 464 species listed as critically endangered (Medina, et al., 2011; Nogales, et al., 2013). Island faunas that have evolved for long periods in the absence of predators are particularly susceptible to cat predation (Dickman, 1992). Dirk Hartog and Christmas Islands, both documented as high biodiversity islands are no exception.

Dirk Hartog Island (DHI), an area of 620 km^2, is the largest island off the Western Australian coast (Abbott & Burbidge, 1995). Since the 1860s, DHI has been managed as a pastoral lease grazed by sheep (*Ovis aries*) and goats (*Capra hircus*). More recently, tourism has been the main commercial activity on the island undertaken by the former pastoralist family, the only permanent inhabitants on the island. Cats were probably introduced by early pastoralists and became feral during the late 19th century (Burbidge, 2001). Ten of the 13 species of native terrestrial mammals once present are now locally extinct (Baynes, 1990; McKenzie, et al., 2000) probably due to predation by cats (Burbidge, 2001; Burbidge & Manly, 2002; Algar, et al., 2011a). The house mouse (*Mus musculus*) has become established on the island, but other invasive species such as European rabbit (*Oryctolagus cuniculus*), red fox (*Vulpes vulpes*) and black rat (*Rattus rattus*) are not present.

Christmas Island (CI) occupies an area of 135 km^2 and is famous for the annual migration of tens of millions of red crabs (*Gecarcoidea natalis*) (Orchard, 2012; Misso & West, 2014). CI has a resident multi-cultural population of 2,239 residents (2015 records, <http://www.abs.gov.au/>), predominately Chinese, Malays and Europeans, who reside on the north-eastern tip of the island. Phosphate mining is a major economic driver on the island, with ecotourism becoming increasingly important. Cats were taken to CI at the time of first settlement in 1888 and a feral population established soon thereafter (Tidemann, et al., 1994). Four of the five mammal and two reptile species that were present on the island at settlement have since become extinct, with the introduction of cats playing a crucial role (Beeton, et al., 2010; Martin, et al., 2012). Two endemic rats, the bulldog rat (*Rattus nativitatis*) and Maclear's rat (*R. macleari*) disappeared shortly after black rats were introduced in 1900 (Green, 2014). In addition, several extant CI birds are listed as species likely to be adversely affected by cats (Beeton, et al., 2010).

Across Australia, cats have caused or contributed to population declines and extinctions on many offshore islands (Dickman, 1992; Dickman, 1996; Burbidge, et al., 1997; Burbidge, 1999). Today, the impact of cats is broadly acknowledged and control of feral cats is recognised as one of the most important fauna conservation issues in Australia. As a consequence of this, a national 'Threat Abatement Plan (TAP) for Predation by Feral Cats' has been developed (EA, 1999; DEWHA, 2008; DE, 2015). The TAP seeks to protect affected native species and ecological communities, and to prevent further species and ecological communities from becoming threatened. In particular, the first objective of the TAP is to "prevent feral cats from occupying new areas in Australia and eradicate feral cats from high-conservation-value islands".

DHI was established as a National Park in November 2009, and this now provides the opportunity to reconstruct the native mammal fauna (Algar, et al., 2011a). The island could potentially support one of the most diverse mammal assemblages in Australia and contribute significantly to their long-term conservation. Successful eradication of feral cats is considered to be a necessity prior to reintroductions. Similarly, the impact of cats on much of the biodiversity of CI has been of significant concern to island land management agencies and local residents. Eradication of cats on the island is necessary to mitigate the socio/health impacts and threat to those remaining extant species and to allow successful re-wilding of species such as the blue-tailed skink (*Cryptoblepharus egeriae*) that are currently restricted to captive breeding programmes.

The islands differ markedly in environmental and human factors but are linked in the agencies involved, that have iteratively resolved site-specific challenges associated with the removal of cat impacts on wildlife populations. In this paper we outline the cat eradication programmes currently underway on both islands, describe the strategies, techniques and application methodology and provide an update on the campaigns' progress.

MATERIALS AND METHODS

Site descriptions

DHI (25° 50’ S, 113° 0.5’ E) lies within the Shark Bay World Heritage Property of Western Australia, 1.5 km from mainland Australia. The island is approximately 79 km long and a maximum of 11 km wide with its long axis in a south-east to north-west direction. Detailed description of geology and vegetation is provided elsewhere (Beard, 1976; Payne, et al., 1987; Algar, et al., 2011a). The climate of the region is ‘semi-desert Mediterranean’ (Beard, 1976; Payne, et al., 1987). The mean annual rainfall for Denham, located 37 km to the east of DHI is 224 mm (Bureau of Meteorology, 2017; long-term records 1893–2016).

CI (10° 25’ S, 105° 40’ E) is located in the Indian Ocean, 360 km south of the Indonesian capital of Jakarta. The oceanic island is composed primarily of Tertiary limestone overlying volcanic andesite and basalt (Tidemann, et al., 1994; EA, 2002). The island consists of a series of fringing limestone terraces, separated by rugged limestone cliffs and scree slopes, rising to an internal central plateau at about 200 m and extending to 360 m above sea level. A National Park was established in 1980 and extended in 1986 and 1989 to include most of the rainforest; it now covers 63% of the island (EA, 2002). There are four main vegetation types described in detail by Claussen (2005). CI has a typical tropical, equatorial climate with a wet and a dry season. The wet season is from December to April when the north-west monsoon blows. For the rest of the year south-east trade winds bring slightly lower temperatures and humidity, and much less rain. The island has a mean annual rainfall of 2,183 mm, high humidity (80–90%) which varies little between months and consistent temperatures (mean daily temperature: 22.9–27.4° C) (Bureau of Meteorology, 2017).

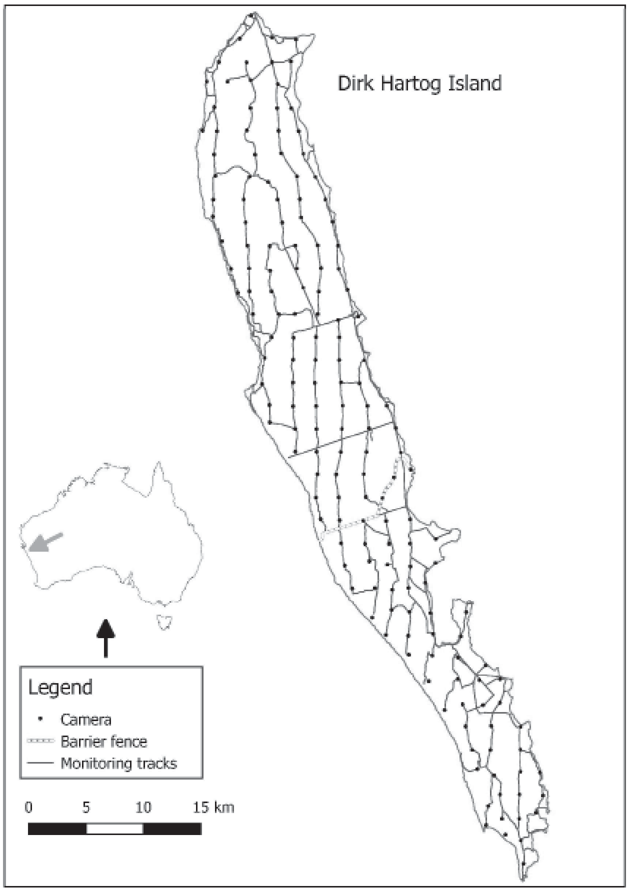

Fig. 1 Dirk Hartog Island.

Planning

To date, feral cats have been successfully eradicated from four Western Australian offshore islands: Serrurier Island (Moro, 1997); Hermite Island in the Montebellos (Algar, et al., 2002); Faure (Algar, et al., 2010) and Rottnest Islands (Algar, et al., 2011b) to enable reconstruction of the original fauna or protection of extant species. These successes and knowledge gained provide the confidence to tackle the more ambitious challenges of DHI and CI. There is a number of key elements used in the operational planning of a successful eradication strategy. The plan may include a pilot study that assesses the efficacy of proposed techniques as well as documenting the procedures to be used in the sequenced eradication phases, the monitoring programmes and the surveillance period prior to verifying eradication has been achieved. Plans for the DHI/CI eradication programmes build strongly on previous research conducted on both islands that examined eradication and monitoring techniques (Algar & Brazell, 2008; Algar, et al., 2010; Algar, et al., 2011a).

Central to the planning for DHI was the construction of a 13 km cat barrier fence. The island’s size, in particular its length, poses logistical constraints on conducting an eradication campaign across the entire island simultaneously. It is not practical to monitor for cat activity over such a large area and therefore, the eradication campaign is being conducted in stages either side of the barrier fence. The fence was constructed with a ‘floppy top’ and electrical hotwires facing to the north to prevent reinvasion of the southern area once it had been cleared (see Fig. 1). Use of a barrier fence has been demonstrated to reduce the cost and increase the overall likelihood of successful eradication on the island (Bode, et al., 2013).

Crucial in the planning for CI was the presence of a domestic cat population. Key land management agencies initiated the preparation of a cat management plan as a critical first step. The plan (Algar & Johnston, 2010) was developed with these agencies, interest groups and the broader community. It was supported and endorsed by the various organisations and has been embraced by the public. Initially, local cat management laws were revised to include a prohibition on the importation of cats, promoting responsible cat ownership, compliance and enforcement of cat management laws. A staged approach to eradicate cats entirely from the island has been adopted, which is complemented by the gradual decrease of owned cats as the de-sexed domestic population dies out. The amended local legislation required all domestic cats to be neutered, micro-chipped and registered with the Shire (Stage 1). Surveys of domestic cats and veterinary programmes are outlined by Algar, et al. (2011c) and Algar, et al. (2014). Stage 2 requires the removal of all stray cats within the township. Without implementation of Stage 2 a significant source of cats, particularly natal recruits, would be available to disperse into or reinvade territories vacated across the rest of the island. Stage 3 involves the implementation of the island-wide (i.e. the national park, mine leases and Unallocated Crown Land) feral cat eradication programme.

Eradication effort

Baits and baiting application

Baiting is recognised as the most effective method for controlling feral cats on mainland Australia (Short, et al., 1997; EA, 1999; Algar & Burrows, 2004; Algar, et al., 2007; Algar, et al., 2013), and has been used as the primary technique for eradicating cats on islands (Algar, et al., 2002; Algar, et al., 2010). World-wide, cat eradications have been attempted on a number of islands with 82 successful campaigns that range in size from 5–29,000 ha (Campbell, et al., 2011). There have also been eradication attempts on a further 15 islands that have failed (ibid.). All successful campaigns on islands >2,500 ha used primary poisoning with toxic baits, with the exception of Santa

Catalina (3,020 ha). Interestingly, seven failed campaigns on the five largest islands (all >400 ha) did not use toxicants (Campbell, et al., 2011). A locally developed bait known as *Eradicat*® (Algar & Burrows, 2004) containing 4.5 mg of directly injected toxin ‘1080’ (sodium monofluoroacetate) is used on both DHI and CI.

The primary eradication technique to be used in the DHI programme was aerial baiting. A pilot study conducted during March–May 2009 assessed the efficacy of this strategy (Johnston, et al., 2010; Algar, et al., 2011a). This achieved very positive results with 80+% of the feral cat population poisoned following bait consumption (ibid). These results demonstrated that a baiting programme, with the *Eradicat*® bait as the primary eradication technique, could be highly effective on DHI.

Deployment of baits from an aircraft was not considered feasible on CI at the commencement of this campaign due to the removal of baits by the abundant land crabs. However, targeted aerial baiting into discrete difficult to access areas is now being contemplated for late in the dry season when land crabs are less active (Johnston, et al., 2016). Preliminary baiting exercises on the island where baits were placed on the ground, highlighted the potential problem of non-target species removing ground-laid baits. Red crabs, robber crabs (*Birgus latro*), which dominate the forest floor, black rats and feral chickens (*Gallus domesticus*) readily removed baits laid on the ground. Bait removal by non-target species reduces bait availability to feral cats and therefore eradication efficacy. In a later trial, Algar & Brazell (2008) demonstrated a device to suspend baits above the ground that effectively reduced bait removal by non-target species yet provided ready access to feral cats. A key finding from this trial was that the bait suspension devices (BSD) would provide an effective primary cat eradication technique on the island. During the eradication campaign, BSD are located at 100 m intervals on both sides of the extensive 160 km road/track, staggered at 50 m intervals across the road/track. Each BSD suspends two *Eradicat*® baits tied at the link, considered a single bait for analysis purposes, at a height of about 550 mm using 6–8 lb fishing line. Baits are replaced when taken and as required to maintain palatability. Suspended baits were also deployed off-track throughout the forest at 50 m intervals in 2015 and, due to unprecedented rainfall, to a lesser extent in 2016.

The total number of toxic baits removed indicates the maximum number of individuals poisoned. The minimum number of individuals poisoned is calculated by ascribing bait removals from consecutive BSDs to the same animal. The actual number of feral cats poisoned would be between these two extremes. While one *Eradicat*® bait contains a lethal dose, it is likely that some cats would visit multiple BSDs given the delay between bait consumption and death.

Trapping

Trapping programmes are being used as the secondary eradication effort to remove those animals that survive the baiting programmes. On DHI, cats are being captured in padded leg-hold traps; (Victor ‘Soft Catch’□ traps No. 3 (Woodstream Corp., Lititz, PA.; U.S.A.) using a mixture of cat faeces and urine as the lure. Trapped cats are destroyed using a 0.22 calibre rifle. All animals captured are sexed and weighed; a broad estimation of age (as either kitten, juvenile or adult) is recorded using weight as a proxy for age. The pregnancy status of females is determined by examining the uterine tissue for embryos. Stomach contents are removed for diet analysis and a sample of hair and tissue taken for DNA microsatellite profiling. Also, prior to the commencement of the two aerial baiting programmes, a number of cats were trapped and fitted with a GPS data-logger/radio-telemetry collar (Sirtrack Ltd, New Zealand). Mortality of radio-collared animals following the baiting programmes was used to provide a measure of baiting efficacy.

On CI, the trapping programme commenced in the township to remove stray cats. Initially, cage traps were used rather than padded leg-hold traps to minimise the risk of injury to domestic cats. Cats were captured using wire cage traps (60 × 20 × 20 cm) with treadle plates (Sheffield Wire Products, Welshpool, Western Australia). All traps were covered with a hessian sack to provide shelter and protection to the captured animals until they could be collected. The traps were usually baited with cooked chicken wings. Outside the township, elevated trap platforms (ETPs) – where trap sets are raised above ground level – are used to exploit cats’ agility and ability to jump, while preventing trap interference from ground-dwelling non-target wildlife such as land crabs. Traps along roads and tracks are generally set on cleaned half 200 l fuel/oil drums in the same configuration and lured as ground sets on DHI.

Monitoring

Monitoring programmes use evidence of actual presence through camera trap images, spotlight records and sign, whether it be footprints, scats or hair, to detect the presence/absence of individuals in an area. In eradication campaigns, monitoring programmes provide information on where further effort is required and whether additional measures and/or resources are needed. A key component of these eradication campaigns is to employ monitoring methods that will provide quantitative estimates of the effectiveness of eradication operations; the techniques must also be capable of detecting animals at low density populations. The physical characteristics of DHI and CI differ significantly and required the adoption of a different suite of monitoring techniques across the two islands.

Of necessity, the monitoring of feral cat activity must be conducted across the entire island. CI has an extensive road/track network (see Fig. 2) whereas, on DHI, much of the former pastoral road network has regenerated, with many roads and fence lines being impassable. The monitoring programme on DHI is being conducted from All Terrain Vehicles (ATVs) which can traverse the entire island in a safe and efficient manner. Prior to implementing the monitoring programme, it was necessary to construct a network of survey tracks to allow monitoring of cat activity across the island. The spacing of these tracks

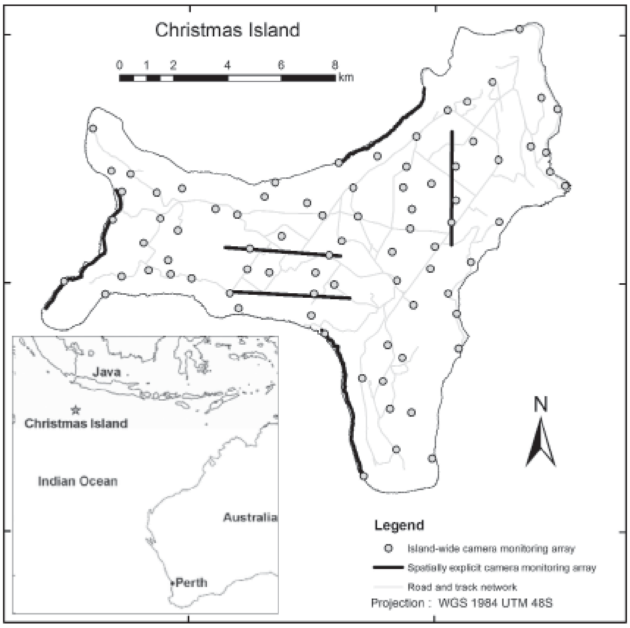

Fig. 2 Christmas Island.

needed to permit detection of any cat during the survey period (i.e. two weeks each month) and therefore provide confidence in the sensitivity of the survey technique. Information obtained from the GPS data-logger radio-collars during the pilot study (Algar, et al., 2011a) was used to determine the likelihood of detection and to optimise the proposed spacing of the survey tracks for the eradication programme. Track lines were parallel to the long axis of the island and the orientation of the dune system. This was the preferred course for survey tracks for logistic reasons and also to minimise disturbance and erosion to dunes. Analysis of daily movement patterns, pooled for all cats, suggested that placement of monitoring tracks at a width of approximately 2.0 km across the full length of the island (see Fig. 1) would be sufficient to enable detection of these animals within each survey period. Choice of this spacing for the monitoring tracks and separation of camera traps (see later) was further strengthened by data collected on home ranges (100% Minimum Convex Polygon) of the radio-collared cats in the pilot study which were 12.7 km^2 for males and 7.8 km^2 for females (Johnston, et al., 2010). Thus, every cat has a very high probability of its sign being observed over a 10-day monitoring period (Algar, et al., 2011a).

Camera trapping

Camera trap studies are useful in providing information on feral cat presence/absence and provide an ideal technique for monitoring the impact of eradication measures through the progression of the eradication campaign as they will allow remote monitoring of cats following each period. On DHI, camera traps were established at 2 km intervals along and overlooking the track network with 105 Reconyx HC600 (Reconyx, Wisconsin; USA) cameras north of the barrier fence and 64 cameras to the south (see Fig. 1). Additional cameras were installed at key locations such as fence ends and around the tourist resort on freehold land. A variety of visual, olfactory or audible attractants were used at camera sites, including no lure. On CI, 84 Scoutguard SG-560C (HCO Outdoors, Norcross, GA, USA) non-lured camera traps were located approximately 1.0 km apart in an island-wide array, with six spatially explicit transects nested within (see Fig. 2). Occupancy analysis and spatial mark/resight modelling was conducted to estimate density over time (The Analytical Edge Pty Ltd., Hobart, Australia).

Sign searches

The sandy surface on DHI enables the search and detection of cat footprints. The network of management tracks is searched daily by skilled observers riding ATVs over a 10-day period on a seasonal basis, that is, four times per year. Circuits ranging in length from 80–140 km, are ridden at a speed of <20 km/h which is adequate to identify footprints on the track surface. The observers alternate the direction of travel and the circuit they inspect on a daily basis. The track surface on CI is hard and does not lend itself to identification of footprints. Other sign monitoring techniques are currently being developed that will complement the use of camera traps to survey for cat activity.

Surveillance period and independent verification

The final phase of the campaign on DHI, an intensive and simultaneous island-wide surveillance period was initiated in October 2016 on the belief that that eradication had been achieved. Assuming no more cats are found, this third phase is expected to be of a two-year duration and will be used to confirm eradication success in October 2018.

On DHI, surveillance monitoring for cat activity is being conducted over a 10-day period in each of the southern and northern sectors every three months. Surveillance monitoring is employing both camera trap recording and cat sign searches. The cat sign searches are being conducted along the pre-existing tracks and the monitoring grid network. Opportunistic cat sign searches along beaches and other areas of interest (e.g. caves and seabird colonies) are also being conducted. The monitoring is undertaken across the entire zone the same day to avoid any issues associated with cat movement.

In addition, on DHI specialist detector dogs and their handlers (Latitude 42 Environmental Consultants Pty Ltd., Tasmania, Australia) have been contracted to further independently verify the absence of cats and corroborate that eradication has been successfully achieved. A team of six dogs and experienced handlers undertake the intensive search effort for cat sign during the winter when weather conditions are the most favourable.

On CI, surveillance monitoring, which is yet to commence, will primarily utilise the island-wide camera array with a range of lures as on DHI. Detector dogs are not being considered for use on CI because of quarantine regulations for re-importation back onto the mainland, the difficult terrain and cultural issues associated with the presence of dogs on the island. A community reporting system will be maintained as well as implementing an intensive and comprehensive spotlighting effort around the island.

Finally, independent verification of eradication success on both islands is to be undertaken by an impartial organisation using data summaries provided.

RESULTS

Dirk Hartog Island

Logistical issues associated with transport of fencing materials prevented construction of the fence on DHI until following the completion of baiting monitoring in 2014. As a result, most of the island (90%) was baited in 2014. However, once completed, the fence alignment has played a key role in restricting the ranging of cats on the northern side.

Data on cat home range size and degree of overlap from the 2009 pilot study were used to derive a best estimate of cat population size pre-eradication effort. This analysis, with multiple assumptions, suggested that a total of 439 cats (range 309–503) was likely present prior to the eradication campaign. Prior to the first baiting campaign in 2014, 17 cats were trapped and fitted with VHF/GPS collars in the southern zone during April 2014. Trapped cats were released at the location of capture. Of these, fifteen were known to be alive when *Eradicat*® baits were applied on the 27–28 May. Fourteen of these animals (>90%) died following bait consumption. The fate of the remaining cat is uncertain but as it was last detected alive in June 2014 and has not be relocated by VHF or photographed since this time. Five cats were trapped, fitted with VHF/GPS collars and released at the location of capture in the northern sector in April 2015 prior to the second baiting programme. All were alive when baits were applied on 25 May 2015. Only one of these cats died following consumption of an *Eradicat*® bait, the remaining four were recovered by trapping. The combined monitoring programmes have detected 36 individual cats that survived the baiting programmes and these animals have subsequently been trapped. January and April seasonal surveillance programmes have failed to detect the presence of any further cat activity. Detector dogs did not locate any fresh sign of cat activity south of the barrier fence in 2016 and examine the area north of the fence during July 2017.

Christmas Island

One hundred and eighty-four domestic owned cats have been registered on CI since 2010, with only 74 domestic cats remaining at the conclusion of the 2017 domestic cat survey. Deregistered cats had either died from natural causes or road fatalities, or were euthanised as the owners had moved off-island. Although the programme on CI commenced in late 2010, funding to commence the island-wide eradication effort (Stage 3) was not secured until 2015. Short-term control programmes were conducted around the township in 2013 and 2014 to protect the significant investment and gains achieved in controlling stray cats until a new source of funding could be obtained. Over the period 2011 to 2015, 336 stray/feral cats were trapped within the township and a further 216–311 were poisoned along roadsides/tracks that surrounded the area. From 2015 to 2017, cage trapping removed 46 stray cats within the township, outside the township limited ETP leg-hold trapping resulted in the removal of (12), shooting (11) and roadside BSDs a further (158–216) cats. An unknown number of cats was removed from forest baiting in 2015 and 2016 due to uncertainty in determining bait uptake by cats. Based on the upper and lower estimation method of baits taken on BSD, between 779–932 stray/feral cats have been removed since 2010. Preliminary results from the 2016 island-wide array camera monitoring estimated that a population of 225 (SE=23) feral cats remains across the island.

DISCUSSION

Globally, the Dirk Hartog project will become the largest island feral cat eradication campaign attempted to date and Christmas Island is a relatively large island with significant human inhabitation. The restoration of former species richness on DHI and recovery of the threatened wildlife populations on CI has required management of feral and domestic cats. The strategies used to achieve the reduction in cat populations have been tailored to suit the specific circumstances applicable to each island. Perhaps the largest challenge on DHI was to ensure that the monitoring tools were sufficiently sensitive given the scale of the island. Removal of cats from Christmas Island is characterised by improving the management of owned cats as well as mitigating the impact of land crabs on poison baiting operations. The guiding principles for successful eradication (Bomford & O'Brien, 1995) have been successfully met in both of these island programmes, although it is worth noting that maintaining the appropriate socio-political environment has been an ongoing and time-consuming component of both programmes. The eradication programmes on both islands have followed a logical progression of intensiveness that aimed to reduce the population rapidly from base levels and then use follow-up trapping to target remaining cats, that is, initial population knockdown with a low cost/broad-scale method followed by high cost/labour intensive mopping up. The monitoring programmes suggest that the cat populations have been reduced to low (CI) or non-detectable (DHI) levels bearing out the prescriptions provided in the operational plans.

Residents on CI have been involved in the development and maintenance of the owned cat population. This has also involved a compliance programme and importation ban that was necessary to maintain the closed population. Maintaining quarantine on DHI has been a more straightforward process given that one family is involved who are invested in the ecological restoration of the island given the anticipated benefits to their tourism enterprise.

Poison baiting has formed a critical part of the eradication tools on both islands but the variable results achieved in these programmes should be noted in preparation for similar programmes in the future. A low baiting efficacy consequently leads to a requirement for greater follow-up control with respect to investments in time and labour. A probable explanation for the observed differences in baiting success in 2014 and 2015 on DHI relates to the meteorological factors at the time of baiting. Just prior to 2014 baiting, a pulse of cooler weather was recorded which would have had the effect of reducing the availability of alternative prey such as small reptiles and mammals. In contrast, the 2015 season was characterised by a rodent irruption that may have been triggered by rainfall associated with Tropical Cyclone Olwyn. On CI, unprecedented rainfall in 2016 reduced baiting efficacy significantly and prompted the development of alternative trap sets that were effective under wet conditions. Alternative removal tools, such as different trap sets, must be ready to implement in situations where baiting is less successful (Robinson, et al., 2015). Project governance and budgeting would ideally include sufficient contingency to adapt or permit operational flexibility to account for environmental factors that influence on-ground outcomes (Springer, 2016).

Ultimately, the success of these programmes will be measured by the response of native wildlife species. On CI, there has been a dramatic increase in the nesting success rate in the red-tailed tropicbird (*Phaethon rubricauda*) populations following improvement in the management of urban cats (Algar, et al., 2012) as well as anecdotal reports of a positive response in forest birds such as the Christmas Island emerald dove (*Chalcophaps indica natalis*). It is premature to make claims about the recovery of extant species on DHI other than to note detections of species on cameras which were not detected in 2014. These include the little long-tailed dunnart (*Sminthopsis dolichura*), painted button quail (*Turnix varius)* and bush stone curlew (*Burhinus grallarius*). The wildlife response on DHI will be intensively monitored in subsequent years during the ecological restoration of the island.

ACKNOWLEDGEMENTS

The Dirk Hartog Island Ecological Restoration Project is funded by the Gorgon Barrow Island Net Conservation Benefits Fund. The DHI cat team comprises Gary Desmond, Jason Fletcher, Neil Hamilton, Mike Onus and Cameron Tiller. The Christmas Island Cat Eradication Project is currently funded by the Director of National Parks, the Threatened Species Commissioner and an environmental mining offset acquired from Phosphate Resources Ltd (Christmas Island). Funding has also been provided by Department of Infrastructure and Regional Development, the Shire of Christmas Island, Christmas Island Phosphates and Border Force. The CI cat team comprises Neil Hamilton, Jason Fletcher, and Cameron Tiller together with the island-wide survey baiting team Dion Maple, Rob Muller, Samantha Flakus, Matt Hudson, Tanya Detto, Jol Muller, Trent Lane, Joanna Chan, Simone Richardson, Brendan Tiernan, Renata de Jonge, Jason Turl, Sean White, Simon Pahor and John Jaycock. The Department of Biodiversity, Conservation and Attractions Animal Ethics Committee approved protocols 2009/35, 2012/41 and 2015/39 which describe activities undertaken in this project.

Abstract The Orkney Islands, off the north-east coast of Scotland, support highly significant cultural and natural heritage. The combined land area of the 70 islands is 990 km^2 (380 sq mi), <1% of the UK, but they host over 20% of the UK's breeding hen harriers (*Circus cyaneus*) (declining over much of its mainland range), 8% of breeding curlews (*Numenius arquata*) (one of only two UK populations not in decline) and an internationally important assemblage of breeding seabirds. The Orkney Islands are naturally free of mammalian predators, and all bird species, including raptors, are ground-nesting in the largely treeless landscape. Rats (*Rattus* spp.), hedgehogs (*Erinaceus europaeus*) and feral cats (*Felis catus*) are present across the archipelago. Stoats (*Mustela erminea*) are native to mainland UK but not Orkney, yet were detected on Orkney Mainland in 2010. Orkney Mainland has an area of 523 km^2 (202 sq mi). Early attempts at removing them were not successful. By 2013 stoats were present across the Orkney Mainland and connected isles. In 2016, SNH and RSPB formed a partnership to eradicate stoats to protect the native wildlife and designated sites of the Orkney islands, and to secure the wider socio-economic and cultural benefits of thriving native wildlife. Difficulties faced in developing the project include predicting the effort required to remove stoats at a rate faster than they can reproduce, securing community support and access to private land and, in particular, funding large scale biodiversity restoration projects. A feasibility study determined that stoat eradication would be possible using DOC200 kill traps, and search dogs in later stages of the eradication. There are no legally available poisons that could be used on stoats in the UK. A Biosecurity Plan has been produced for the archipelago, with a current focus on preventing the spread of stoats to the un-invaded isles. The partnership is working to secure funds and community support for what will be the world's largest stoat eradication attempted to date. We present the findings of the feasibility study and our proposed methodology.

Keywords: biosecurity, feasibility, hen harrier, Orkney vole, predator eradication, Scotland, short-eared owl

INTRODUCTION

The Orkney Islands are situated 10 km from the north-east coast of Caithness, at the northernmost point of mainland Scotland. The archipelago is made up of around 70 islands, of which 20 are inhabited with a total population of around 21,000 residents (National Records of Scotland, 2016). The largest island, Orkney Mainland, is some 523 km^2 and is home to 75% of the human population. The islands of Burray and South Ronaldsay are connected to the Orkney Mainland by causeways carrying road infrastructure. The remaining islands are not physically linked, and are reachable via air or inter-island ferry.

Orkney supports a wide range of natural and cultural heritage for which it is world-famous. There is abundant native wildlife with seabirds, ground-nesting and wading birds, corncrake and sea mammals – all important parts of the ecosystem. Although the islands represent only 0.4% of the UK land area, they are home to a significant proportion of native UK seabirds and terrestrial species. About 14% of the UK breeding kittiwake (*Rissa tridactyla*) population, 34% of arctic skua (*Stercorarius parasiticus*), 10% of puffin (*Fratercula arctica*), 25% of arctic tern (*Sterna paradisaea*) and 14% of the global population of breeding great skuas (*Catharacta skua*) are found in Orkney. Orkney is a UK stronghold for hen harrier (*Circus cyaneus*) and short-eared owl (*Asio flammeus).* Over 20% of the UK population of hen harrier is known to breed in Orkney. The islands are one of the few remaining core areas for breeding corncrake (*Crex crex*) and a stronghold for breeding waders and especially the curlew (*Numenius arquata*) – the UK's highest conservation priority bird species. At a time of large-scale decline across the UK, wader populations in the lowlands of Orkney are thought to be stable or increasing, bucking the national and global trends. Densities in these areas are amongst the highest recorded in Europe.

The quality and importance of Orkney's natural heritage is recognised through the number of nationally and internationally designated sites across the islands. These cover approximately 30% of the islands' land area. There are 13 Special Protection Areas (SPAs), strictly protected sites for rare and vulnerable birds, and for regularly occurring migratory species, under the EU Birds Directive, as well as five Special Areas for Conservation (SACs) which offer strict protection for threatened habitats under the EU Habitats Directive. Orkney also has 36 Sites of Special Scientific Interest (SSSIs), a designation for sites which best represent Scottish natural heritage and are designated under the Nature Conservation (Scotland) Act 2004; one National Scenic Area (NSA), a designation representing Scotland's finest landscapes; two nature conservation Marine Protected Areas (NC MPAs), nature conservation sites in the marine environment designated under the Marine (Scotland) Act 2010; and three proposed marine SPAs. The unique natural and historic heritage of the islands underpins Orkney's distinctive culture and economy and supports a thriving tourism industry.

Although stoats (*Mustela erminea*) are native, widespread and common throughout mainland Britain and Ireland they are not native to the Orkney archipelago. The first confirmed sighting of a stoat in Orkney was reported in August 2010, following verbal reports of possible sightings in June and July of the same year. It is not known how stoats arrived in Orkney; possible vectors include accidental release from imported hay or straw, shipping, or deliberate release (e.g. to control rabbits). Sightings of stoats reported to Scottish Natural Heritage (SNH) have increased in frequency and stoats are now considered to be present across the entire Mainland and linked isles.

This paper examines the risks to Orkney's native wildlife from the impact of predation by stoats and describes efforts to date to deal with the problem. We present the findings of the feasibility study into eradication, our proposed methodology for eradication and outline some of the major challenges to what will be the largest removal of stoats anywhere in the world.

MATERIALS AND METHODS

This paper summarises the results and discussions arising from stoat sightings across the islands, a desk study conducted to predict the likely impact of stoats on native wildlife, an independent technical feasibility study of stoat eradication (Harper, 2017a), and a Biosecurity Plan (Harper, 2017b) which identifies measures to prevent increase in range and re-colonisation post-eradication.

RESULTS

Likely impact of stoats

When stoats are introduced into ecosystems that have no native mammalian predators, such as those of the Orkney islands, they can have a devastating impact on the native species present. In New Zealand, the stoat is thought to be the main driver of declines and some local extirpations of many native bird populations (Dowding & Murphy, 2001). A desk study that was conducted predicts that the ecological consequences of stoat introduction to Orkney are likely to be devastating (Fraser, et al., 2015). It is highly likely that the presence of stoats on Orkney will have a catastrophic effect on ground nesting birds and mammals on Orkney due to the absence of other mammalian predators including the red fox (*Vulpes vulpes*) "*... it is highly likely that the introduction of stoats will profoundly change the ecology of Orkney and its value for birds of prey and the SPAs that have been designated for protecting these species.*" (Fraser, et al., 2015). Stoats have never been part of the ecosystem in Orkney and therefore many native species, cannot respond rapidly enough to the introduction of this predator. The potential scale and range of the impact of this non-native predator is such that little wildlife in Orkney is currently safe. Impact will be of national and international significance due to the proportion of populations living on the islands.

One critical linkage within the Orkney ecosystem is the predator-prey relationship of the Orkney vole with the hen harrier and short-eared owl. Fraser, et al. (2015) suggest that a decline in Orkney voles will have direct consequences on the hen harrier and short-eared owl populations because both of these species rely to varying extents on the Orkney vole as a component of their diet. The short-eared owl has developed a specialist hunting behaviour to match Orkney vole activity (Reynolds & Gorman, 1999). A range of evidence suggests that the abundance of Orkney voles (which do not display the cyclical population abundance observed in other *Microtus* species) is directly linked to the breeding success of the hen harrier and short-eared owl. It is therefore suggested that significant depredation of voles by introduced stoats will have an indirect detrimental impact on these species. The RSPB Orkney reserves data on numbers of hen harriers fledging suggests a sustained decline which started in 2011 (RSPB 2016, unpublished data). In relation to other species, Fraser, et al. (2015) raise concerns over a range of ground-nesting birds including curlew (another bird on the UK Red list of conservation concern), as stoats are well known to be significant predators, especially where other terrestrial mammalian predators such as foxes are absent, as is the case in Orkney – and so curlew and similar birds are now under severe risk.

Whilst there are other threats to Orkney's native wildlife, including climate change and changes in land management practices, the stoat is considered to be the most pressing and widespread current threat.

Decline in the native wildlife populations is predicted to have a significant effect on socio-economic benefits that Orkney's nature and landscapes provide in terms of tourism and farming. The 2012–2013 (the most recently completed) Islands Visitor Survey (Visit Scotland, 2013) shows that just over 142,800 people visited Orkney, spending over £31 million in the local economy over the period of a year. The main influence on visitors deciding to come to Orkney was an interest in the archaeology and history of Orkney, followed by the scenery and landscape. Given the importance of wildlife tourism to the overall tourism market in Orkney, the predicted declines of many native species caused by stoat predation is a cause for concern amongst tourism businesses.

Stoats are also predicted to affect free-range poultry operations. Free-range poultry farming is common practice in Orkney, where the absence of mammalian predators makes this an economically viable management option for poultry. If stoats continue to persist on the archipelago, future impacts on this industry are expected to include loss of stock to stoat predation as well as the financial impact of implementing predator control and mitigation measures.

Population expansion

No population estimates are available for the stoat population in Orkney, and the available information on their range comes from sightings reported by members of the public. Sightings (both those reported directly and through the 'Stoats in Orkney' Facebook page, maintained by interested local volunteers) have increased steadily since 2010, with a marked increase in sightings since 2016. However, caution must be used when correlating this to any indication of abundance of stoats. Press activity and awareness-raising campaigns by SNH and RSPB Scotland (including posters designed to increase recording of sightings – see Fig. 2) may have increased peoples' awareness of stoats. This could partially lie behind the recent increases in the rate of sightings, although no particular spikes in sightings have been recorded after media activity in the past (Fraser, et al., 2015). The overall distribution map of all sightings (Fig. 1) tends to reflect where people live, work and travel, rather than any accurate estimate of the distribution of stoats per se.

Stoats were first reported in two areas, one on Orkney Mainland and one on South Ronaldsay in 2010. Since this time their numbers and range have increased rapidly and they are now known to be distributed across Mainland

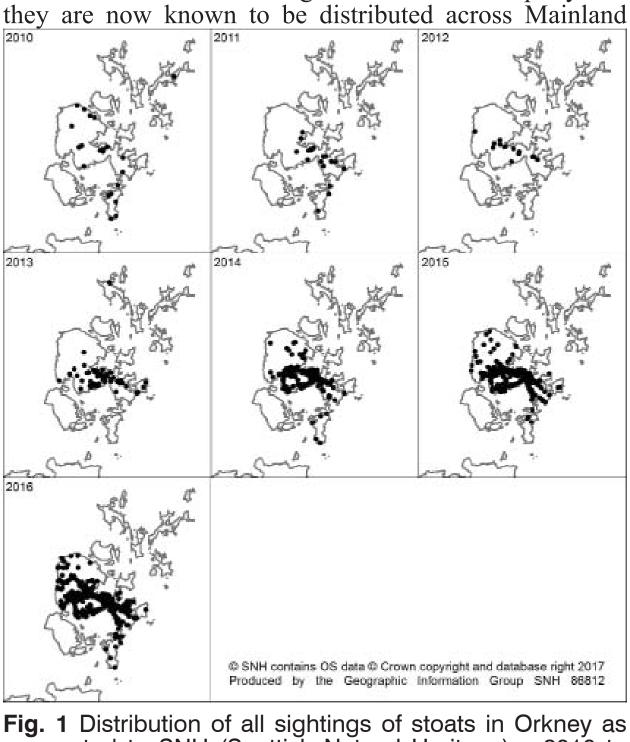

Fig. 1 Distribution of all sightings of stoats in Orkney as reported to SNH (Scottish Natural Heritage) – 2010 to 2016.

Fig. 2 Poster to raise awareness of stoats and their potential impact – and encourage sightings to be reported to SNH (Scottish Natural Heritage).

Orkney and the linked isles of Burray and South Ronaldsay (Fig. 1). Figure 3 shows the clear increase in sightings from 2010–2016. There are obvious seasonal peaks in stoat sightings which would correlate with seasonal activity of the animals (Fig. 4).

Although a number of live and lethal trapping efforts were implemented, they were unsuccessful in completely removing the species or controlling range and population growth. When stoats were first confirmed in 2010 an early 'rapid response' was put in place with volunteers using live traps to remove stoats from the two sites in South Ronaldsay and the west Mainland. Any stoats caught were relocated to mainland Scotland. This was most successful in South Ronaldsay where sightings decreased to two in 2011 and none at all in 2012 and 2013. However, it clearly did not remove the problem on West Mainland where sightings continued to be reported, and eventually increased in numbers and over a wider area.

In 2011–2013, SNH employed a contractor to remove stoats using kill traps mainly on the west Mainland, across an area of some 300 km^2 (115 sq mi). This was unfortunately unsuccessful, possibly due to inexperience of the contractor and/or an inadequate methodology. Fewer than five stoats were caught – nowhere near the numbers required to contain or remove the problem. In 2014, SNH recruited a relatively large number of volunteers from the local community following an awareness raising campaign and increasing concern from interested parties. Over 50 volunteers were trained in the use of kill traps and a trapping project was launched to remove stoats. The purpose of this project was three-fold; in addition to attempting to remove or control the spread of stoats, it was to test whether a large scale volunteer effort was feasible and sustainable in Orkney, and finally to trial approaches to data handling and management for an eradication project.

The volunteering project was ultimately scaled down in 2016 as it had been shown that sustaining a large volunteer force of this size was very resource intensive, few stoats (under 10) were trapped and keeping volunteers motivated when stoats were not being caught was very difficult.

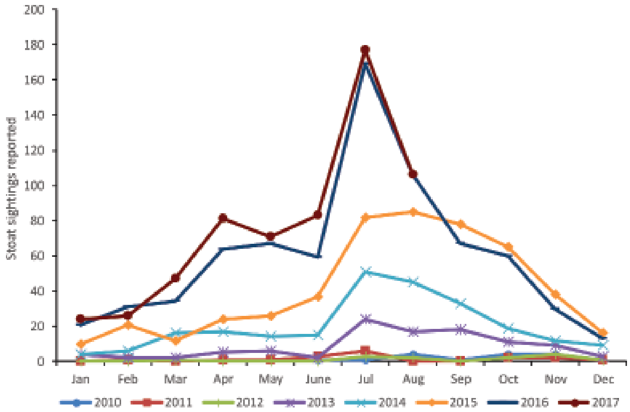

Fig. 3 Number of stoat sightings reported each month on Orkney between June 2010 and June 2017.

Feasibility of stoat eradication

A proposed methodology for eradicating stoats was initially developed by SNH following their experience gained during the Hebridean Mink Project (HMP) and the Uist Wader Project (UWP) which carries out live trapping and translocation of hedgehogs. It was revised following advice from the project's Technical Advisory Group (TAG).

This methodology and the technical, political and environmental feasibility of stoat eradication was assessed independently in an independent Technical Feasibility Study commissioned by RSPB Scotland and completed by Grant Harper of Biodiversity Restoration (Harper, 2017a) following best practice guidelines.

The feasibility study determined that an eradication project was feasible given the current range, but that a new methodology should be adopted. Draft costings were developed for this methodology to determine capacity to eradicate. This methodology has now been assessed by the TAG and adopted by the partnership.

The only legal method to remove stoats in the UK is humane trapping. There are no approved viruses or poisons available for use at present, nor are any likely to be approved within the time frame of eradication. The feasibility study identifies only NZ Department of Conservation (DOC) and Goodnature A24 self-setting traps as AIHTS (Agreement on the International Humane Trapping Standard) compliant in the UK. In Scotland only DOC traps are currently legally compliant. Dogs can be used to locate but not harm or kill an animal.

The legal circumstances surrounding land access are simplified as SNH has the power to issue a Species Control Order which allows them to compulsorily access land in order to control invasive species in the event that landowner permission is withheld. This is of course a last resort, and landowner permission, and the inclusion of landowning interests in the partnership, is of paramount importance.

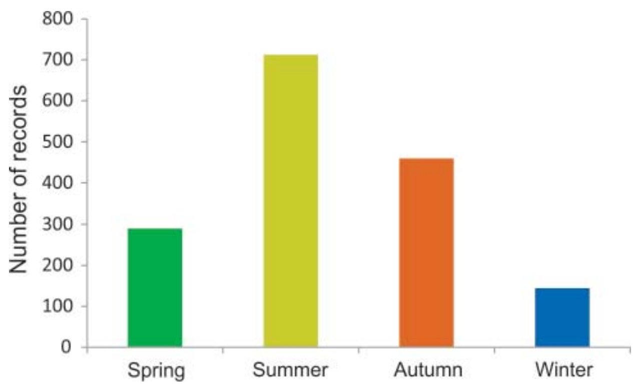

Fig. 4 Seasonality of reported stoat sightings on Orkney.

Environmental acceptability was assessed to determine if the impact of the project on native wildlife can be reduced to an acceptably low level and ensure eradication will not lead to permanent negative changes impact on non-target species. It is accepted that there is always a short-term risk to non-target species, and the project is designed so that this balances out to give a positive long-term change. Harper shows that the species most at risk are rats (which are also non-native to Orkney), but a smaller number of Orkney vole, mice and (potentially) small feral cats are also at risk (Harper, 2017a). However, based on New Zealand data, none of these bycatches are predicted to be of big enough volume to impact population size or stability of non-target species or will be anywhere near the estimated impact of stoats on their long-term populations (Harper, 2017a).

Setting and inspecting traps will inevitably create disturbance in areas of high breeding density for native wildlife. This risk will be minimised in the eradication phase by sensitive placing and minimising disturbance through remote monitoring of trap triggers. The effect of this is also asserted to be much less than the effect of stoats on the native wildlife.

To achieve eradication, a methodology must be implemented that removes animals at a rate faster than they can reproduce and target all of the animals within the population. Stoats in the UK can have home range sizes from 2–254 ha but average about 40 ha. Their home range in Orkney is unknown but a home-range analysis now, when the stoats still have room for expansion, would delay the project unacceptably. A precautionary approach is proposed that works on the assumption of the smallest home range size. This is considered to be required due to the year round food supply, density of food supply and novelty of the predator.

A methodology is proposed that uses a uniform trapping density of 16 traps per km^2 in the first instance. Baited DOC200 kill-traps in standard housing will be used and it is proposed that Goodnature A24 self-resetting traps are also deployed, to target trap-shy individuals that may avoid the DOC traps if these traps are made legal in Scotland. Dogs are also an option to locate trap shy individuals. Within the currently affected area, all land is considered easily accessible and well provisioned with access routes.

This density of trapping gives a total number of traps of 9270, each will be roughly 250 m apart based on a square grid. It is expected to take roughly two months to set these traps, based on 10 trappers setting 20–30 traps per day. Utilisation of habitats is likely to vary and it is expected that, in the largely open farmland habitat, stoats will use field margins that provide both cover and more food. In these habitats, traps will be set according to linear features including fences, walls, ditches, roads and tracks. The proposed grid will be used as a guide for the placement of the traps but trappers will have the discretion to move the traps up to 50 m from the proposed position to the best location on the ground for the interception of stoats.

Trap density and distribution in each habitat type will be reviewed as the project develops using an adaptive management approach.

Draft costings were developed to determine the financial feasibility and the capacity of the relevant organisations to deliver the project in a timely manner. These figures have been further developed by the partnership to ensure social feasibility through community support and involvement. The cost of the project is around £4.5 million. This resource is not available through government so external funding will need to be sourced.

The feasibility study did identify some aspects unique to this project and in particular interaction with the man-made environment. To date stoat eradications have been carried out in largely uninhabited areas so association and behaviour of stoats with areas such as gardens, and farmyards is not known. It is also worth noting that, whilst effectiveness of traps, baits and lures is well documented in New Zealand, this is less well known in the UK and there have been no trials on Orkney.

Biosecurity plan

Finally, the sustainability of the proposed project has been assessed through an RSPB commissioned independent biosecurity plan (Harper, 2017b) to determine if the likelihood of reinvasion is suitably low, or the risks of re-invasion can be reduced sufficiently, through affordable biosecurity measures. All potential invasion and re-invasion risks have been assessed. Two main pathways have been identified for the re-introduction of stoats to Orkney, firstly through intentional introduction and secondly accidentally through haulage of fodder and bedding. A high level of community engagement in an eradication and increased vigilance is considered to reduce the risk of intentional introduction and on-going use of sniffer dogs and an isolation and trapping method for cargoes to sufficiently reduce the risk of accidental re-introduction. It should be noted that this risk is considered small. For decades Orkney has had a high volume of bedding and fodder imported each year, but only the 2010 incident of stoat introduction. Measures can also be taken to reduce the source risk by wrapping and timely movement of bales.

The Biosecurity plan does identify a major risk of expansion to new islands. While no comprehensive survey of stoat population on Orkney has been carried out, the distribution and extent of stoat sightings across the whole of the Mainland and linked isles suggests that the stoat population has ended the invasion phase and it is suggested (Harper, 2017b) that they are at or near carrying capacity within the current range. There are over 60 islands that are still thought to be stoat-free. This means that the situation for stoats on Orkney is at a critical stage, as dispersal to other islands is highly likely. Stoats are thought to be good swimmers, and written accounts exist of stoats swimming 400 m in Ireland, and much further between islands in New Zealand (Veale, 2013), although this has not yet been observed on Orkney. There are many islands within theoretical swimming distance for stoats which could act as staging-posts for dispersing animals onto non-linked isles which are currently biological refuges. Whilst the plan clearly identifies eradication of stoats from the current range as the most effective biosecurity measure to prevent dispersal to new islands it is suggested that trapping on the Orkney Mainland can reduce the risk of spread until eradication can begin. There are five areas of Orkney Mainland coast that have been identified where stoat-free islands are within swimming distance. Immediate deployment of DOC traps in these areas will reduce risk of dispersal. Whilst eradication is considered currently feasible a successful eradication would already be three times greater in area than the largest successful eradication to date. Any extension of range, particularly to islands with less accessible land could make an eradication no longer technically or financially feasible.

DISCUSSION

Due to the native status of the stoat through most of the UK, there is little direct evidence of impact of stoat predation. However, due to the importance of the Orkney islands in a national and international context for wildlife, the SNH commissioned a report, assessing likely impacts of stoats on Orkney's native wildlife through comparison with impacts in other areas of the globe where they are not native. This report clearly demonstrates an ecological imperative to eradicate (Fraser, et al., 2015).

Our learning from early unsuccessful attempts to remove and contain stoats through volunteer response and small contracts has been put to good use in demonstrating that a full scale professional eradication project is required to deal with this issue.

An independent feasibility study (Harper, 2017a) has clearly shown that it is possible to eradicate stoats given the current range of presence across the Mainland and connected isles (as shown in Fig. 1). An assessment of sustainability has shown that we can sufficiently reduce the risk of re-invasion but that we must act now to prevent spread to other islands which could threaten feasibility of eradication (Harper, 2017b).

Since this work has been completed the SNH and RSPB Partnership have focused on developing a costed project, applying for funding for both the eradication and ongoing biosecurity measures, developing community support and implementing immediate biosecurity measures to prevent spread to more islands in Orkney.

We have developed a fully-costed plan, called the Orkney Native Wildlife Project, costing £4.5 million. We have applied to the Heritage Lottery Fund for support and are also in the process of developing and submitting two further grant applications for the eradication and supporting ongoing biosecurity measures. RSPB Scotland is about to commence biosecurity trapping measures on the Orkney Mainland, in accordance with the biosecurity plan. These measures will be kept in place until we start eradication. We also have developed a trial trapping phase within project development that will investigate success of traps, lures and baits in different habitats and will fill gaps in knowledge and be used to fine tune our trapping methodology.

The Orkney Native Wildlife Project is unique. It will be the first eradication of stoats in Europe, and also the first project to consider stoat eradication in areas which include urban and rural settlements.

Rhesus macaque eradication to restore the ecological integrity of Desecheo National Wildlife Refuge, Puerto Rico

Abstract A non-native introduced population of rhesus macaques (*Macaca mulatta*) was targeted for removal from Desecheo Island (117 ha), Puerto Rico. Macaques were introduced in 1966 and contributed to several plant and animal extirpations. Since their release, three eradication campaigns were unsuccessful at removing the population; a fourth campaign that addressed potential causes for previous failures was declared successful in 2017. Key attributes that led to the success of this campaign included a robust partnership, adequate funding, and skilled field staff with a strong eradication ethic that followed a plan based on eradication theory. Furthermore, the incorporation of modern technology including strategic use of remote camera traps, monitoring of radio-collared Judas animals, night hunting with night vision and thermal rifle scopes, and the use of high-power semi-automatic firearms made eradication feasible due to an increase in the probability of detection and likelihood of removal. Precision shooting and trapping were the primary methods used throughout the campaign. Long-term monitoring using camera traps and observed sign guided a management strategy that adapted over time in response to population density and structure. Lessons learnt include, 1) macaques quickly adjusted their behaviour in response to human presence and removal methods, 2) camera traps and thermal scopes provided high detection likelihood compared to other methods, and 3) the use of Judas animals and night hunting with thermal and night vision rifle-scopes facilitated removals. The removal of macaques from Desecheo Island appears to be the first introduced non-hominid primate eradication from an island.

Keywords: conservation, invasive species, island restoration, Judas, *Macaca mulatta,* primate

INTRODUCTION

Islands occupy ~5.5% of Earth's terrestrial surface area but contain more than 15% of terrestrial species (Kier, et al., 2009), 61% of all recently extinct species, and 37% of all critically endangered species on the International Union for Conservation of Nature (IUCN) Red List (Tershy, et al., 2015). Non-hominid primates (NHPs) are intelligent and adaptable animals (Fooden, 2000). World-wide, 78 introduced insular populations are known on 63 islands (Jones, et al., 2018). Despite their potential for ecological impacts, including being implicated in 69 insular species extinctions and extirpations globally (Jones, et al., 2018), management is problematic as NHP's demonstrate behavioural traits making them challenging to remove and few practitioners are experienced in their control or eradication (Evans, 1989; Feild, et al., 1997; Breckon, 2000; Kemp & Burnett, 2003; Strier, 2016; Jones, et al., 2018). Six eradication attempts have been documented globally and all were unsuccessful (Jones, et al., 2018). Desecheo Island (Desecheo), has been the site of half of these attempts targeting a population of invasive rhesus macaques (*Macaca mulatta*).

Historically, Desecheo was a major seabird rookery. In the early 1900s tens of thousands of seabirds representing seven species were nesting on the island (Bowdish, 1900; Wetmore, 1918; Struthers, 1927; Meier, et al., 1989; Noble & Meier, 1989). The most numerous species, brown boobies (*Sula leucogaster*), numbered 8,000 - 15,000 individuals (Danforth, 1931 cited by Noble & Meier, 1989; Wetmore, 1918) with red-footed boobies (*S. sula*), brown noddies (*Anous stolidus*), and bridled terns (*Sterna anaethetus*) accounting for another 12–14,000 birds. Humans shooting birds and harvesting eggs, habitat destruction through farming, ranching and military munitions training, and introduced feral goats (*Capra hircus*) and black rats (*Rattus rattus*) reduced populations of most seabird species and restricted many species to less accessible areas of the island (Wetmore, 1918; Struthers, 1927; Evans, 1989; Meier, et al., 1989). Feral goats were recently eradicated (2009; Hanson, unpublished data) while black rats were eradicated in 2016 after an initial attempt failed in 2012 (Will, et al., 2019). However, predation by rhesus macaques (macaques), introduced in 1966 for research purposes, resulted in the complete loss of seabird breeding on the island and was considered the most significant threat to wildlife on Desecheo (Evans, 1989; Meier, et al., 1989; Noble & Meier, 1989). In 1969, massive raids by macaques on booby nests were reported, with macaques pushing boobies off their nests and consuming an estimated 200–300 eggs per week (Noble & Meier, 1989). In 1987, although nests were built and eggs laid, brown and red-footed booby nesting success was zero (Noble & Meier, 1989). Macaques contributed to the extirpation of at least five seabird species, one land bird species, and led to the depauperate state of resident land birds on Desecheo (Noble & Meier, 1989; Island Conservation, 2007). Macaques on Desecheo have also been implicated in modifying vegetation structure, contributing to the extirpation of several plant species, and preying on native reptiles including three island-endemic lizards (Evans, 1989; Breckon, 2000; Island Conservation, 2007).

In 1976, Desecheo was designated a National Wildlife Refuge and the island was transferred from the Department of Health, Education, and Welfare to the U.S. Fish and Wildlife Service (USFWS). At this time the removal of macaques was identified as an objective to restore the island's ecological integrity (Island Conservation, 2007). Between 1976 and 1988, three eradication attempts took place with a total of 155 animals removed (Herbert, 1987; Evans, 1989; Breckon, 2000; USFWS, 2007). An initial attempt was reported to have insufficient funding to proceed (USFWS, 2007). The second eradication attempt required multiple removal methods to target wary individuals. After 246 days of effort it was assumed all individuals had been removed, but less than a year later 15 individuals were confirmed on the island (Evans, 1989). The third eradication attempt ended prematurely in 1988 due to a lack of resources; it was believed at that time that two

Fig. 1 Aerial images of Desecheo National Wildlife Refuge.

males and an unidentified juvenile were all that remained (USFWS, 2007). However, Breckon (2000) reported 11 animals in a single troop in 1996. Lack of funding, animals becoming educated to removal techniques, and unreliable detection methods contributed to the lack of eradication success. In April 2007, Island Conservation in partnership with USFWS developed a restoration plan (Island Conservation, 2007) that outlined a strategy and methods to eradicate macaques from the island. The planning effort coincided with the development of an environmental assessment covering the removal of non-hominid primates from the Commonwealth of Puerto Rico and its offshore islands (USDA, et al., 2008), including Desecheo. Here we report on the 2008–2017 eradication of macaques from Desecheo National Wildlife Refuge.

STUDY SITE

Desecheo is a small (117 ha) uninhabited hilly island (18° 23’ N, 67° 29’ W) situated roughly 21 km off the west coast of Puerto Rico. The vegetation is a mosaic of grassy patches, shrublands, woodlands, and semi-deciduous forest. The grassy patches and shrublands are on exposed ridges and screes, especially on the northern and north-eastern slopes, which face the prevailing winds. The woodlands are typically found covering coastal slopes, upper east- and south-facing slopes, along drainages, and within valley floors. The floral community of Desecheo is dry forest habitat. The island is composed primarily of Tertiary volcanic sandstones and rises to 218 m. Steep slopes fall away from five ridges interconnected by a perpendicular ridge which rises abruptly from the northeast coast (Fig. 1). There is no permanent surface water or spring on the island.

METHODS

Macaques carry B-virus (*Cercopithecine herpesvirus* 1), which can be lethal to humans (Huff & Barry, 2003), so animal handling was minimised where possible. The Desecheo macaque population originated from a population with a high occurrence of the disease (Shah & Morrison, 1969) and most likely had B-virus. When animals were handled, strict protocols were followed (Holmes, et al., 1995).

Several principles were employed to increase the likelihood of success: 1) target whole groups where possible, 2) limit opportunities to educate animals, 3) first utilise methods that would not impact the efficacy of other methods, 4) have sufficient methods to remove animals faster than the rate of reproduction, and 5) provide multiple detection methods that were independent of removal techniques, capable of detecting animals at very low densities. Variations of live-trapping and hunting were selected after a suite of possible techniques, including the use of toxicants, biological control, kill trapping, and immunocontraception, were evaluated for use on Desecheo (Island Conservation, 2007). The strategy to remove macaques was structured around three general phases and was adaptively managed from 2008 to 2017 (Fig. 2). The initial phase relied on live-trapping to provide a population reduction without educating animals to subsequent hunting methods. Select individuals captured were radio collared then released and tracked as sentinel (Judas) animals to facilitate hunting of a social species. The second phase aimed to remove remaining individuals through hunting and transitioned to a third phase where monitoring was anticipated to confirm eradication. A revised approach was required when macaques could only be detected by remote cameras. This involved specialised night hunting technology paired with the use of Judas animals and a distinct change in hunting strategy which primarily occurred outside of daylight hours.

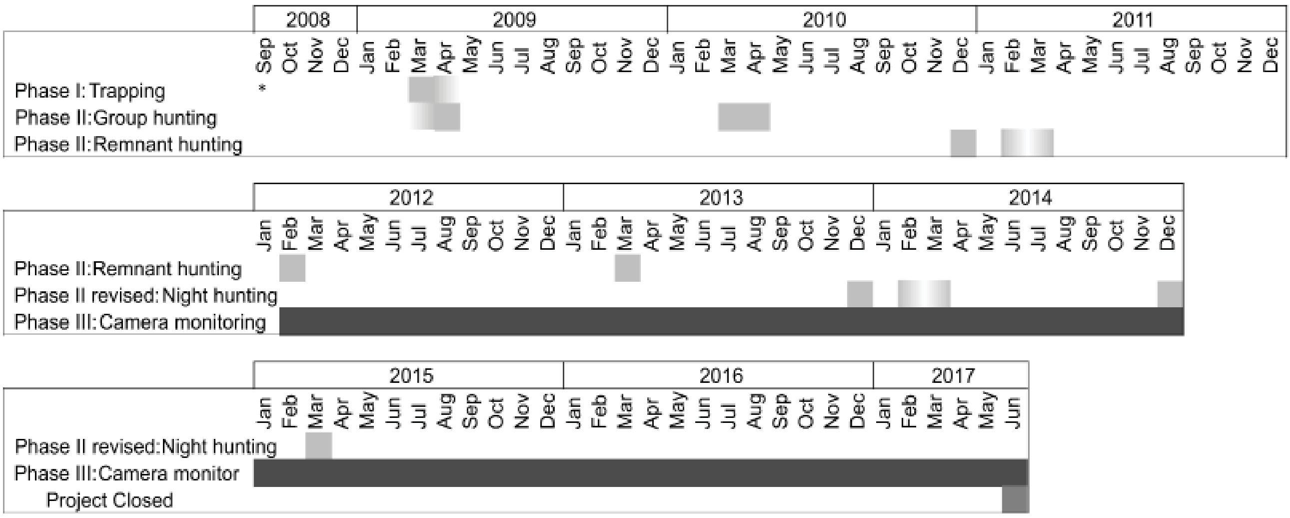

Fig. 2 Project timeline of events. (*) field work initiated by seasoning traps on site.

Phases relied on a team temporarily camped at one of two sites on the island with all equipment and supplies being delivered then removed each trip. The first campsite, serviced by helicopter, was located near the peak of the island. This site supported up to nine staff, was utilised from project initiation through the duration of group hunting (see Fig. 3) and allowed centralised access to the entire island. A second site was later established along the coastline to allow boat access and minimise logistic expenses for a reduced field team to complete the eradication.

Phase I. Trapping and Judas animal release (2008–2009)

Eighteen *#208 dual-door cage traps* (Tomahawk Live Trap, Hazelhurst, WI) were placed in groups of three across the island at sites of known macaque activity. Trap dimensions of 107 × 38 × 38 cm were considered large enough to capture multiple animals, based on mainland Puerto Rico trapping efforts (López Ortiz, 2015). Concurrently, a single, large 5 m wide group-style trap (Day, 2004) was built upon a flat, ridgetop location. This trap was constructed in an octagon shape with a wood frame, cyclone fence sides and skirt. A 60 cm overhanging eave and 60 cm vertical wall made from sheet metal faced internally to prevent animals from exiting. A remote-controlled drop-net was used in another site, comprising an 11 × 11 m reinforced net elevated above the ground by roughly 2 m around the edge with a tented peak of 5 m. Pre-baiting took place across all trap sites for two weeks with whole and sliced oranges. Oranges were chosen based on successful results experienced during previous eradication campaigns (Evans, 1989). Prior to departing the island, all cage traps and a single side of the octagon trap were wired open for animals to become familiar with their presence.

Seven months later all traps were activated and a network of 48 padded leg-hold traps was installed along areas suspected to have macaque activity. Traps were typically set in groups of two or more and each were accompanied by a magnetically triggered trap-monitor. Monitors were in place to support near-real-time monitoring of each trap's status which was communicated by radio-transmitter to a R-1000 telemetry receiver (Communications Specialist, Orange, CA); traps were monitored several times daily. A second pre-baiting effort took place during this time. To supplement oranges and provide greater variety, additional bait types including mangos, chicken eggs, and a water drip pan were utilised and replaced regularly. A remote-controlled audio lure (FoxPro Crossfire, Lewistown, PA) programmed with macaque calls also was deployed in association with baits at the drop-net location. Various leg-hold traps were set with lures including mirrors, wind chimes, streamers, feathers, or brightly coloured objects suspended above the trap site. Traps that did not receive a lure were set as a blind set with no distinguishing features separating it from the original site.

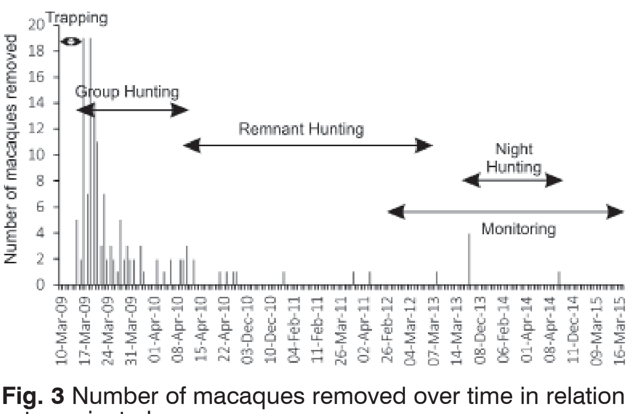

Fig. 3 Number of macaques removed over time in relation to project phase.

During this timeframe, a wild-caught adult male macaque from mainland Puerto Rico was quarantined, sterilised by vasectomy, radio-collared (Telenax, TXE-311C, Playa del Carmen, Mexico), and transported to Desecheo. This individual was released upon arrival and monitored daily as a Judas animal.

Phase II. Hunting (2009–2013)

Trapping activities from Phase I overlapped with this phase for one field trip. Hunting was intended to remove remnant individuals that were avoiding trap sets. Timing of this phase was based on the seasonally deciduous dominant tree species (*Bursera simaruba*) which leafed-out in response to rainfall. Field staff were selected from within Island Conservation and from White Buffalo Inc. (Connecticut, USA) based on their experience in precision shooting and demonstration of eradication ethic. In preparation, key vantage points were identified while conducting a census of the population before any removals took place. This assessment effort also was used to identify concealed shooting hides that offered a wide field of view for observation and clear shooting lanes. Hunting was considered capable of placing all individuals at risk of removal, particularly once population numbers were reduced with a successful trapping phase.

Troop removal (2009–2010)

Hunting predominately relied on an ambush-then-stalk strategy that collected troop characteristics (number of individuals, body size of individuals) and movements at dusk while macaques located a location to roost. In certain circumstances, where specific trees were identified as a roost site, field staff would proceed with hunting in the middle of the night while utilising spotlights and close-range shooting. In most circumstances, staff would wait until nightfall before returning to camp to develop a strategy of engagement for the following day. Before first light, field staff would be dispatched to pre-established hides or to new locations thought to offer a better vantage point of a troop's roost location. Field staff were equipped with high-capacity centrefire semi-automatic .223 Remington or 6.5 Grendel rifles with telescopic sights ranging from 4.5× to 20× magnification and reticles matched to each firearm's ballistics. Other field staff were stationed along known escape routes with high capacity 12-gauge semi-automatic shotguns.

Shooters would communicate via 2-way radio to assess the troop and attempt to identify the number of individuals, their hierarchy, and body size. Body size class was estimated based on body mass and ranked as one through five. Groups would only be engaged if it was considered a high likelihood that all individuals could be removed. Field staff that had a visual on the dominant individual would engage with the first shot, with other staff following by removing individuals that presented a lethal shot opportunity. Adult females (often dominant) were removed first, followed by adult males and juveniles. Field staff would continue to monitor the site while supporting shooters would be redistributed to areas where escapes were thought to have possibly occurred. Once macaque activity ceased in the canopy, field staff equipped with close-range firearms would enter the site to remove any remnant individuals. Removals were tallied and the animals' body size classes would be recorded. Follow-up visual confirmation of carcasses occurred whenever possible. Any known escapes were recorded, along with their size class. Confirmed removals and escapes would be cross-referenced with the troop size estimate. To improve the detection of roosting troops during this phase a commercial-grade handheld thermal camera (FLIR, P620, Wilsonville, Oregon, USA) was trialled.

Remnant removal (2011–2013)

After the initial knock-down of the macaque population, the project shifted focus to the detection and removal of lone individuals and reconstituted groups created after troops were fractured. Before dawn, field staff were stationed across the island to conduct focused observations over as much landscape as possible. Visual observation of canopy movement and audible cracks of tree limbs and masticated seeds were the primary cues of macaque presence prior to direct observation. If a detection was made, the number of animals was estimated and, if confidence existed that the group or individual could be removed, field staff would proceed by removing individuals through shooting. When assistance was required, additional field staff would be guided to the site offering the highest likelihood of removing the entire group. If escapes were thought to be probable, the team would reassess the opportunity and hold off until another situation presented greater confidence in removal.

Phase II revision. Night hunting (2013–2015)

Remote cameras (see monitoring) continued to detect macaques that were undetectable to field staff. Methods employed were re-analysed, leading to detection dogs and night hunting technology being considered. Dogs that could effectively track animals traveling on the ground and through forest canopy were considered necessary and a breed of mountain cur that is used to pursue squirrels was identified. Additionally, managers of NHPs on mainland Puerto Rico had sourced effective thermal hunting optics and began demonstrating success with night hunting.

In 2013, three macaques were selected from mainland Puerto Rico to be used as Judas animals to support night hunting. Young female macaques were chosen as they were considered more likely to readily associate with remnant animals on Desecheo. Replicating methods developed for Judas goats, each macaque was sterilised via tubal ligation, fitted with a radio-telemetry collar (ATS, M2950B, Isanti, Minnesota, USA), and received a Compudose® 200 (25.7 mg estradiol; Elanco, Indianapolis, USA) implant to induce prolonged oestrus (Zehr, et al., 1998; Campbell, et al., 2005; Campbell, et al., 2007). Radio telemetry collars had infrared (IR) reflective patches sewn in and a solar powered light-emitting diode (LED) epoxied to them to facilitate detection at night. Judas macaques were transported to Desecheo via boat and released.

Hunting methodology changed to working strictly at night, initially incorporating mainland Puerto Rico staff and their equipment to train the project team. Based on the success of these methods, thermal weapons scopes with a built in adjustable reticle (BAE Systems, Inc. ATS-6000M, Arlington, Virginia, USA), a 3rd generation night vision clip-on unit (Knight Optics Ltd., Krystal 950, Harrietsham, Kent, UK) used in combination with pre-existing telescopic firearms optics, and an IR laser illuminator (Jager-Pro LLC., JP-IR Laser, Fortson, Georgia, USA) were procured to improve detection and facilitate removals. Night operations continued with 2–3 field staff using the thermal scope to detect heat signatures of macaques in conjunction with telemetry scans for Judas animals (described in Phase III). When no Judas animals were present in a group all were targeted. When Judas animals were present night vision in conjunction with infrared illuminators were used to detect IR reflective patches sewn into collars to determine which macaque in the group was the Judas, facilitating removal of only uncollared macaques.

Phase III. Monitoring (2012–2017)

Monitoring occurred simultaneously with the removal of remnants and night hunting in Phase II. The presence of macaques was assessed through active and passive monitoring techniques; each independent of removal methods. Active monitoring occurred through visual observation of animals and the detection of fresh sign. Passive monitoring trialled acoustic recording units (Wildlife Acoustics, Maynard, MA), but relied primarily on a network of 16–26 Hyperfire PC900 no-glow cameras (Reconyx, Holmen WI). Cameras were placed in locations known to have had previous macaque activity or at sites which offered a clear field of view across a travel route. Specific attention was given to rocky bluffs, exposed patches of slope, or within tree canopies that were dominated by horizontal tree branches. Tuning the camera field-of-view used an integrated "walk-test" function which indicated where the camera would be triggered by movement. Lures made from cord passed through brightly coloured balls were installed at sites which could accommodate a swinging item without triggering the camera's motion sensor. Cameras were serviced every 3–9 months, where memory cards (32GB, 95mb/s write speed) were switched for empty ones and batteries were replaced if below 60% charge. Camera operational settings were programmed to operate from one hour prior to dawn to one hour after dusk, provide the highest sensor sensitivity, take five photos in succession, and reset immediately after a trigger event.

RESULTS

A total of 140 macaques were removed from Desecheo Island between 2009 and 2015, excluding Judas animals translocated from mainland Puerto Rico (Fig. 3). The cost of the 2007–2017 campaign was US$ 1.229m. The majority of costs (73%) were associated with implementation and monitoring from 2009 to 2015 at US$ 893k. Planning and preparation in 2007/8 utilised US$ 214k and US$ 121k was spent on confirmation over 2015–2017.

Phase I. Trapping

Baiting to encourage macaques into traps was ineffective. Additional lures such as a water drip and audio lures also proved unsuccessful as evidenced by camera traps. Non-target species, primarily black rats and hermit crabs, would consume any bait not suspended from the ground. Bait that did persist required regular replacement due to the arid climate on the island; fruits quickly desiccated and non-boiled eggs rapidly spoiled. After 26 days, unsuccessful traps that were located in remote sites and not easily accessible by field staff were closed to ration bait and improve the efficiency of trap monitoring. Traps left open were outfitted with florescent flagging as a visual lure and left open. A total of 546 trap nights accrued between cage traps, the group-style octagon trap, and the drop net with zero trap success.

Padded leg-hold traps were in place for 1,344 trap nights and resulted in the capture of 13 macaques; 10.7% of the population. Three received radio collars and were released as Judas animals; all but one was sterilised. Traps equipped with novel visual lures, particularly reflective materials, demonstrated a higher catch rate than non-reflective items. Two blind sets established as a part of a three-trap grouping, demonstrated success simultaneously. Traps placed at the base of trees where macaques would leap into the tree were particularly successful.

The adult male Judas animal transported to Desecheo from mainland Puerto Rico was found dead 16 days after its release for unknown reasons.

Phase II. Hunting

Hunting reduced the population of macaques to near undetectable levels by removing 118 individuals (84% of 140 macaques removed) over the span of two trips (46 days where hunting took place) across two years. Estimates of animals remaining at the end of each trip significantly underestimated the population. Three animals were known to be present at the end of the second trip, one of which was a sterilised Judas macaque. Follow-up hunting focused on the detection and removal of remnant macaques, which removed four individuals in five field trips (66 days where hunting took place) over three years. At this time, camera monitoring indicated six individuals remained and evidence of population recruitment, shown by one newborn juvenile.

Phase II. Revision

The introduction of night hunting strategies supported by thermal and night vision technology, field staff's intimate knowledge of the island's terrain, and leveraging Judas animal behaviour resulted in five macaque removals over five trips (50 days where hunting took place) over 2.5 years.

Phase III. Monitoring

The single most effective monitoring tool proved to be the remote camera network. Camera density ranged from one camera per 4.5–7.25 ha. Roughly 450,000 images were collected throughout the entire campaign. The volume of images varied greatly depending on the length of a monitoring period (2–9 months) with a mean of ~50K images. More than 2K macaque detections were compiled. Camera placement was impacted by vegetation growth over time leading to the majority of images being false captures. Once population numbers were reduced to five individuals the entire group could be tracked with at least one detection of each individual occurring per monitoring period. Judas animals, with unique physical and collar characteristics, could be identified within camera images and were used to indicate camera network efficacy; all Judas animals were detected per monitoring session and were easily distinguishable from wild individuals due to the presence of the collar.

Acoustic recording units were trialled but did not result in confident detections by monitoring macaque vocalisation. This tool was quickly discounted as an effective option to monitor animals at low density. The lack of vocalisation was corroborated by field staff who indicated macaques no longer vocalised with the same frequency once the population was reduced to less than ten individuals.

Additional monitoring took place though the tracking and assessment of Judas animals. Of the three animals captured on-island, one unsterilised male was found dead due to unknown causes, a second sterilised male was inadvertently shot during the hunting phase of the project, and a third sterilised female experienced a collar failure and integrated back into the population. This individual was one of the last macaques removed. Of the three additional Judas animals later captured on mainland Puerto Rico and released in Phase III, none experienced collar failure although the installed LED lights did not function in the field. After release, one was indistinguishable amongst a group of wild macaques and shot while night hunting with thermal optics. The remaining two Judas macaques formed an independent pair. One Judas animal was later removed to disrupt the social balance which resulted in a more consistent interaction between the remaining Judas animal and the two known remnant animals. Field staff removed one remnant animal before the final Judas animal was found dead in 2016. This Judas animal was associating with the last wild macaque known to remain on island.

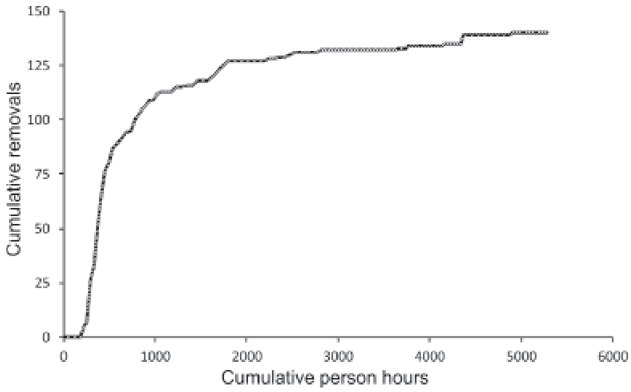

Fig. 4 Number of removals in relation to effort expended over time.

Twelve hunting trips were conducted totalling 5,280 detection hours (Fig. 4). A single wild adult matching the description of the last known wild macaque was detected on 15 occasions by the camera trap network over approximately 41 months indicating that this was the only wild individual that remained. Over the same timeframe, no juveniles were shot or detected, reflecting no reproduction. As a result, the project was closed in June 2017 with the understanding that the population was functionally extinct.

DISCUSSION AND LESSONS LEARNT

The campaign to remove macaques from Desecheo took 10 years, 17 field trips, variations of two primary methods – trapping and hunting – and a network of remote monitoring cameras to complete.

Pre-baiting attempts were unsuccessful, resulting in the ineffectiveness of baited traps. Trapping efforts may have benefited from trials and a longer pre-baiting period which also would take into account timing to allow learnt behaviours to transfer through the population. Locally available food items including nuts and berries were considered but discounted as they were found in abundance across Desecheo. Having a diet with limited exposure to novel food items on Desecheo is thought to have contributed to their disinterest in baits provided. Once baited trapping ceased, hunting and leg-hold trapping were then relied upon as the sole methods. Trapping efforts on mainland Puerto Rico that utilise a variety of fruits have resulted in up to 50% of project removals (López Ortiz, 2015) suggesting that trap success is variable across sites and should remain a management consideration.

When hunting was initiated, only troops where all individuals were thought to be at risk of removal were targeted. Although this method proved to be effective and efficient, it became apparent that escapes likely occurred unbeknownst to field staff as macaques quickly adjusted their behaviour in response to human presence and removal methods. Macaques increasingly avoided detection during the day, and if field staff were detected, would regularly select a route of escape that placed an object between them and the observer, limiting shot opportunities, as they fled to an adjacent watershed. This behaviour eventually nullified daylight hunting and required revised methods and tactics to improve the probability that an individual would be detected.

Advanced night hunting equipment facilitated both detections and removals. In many instances macaques were detectable only with a thermal scope, even when field staff knew the location of the animal. As a result, an integrated shooting reticle with the ability to remove and return the scope to the firearm without having any shift in the scope's point of aim was considered critical. Furthermore, having the ability to de-couple the night vision from traditional hunting scopes proved valuable as the firearm's point of aim did not need to be recalibrated for daylight hunting; only the thermal scope could be used in daylight without damaging the equipment or losing the capability to continue hunting into dawn with the firearm paired with night vision. A less sophisticated general-use FLIR thermal camera was trialled early in the project although low image resolution limited the unit's detection range. At ranges beyond ~150 m, individual pixels were estimated to be larger than a macaque's heat signature. The camera's limited range resulted in zero detections and thus general-use thermal tools were abandoned.

If the project had been initiated with advanced night hunting thermal equipment and Judas animals it is estimated that its duration and cost would have been significantly reduced. Hunting activities could have taken place regardless of seasonal variation in vegetation, detections would have been more frequent, and entire groups could have been removed with greater confidence, precision, and frequency. Furthermore, the incorporation of suppressed firearms with subsonic ammunition would have offered additional advantages. Suppressed firearms would likely have reduced the flight response of any associated macaques due to abated firearm report, projectile "crack," and identification of shot origin.

Camera traps provided high detection likelihood as compared to other passive detection methods, particularly once the density of animals was reduced to near-zero. Camera placement, and the decision to increase the size of the network, was guided by weeks of observation before and after removals took place and is believed to have significantly improved detection probability. Staff were familiar with the use of the same cameras with feral cats (*Felis catus*), however, a greater awareness of the camera's field-of-view and trigger window was necessary when setting cameras to monitor a three-dimensional environment. The presence of an accurate walk-test function offered confidence that cameras were set to detect animals at varying elevations and distances. In addition, a robust camera design offered confidence that cameras would have a low failure rate regardless of adverse field conditions including hurricanes, intense heat, and sustained humidity. Failures generally included screen malfunctions, walk-test function ceasing to work, and component corrosion due to termites burrowing into the camera case.

Ongoing commitment from the partners throughout a dynamic project enabled the eradication to succeed. There was a significant investment up front to start the project and the initial projected methodologies and associated tools did not result in eradication. As a result, the project lasted longer than expected and overall costs were higher than anticipated. These costs may have been reduced if the funding was available in larger amounts rather than in annual allocations, allowing higher intensity effort over a shorter period of time. However, it is also believed that the long periods between hunting trips was beneficial because macaques became less agitated, resumed routine behaviours, and were more likely to be detected.

Macaques becoming educated to removal techniques, unreliable detection methods, and a lack of funding were linked to previous failures on Desecheo. To reduce the probability that similar issues would impact the success of this attempt, the partnership routinely and transparently reassessed all aspects of the project including the funding required to proceed, equipment and field trips considered necessary to achieve eradication, and how to interpret results. These factors guided an adaptive management strategy that supported principles outlined within original project planning. This shared effort resulted in a robust relationship that was capable of addressing a dynamic project and uncertainty in a solution-oriented, step-by-step manner. As a result, a project with no precedent of success – incentivised by a high conservation reward – was completed in a conscious and calculated fashion.

CONCLUSION

Desecheo Island is the location of the first successful removal of introduced non-hominid primates from an island that we are aware of. The project was contingent on the strength of the partnership, specialised equipment, and commitment of an experienced field team with a strong eradication ethic that followed a plan based on eradication theory. These factors were all critical to the project's success after a protracted time-period. The challenges of this eradication required several revisions to the original methodologies and strategies, as well as continued funding beyond the original budget projections.

Desecheo Island, and the unique species that are found there are now safe from invasive mammals after nearly a century. This restoration action should enable the island's return as the most important seabird colony within the region.

ACKNOWLEDGEMENTS

This work was made possible by the generous support of our philanthropic donors and funding from the United States Fish and Wildlife Service. We also would like to thank W. Wolfrom and B. Mancial, J. Padilla, F. Boyd, L. Figueroa, M. Evans, J. Herbert, J. Schwagerl, E. Melendez, A. Saunders, B. Tershy, J. Bonham, C. Bergman, L. Bennett, W. Jolley, D. Will, E. Oberg, J.L. Herrera-Giraldo, K. Swinnerton, C. Figuerola-Hernandez, R. Rodts, T. Robinson, W. Shockley, M. Garcia, O. Acevedo, and many other USFWS, DNER, Puerto Rico law enforcement, and IC staff for assisting with planning, field work or logistical support. Mayaguez Zoo and Puerto Rico DNER provided support with sourcing and preparing Judas macaques. USDA Wildlife Services and DNER staff assisted with two field trips and graciously shared their skills and knowledge acquired from their own night fieldwork.

Eradication of red deer from Secretary Island, New Zealand: changing tactics to achieve success

N. Macdonald[1], G. Nugent[2], K-A. Edge[3] and J.P. Parkes[4]

[1]Department of Conservation, PO Box 743, Invercargill 9840 <nmacdonald@doc.govt.nz>. [2]Landcare Research, PO Box 69040, Lincoln 7640, NZ. [3]Edge-Effect, 48 Bligh St., Te Anau, NZ. [4]Kurahaupo Consulting, 2 Ashdale Lane, Christchurch, NZ.

Abstract Red deer (*Cervus elaphus*) established on 8,140 ha Secretary Island after swimming from the mainland in the early 1960s. Attempts to remove them began in the 1970s and after several starts and stops they were eradicated in late 2014. Since late 2006, 688 deer have been removed. Ground hunters killed 365 deer in 1,827 hunter-days, 320 deer were shot from helicopters in 211 flying-hours, two deer were trapped and one was known to have been killed by a fisherman. The campaign since 2006 was planned in three phases – an initial population reduction, a mop-up phase and a surveillance and rapid response to any new immigration phase. An initial reduction of 80% of the population, between 530 and 550 in 2006, was planned and achieved in the first two years. The removal of surviving deer was planned to take a further four years but despite 114 being shot and probably less than 14 deer remaining in 2013 eradication was not achieved using the methods that succeeded in the initial phase. The change in tactics in 2014 that allowed for eradication was to (a) ground survey the island and use camera traps to locate areas with deer, (b) identify individual deer from faecal DNA to estimate numbers, know when they were shot or still alive, and to estimate potential new immigration from the mainland – which was low, and (c) move from individual hunters seeking any deer within a widespread population, when about 10% of hunter-deer encounters led to a kill, to re-train hunters as teams using GPS/radio systems and integrate them with aerial hunting to seek individual deer at known locations, when 100% of encounters led to a kill. The change of tactics that led to eradication success required about half the costs, i.e. $25,000 to $10,500 per deer direct operational costs, expected if no change had been made.

Keywords: aerial hunting, catch-per-unit-effort, density, faecal DNA profiles, ground hunting, operational costs, World Heritage Area

INTRODUCTION

There are few published examples of successful deer eradication campaigns in the world. This is mostly because deer are generally valued as resources rather than as pests but, in New Zealand, red deer are an introduced species so there is interest in completely removing deer from some places in order to protect the native biota (Parkes & Murphy, 2003). Here we document a prolonged but ultimately successful campaign to remove deer from a large island in south-western New Zealand.

Secretary Island covers 8,140 ha and rises to 1,196 m a.s.l. at 45°14' S 166°55' E in Fiordland National Park, part of Te Wahi Pounamu South-west New Zealand World Heritage Area (Fig. 1). Red deer (*Cervus elaphus*) swam to Secretary Island from the mainland in the early 1960s (Mark & Baylis, 1975; Crouchley, et al., 2007) across a sea gap of at least 630 m. A population established and their impact on the pristine native forests was severe and rapid (Mark & Baylis, 1975; Mark, et al., 1991) so in the 1970s, New Zealand Forest Service attempted, unsuccessfully, to remove the deer (Tustin, 1977). However, in the early 2000s, the New Zealand Department of Conservation (DOC) initiated a new campaign (Brown, 2005; Crouchley, et al., 2007) that began in earnest in late 2006. This second eradication attempt was itself reassessed by DOC once the population had been reduced to very low numbers (estimated at 14 individuals) in 2012/13, resulting in changes in strategy and operational tactics that eventually led to successful eradication of the deer. In this paper, we briefly reiterate the results presented in early reports and in the second Island Invasives conference for the first eradication attempt, and update the results from the initial reduction phase (Crouchley, et al., 2011; Edge, et al., 2011). We then focus on the new data to report on the change in strategy and tactics to remove the last few deer from the island and compare the predictions of a catch-per-unit-effort (CPUE) model produced in 2012 (Nugent & Arienti-Latham, 2012) with the actual outcomes of the deer control during the final phase of the project.

MAIN FINDINGS

First eradication attempt: 1970–1989

Ground and aerial hunting began in the early 1970s and although 250 deer were reported as killed by the New Zealand Forest Service between 1970 and 1985 (Brown, 2005) the population, in the presence of abundant food (Mark & Baylis, 1975), continued to increase. Tustin (1977) guessed about 200 deer were present in 1975. A poisoning technique (1080 gel smeared on the leaves of deer-preferred plants; see Parkes, 1983) was trialled from 1975 to1987 (when 10% of the island was poisoned) but informal track and pellet counts suggested efficacy was moderate at best (Brown, 2005). The abundance of preferred food species and a perception that the difficult terrain on Secretary Island restricted ground access (later disproved when hunters covered the whole island to survey for surviving deer) were likely reasons this trial did not lead to eradication of the deer. In contrast, in an area on Stewart Island, where white-tailed deer (*Odocoileus virgineanus*) had removed most palatable food plants and accessibility to people was not difficult, the 1080-gel technique removed close to 100% of the population of deer in the treated area (Nugent, 1990). The best control methods depend on context, showing that successful precedent does not supply a recipe for new projects.

By the early 1980s it was concluded that neither hunting nor the 1080-gel method could remove all deer, so the policy shifted in 1985 to one of sustained control to low residual densities (Sanson & von Tunzelman, 1985). By 1989, official deer control on the island was halted because of budget constraints and the expectation that reinvasion would always compromise the project (W. Chisholm, 1989, unpubl. DOC Invercargill file ANI 4/6). Deer were still shot on Secretary Island by commercial venison recovery helicopter operators. However, the goals of restoring the island's ecosystems by controlling deer and stoats were

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 256–260. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

not forgotten (Munn, 2001) and in the early 2000s a new eradication project was proposed (Brown, 2005) with a formal operational plan developed in 2007 (Crouchley, et al., 2007).

Second eradication attempt: November 2006–April 2013

A new decision to attempt eradication of red deer (and also stoats (*Mustela erminea*)) from Secretary Island and nearby Resolution Island (21,000 ha) was proposed in 2004 and a budget of NZ$7.1 million was allocated (Edge, et al., 2011). This second attempt adopted a more strategic approach, aiming to reduce the population by 80% within two years, then remove survivors within four years, and subsequently detect and remove any new immigrants in perpetuity (Crouchley, et al., 2011). It was expected that the initial knockdown would rely on two main methods (ground hunting with indicator dogs and helicopter shooting) but that a variety of 'niche' control methods (17 capture pens, fences, the use of telemetered deer) would probably be required during the 'mop-up' phase (Crouchley, et al., 2011). The ground hunting involved hunters (and their dogs) operating individually from nine huts across the island, so each hunter covered different areas in each hunting period (usually about nine days) with hunters often swapping areas between hunting periods (see Crouchley, et al. (2011) for a detailed description of the hunting and other methods). Aerial and ground hunting began in November 2006.

The 'rapid knockdown' aim was effectively met as 84% of the total deer killed were shot within three years (by the end of 2009). We estimated that hunters operating individually killed only about 10% of deer they 'encountered', i.e. seen, heard or known to be in the area being hunted from fresh sign. There was little motivation to persist with hunting a particular deer that escaped when there were plenty of other deer in the area being hunted. However, the aim to eradicate the population by the end of 2012 was not met as deer were still present. In retrospect, 98% of the final tally had been killed by then, but not the 100% required for eradication.

Final push: January 2014–August 2014

Failure to eradicate by 2012 (Fig. 2) led to a hiatus in activity while the strategy and tactics being used for the 'mop-up' phase were reconsidered. The surviving deer were extremely wary and could detect and escape hunters (with dogs) operating as individuals and were avoiding the open grasslands where they would be most vulnerable to aerial shooting. The Department of Conservation had no novel control tools to add to the mix it had already used so decided that they had to apply ground and aerial hunting in a different way to counter these learnt avoidance behaviours of the deer. A decision was made to shift from individual hunting to team hunting informed by all available information. To some extent this was informed by the experience of the new project manager (the senior author) who with a private company (Prohunt Ltd, now Native Range Ltd) had recently achieved eradication of feral pigs (*Sus scrofa*) from Santa Cruz Island (Parkes, et al., 2010). Technological advances available in the final phases of the Secretary Island project included the use of hand-held GPS and radios that allowed immediate contact and location details to be shared between hunters, high definition remote trail cameras, and the ability to identify individual deer from DNA in faecal pellets.

The first step, in February 2013, under the revised strategy, was to use hunters with indicator dogs to search the whole island from ridge tops to the sea along transects about 200 m apart for sign of deer. Analysis of the DNA in the mucus layer of fresh (i.e. moist with unbroken exterior estimated to be only a few day's old) faecal pellets (see Ramón-Laca, et al., 2014 for details of the methods; such

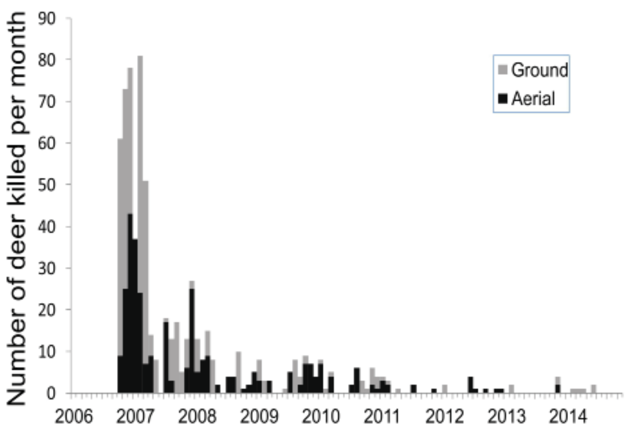

Fig. 2 Monthly kills of red deer on Secretary Island between the start of the second eradication campaign in late 2006 and the last deer killed in August 2014.

analyses currently cost about NZ$90 per sample depending on sample size) found during this survey allowed individual deer to be identified and the area in which they lived to be located. The whole-island sign survey suggested that possibly 14 deer remained at the end of April 2013 (Macdonald, 2013). The second step, in late 2013, was to select and train the hunters in the skills (and attitudes) required for a team hunting and targeting individual deer. The logic of this change in hunting method depended on (a) identifying from ground surveys for sign roughly where a targeted survivor was living, (b) using a helicopter to place a team of hunters at key exit points around that location, (c) then deploying the best hunter-and-dog teams in the suspected range of the deer to attempt to find and kill it, (d) and, where that failed and the deer also avoided the perimeter hunters, to then use the dog to track the deer and the helicopter to either relocate the perimeter ambushers or to shoot the deer if it became visible.

As hunting under a new strategy proceeded and the DNA taken from shot animals was compared with DNA found in an ongoing collection of faecal pellets it was estimated that only eight deer remained by the end of 2013. Deployment of 13 trail cameras at key sites around the island combined with ongoing DNA sampling did not identify any new 'unknown' deer at this stage of the mop-up. All deer shot after the island-wide survey in 2013/14 were (apart from two fawns shot with their mothers) identified with the DNA faecal pellet database, and all but one had an image captured by a trail camera.

Nine deer were shot in in 2014 under the new strategy. Seven were adults (3F, 4M) and two were fawns. Three deer were shot by ground hunters, two from helicopters, and four from helicopters after the deer had been flushed out of the forest by ground hunters and their dogs. The last known animals were shot during August 2014 – a pregnant female which was flushed out of the forest by hunters and their dogs and shot from a helicopter, and an adult male shot by the ground hunters.

Initial population size

The careful collection of hunting statistics – numbers of deer killed, their age and sex and hunting effort – allows us to construct models of the population size and structure at any point during the project since 2006. The ages of 78 females shot on the island in 2006/07 and classed as adults by the hunters were determined from tooth cementum layers (Fraser & Sweetapple, 1993). All other animals were aged into three classes (young of the year, yearling, and older) by the hunters in the field. The population size in 2006 can be estimated using a form of the 'minimum number known to be alive' (MNA) analysis of McCullough, et al. (1990). Simply, the age of each animal shot was used to determine if it was alive in 2006 and the pre-fawning MNA population size in December 2006 (fawns are assumed all born at this time of year) is all animals shot after December 2006 that had been born before December 2006, plus all deer killed in 2007 other than fawns born in December 2006, plus all deer shot in 2008 other than fawns born in 2008 and sub-adults born in 2007, and so on. After 2009 an unknown number of deer in the oldest age class may have been born after 2006. To subtract these from our estimate of the initial population we used the age-class distribution of the 78 deer accurately aged and assumed the proportions remained the same across the post-2009 deer that were killed. Given 84% of the estimate of initial population size accumulates in the first three years, the potential errors in using this age distribution for older deer born after 2006 are minor. We assumed all deer were accurately aged, particularly when allocated an age class in the field, there was no immigration from the mainland and hunting by the official hunters was the major cause of mortality.

Between November 2006 and August 2014, a total of 688 deer were killed, of which at least between 530 and 550 would have been alive at the start of the eradication project in late 2006: an MNA 2006 density of 6.7 deer/km^2. The actual number was probably slightly higher as our estimate is based on known deaths and does not include animals that may have been wounded and died, died naturally, or were shot by other hunters and not reported.

Costs

Assuming direct operational costs of NZ$950 per flying-hour and $330 per hunter-day (the hunters were contracted for set periods but paid whether they actually hunted on a particular day or not) and using a population reconstruction model with a starting population size of 530 animals and an annual recruitment rate of 24%, the cost per deer shot increased rapidly as deer density declined for both aerial and ground hunting methods (Fig. 3). The cumulative 2006–2014 direct operational costs totalled $732,830 plus unknown management overheads that are likely to be roughly similar across years as they are less related to hunting effort.

We fitted a negative power function to the cost per deer versus density data from 2006 to 2012 (Fig. 3). Extrapolation from that curve suggested that expenditure of > $200,000 in direct costs would be required to remove the estimated residual population of eight deer within one year if there were no change in tactics. However, with the change in tactics in 2014, the actual direct costs were only about $84,000, indicating that the change in tactics was not only successful but much more cost-efficient. This of course ignores the significant factor of good luck (or bad luck from the deer's point of view) at the end of such

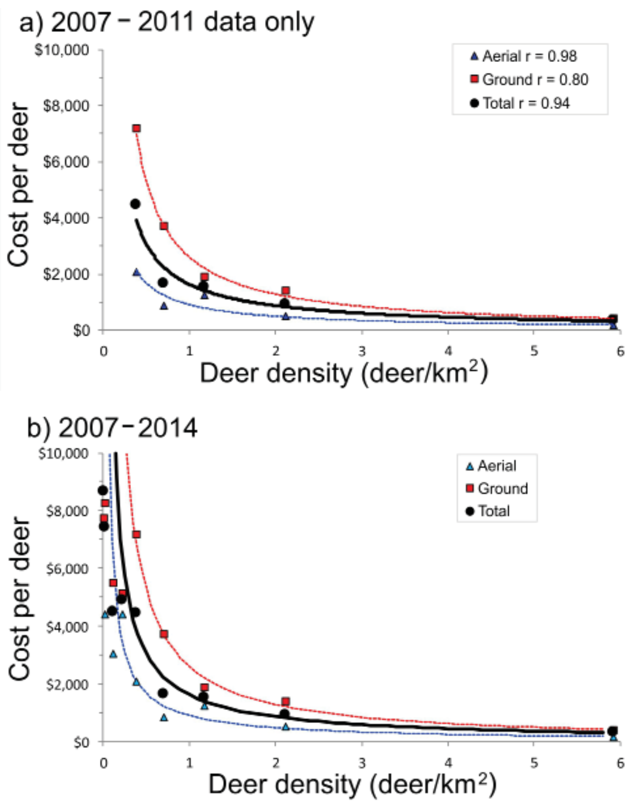

Fig. 3 Direct costs (hunter-days and flying hours) per deer killed with decreasing density, for aerial hunting, ground hunting and overall, for (a) the data from the first five years, and (b) for the whole campaign. The power curves in (b) are extrapolations from the 2007–2011 data and show that costs in the final stages (after adoption of new tactics) were lower than predicted from the initial data.

eradication projects, e.g. see the last pig from Santa Cruz Island which was shot incidentally to another task (Parkes, et al., 2010).

DISCUSSION

Eradication projects that rely on a succession of control events to eventually remove the population have one advantage over single-event projects, such as aerial baiting for rodents, in that information on progress and problems accrues as data are collected from each event. This allows managers to change tactics as the population is reduced and especially when surviving animals are less accessible or have learnt to avoid the control methods deployed at the start of the project. Previous successful and efficient eradication projects of this type have developed some practices (e.g. Ramsey, et al., 2009; Parkes, et al., 2010) that were, in part, used in the Secretary Island project.

The first success factor in such projects is that they reduce the population to very low densities as quickly as possible using control techniques that maximize the probability that every animal is killed at first encounter and thus minimize the possibility that surviving animals learn to avoid all control methods. It might be argued that live trapping in capture pens or 1080-gel on natural bait poisoning does not make surviving deer more wary, at least to subsequent hunting if not to the danger of traps, and should be used first. However, trapping is capital and labour intensive, unlikely to achieve rapid reduction in deer populations, while the earlier attempts at natural bait poisoning in Secretary Island were thought to be unsuccessful in achieving a large reduction. This left aerial and ground-based hunting as the only practical tools to achieve the initial population reduction, but which inevitably do not kill all deer at first encounter and so leave wary survivors. It is unknown whether the same successful initial reduction could have been achieved, and without creating wary survivors, by starting with the approach (team hunting with the additional improved GPS/radio and DNA technologies, and closer integration between ground and aerial hunting) deployed in the mop-up phase after 2013.

Many of the estimates of the number of deer left at various points across the campaign were essentially informed guesses. However, three tools were used to improve confidence in estimates of the number and identity of deer surviving on the island – a model based on catch per unit effort data, camera traps and the use of DNA from faecal pellets and aged and sexed shot individuals to determine presence of un-shot deer (pellets present for an individual not yet shot) and familial relationships (younger animal shot but not yet its parents) and potentially whether the DNA is from a resident survivor or an immigrant from the South Island.

The DNA from the deer shot during the campaign suggested they were all closely related (Crouchley, et al., 2011). This precluded trying to use the DNA in young animals (which were easier to shoot than adults) as a marker to see if their parents are eventually shot (e.g. see Nugent, et al., 2005). However, this is good news as the island deer had few of the rarer alleles present on the mainland. This suggests that the initial immigration in the 1960s had not been repeated, probably because deer populations throughout Fiordland were greatly reduced by commercial aerial hunting after that time (Nugent, et al., 1987). Therefore, the extirpation of the resident population on Secretary Island might indeed be eradication sensu stricto – still, a precautionary approach of surveillance and rapid response to any new incursions is intended.

Some general observations to ensure surviving deer did not escape are:

(a) to deploy hunters at optimal times/weather rather than on a set schedule,

(b) to know the general areas on the island where the surviving deer are living by extensive ground searches and use of camera traps,

(c) to know which individual deer have escaped the hunters by comparing DNA in faeces with DNA in animals shot and,

(d) to change the mindset of the hunters from ‘control’ to ‘eradication’, i.e. from acting as individuals, however skilled, each hunting any deer in their hunting block, to team hunters with appropriate technologies to act as a team and target individual deer.

The success on Secretary Island, and other smaller islands in Fiordland National Park, provides some templates for the proposed projects against red deer on similar islands. Eradication of red deer has been attempted on Resolution Island (21,000 ha), which is also in Fiordland National Park (Edge, et al., 2011). This project has not succeeded and is currently being reviewed (N. Macdonald, pers. comm.). The Government of Argentina is also considering whether to attempt to eradicate red deer and feral goats (*Capra hircus*) from Isla los Estados (Staten) Island (53,400 ha) in Tierra del Fuego – another remote, mountainous island dominated by southern beech forests (A. Schiavini, pers. comm.). New technologies to locate cryptic deer are also becoming available with improvements in infrared systems (FLIR) currently being deployed against black-tailed deer (*Odocoileus hemionus*) that have survived an eradication attempt on 1,637 ha Ramsay Island in British Columbia (N. Macdonald, unpubl. data).

The general strategy used on Secretary Island, of an initial rapid reduction in the deer population followed by removal of survivors, succeeded in its aim of eradication. However, in retrospect there is always going to be a difficult decision for managers when deciding when to deploy different control tactics across such a campaign. An ideal approach would be to begin with control methods that do not teach surviving animals to avoid later control, and then to apply control methods in a way that minimises the chance of animals escaping each encounter. On Secretary Island, and potentially for other deer eradication projects, we suggest that the team hunting system and coordination between ground and aerial hunting may have been better applied from the start of the 2006 hunting campaign rather than towards the end of the eradication.

ACKNOWLEDGEMENTS

We thank the many hunters without whose skills such projects could not succeed. The DNA profiling was conducted by Ecogene of Landcare Research, Cecilia Arienti-Latham contributed to development of the population model in 2012, and the whole project was funded by the New Zealand Department of Conservation. We also thank Dave Forsyth and Dick Veitch for useful comments on drafts of this paper.

Large scale eradication of non-native invasive American mink (*Neovison vison*) from the Outer Hebrides of Scotland

I.A. Macleod, D. Maclennan, R. Raynor, D.B.A. Thompson and S. Whitaker

Scottish Natural Heritage, Great Glen House, Leachkin Road, Inverness, IV3 8NW, UK. <iain.macleod@nature.scot>.

Abstract The Hebridean Mink Project was tasked with eradicating American mink (*Neovison vison*) from the Outer Hebrides, an extensive, complex island archipelago, amounting to 3,050 km^2. Hundreds of islands contribute to a coastline of approximately 2,500 km, 15% of Scotland's total. The geographical complexity continues inland with over 7,500 freshwater lochs, ~24% of Scotland's total, which enables invasive American mink, in suitable habitats, to reach densities seldom encountered elsewhere. With major funding from the EU LIFE programme, removal from the Uists began in 2001. By 2006 eradication was declared there, as no captures had occurred for 16 months. In 2007 the project extended into Harris and Lewis, adopting a systematic network of live capture traps (7,039 spaced at 450–500 m intervals utilising prominent features of the riparian network and coastline). The traps were checked in rotation until at least a 95% reduction in population had been achieved. An incremental, strategic change from systematic trapping to detection; by means of footprint monitoring, cameras and dog searching, followed by responsive trapping then occurred from 2011 onwards. By 2013 a lethal monitoring system utilising 'kill traps' was employed alongside remote alert systems which allowed the project to remove the remaining population of mink from Lewis and Harris, with a reduced staff resource, and increase the trap night total to in excess of 500,000. To date, 2,198 mink have been caught, but only two non-breeding females and associated males have been caught in Lewis and Harris in the last 18 months (no juveniles captured). The challenges of geographical scale, terrain, climatic conditions and a continuously reducing staff complement have required an adaptive management approach to achieve the project goal of a mink-free Outer Hebrides that benefits ground nesting birds and migratory fisheries. This is viewed as a highly effective eradication project, and lessons learnt can be put into place for other ambitious control programmes.

Keywords: adaptive management, anal gland lure, dog searching, monitoring techniques, remote alert systems, trapping

INTRODUCTION

The Outer Hebrides of Scotland support some of the most important breeding populations of waders in Europe. Species include redshank (*Tringa totanus*), snipe (*Gallinago gallinago*), lapwing (*Vanellus vanellus*) and oystercatcher (*Haematopus ostralegus*); with dunlin (*Calidris alpina*) and ringed plover (*Charadrius hiaticula*) nesting at the highest densities recorded anywhere in the world (Stroud, et al., 2001). In recognition of this, many of the nesting areas have been notified as Sites of Special Scientific Interest (SSSI) under the Nature Conservation (Scotland) Act 2004, and classified as Special Protection Areas (SPA) under the EC Birds Directive, covering an area of about 37,596 ha and 87,158 ha respectively.

At the international level, there are many more species of birds that are represented by important populations on these sites. Species include red-throated diver (*Gavia stellata*), black-throated diver (*Gavia arctica*), great northern diver (*Gavia immer*), hen harrier (*Circus cyaneus*), merlin (*Falco columbarius*), short-eared owl (*Asio flammeus*), greylag goose (*Anser anser*), mallard (*Anas platyrhynchos*), teal (*Anas crecca*), wigeon (*Anas penelope*), gadwall (*Anas strepera*), shoveler (*Anas clypeata*), tufted duck (*Aythya fuligula*), eider (*Somateria mollissima*), shelduck (*Tadorna tadorna*), red-breasted merganser (*Mergus serrator*), golden plover (*Pluvialis apricaria*), common sandpiper (*Actitis hypoleucos*), curlew (*Numenius arquata*), corncrake (*Crex crex*), common tern (*Sterna hirundo*). Ground nesting seabirds such as little tern (*Sternula albifrons*), arctic tern (*Sterna paradisaea*) (Clode & Macdonald, 2002) and arctic skua (*Stercorarius parasiticus*) also occur in significant numbers.

Historically, the introduction of mink in Scotland has been directly connected to the fur farming industry which was established in the 1950s (Dunstone, 1993; Bonesi & Palazon, 2007). In the Outer Hebrides this was mirrored when two fur farms on the Isle of Lewis went out of business in the 1960s resulting in a feral mink population becoming established (Angus, 1993). Small scale control operations carried out by sporting estates and an attempt by SNH to prevent the mink population spreading south had little effect. By 1999, breeding populations of mink were established on North Uist and Benbecula (Harrington, et al., 1999).

Invasive non-native species are one of the main causes of biodiversity loss worldwide (Genovesi, 2009) and predatory species, such as mink, can have a devastating impact on native species (Macdonald, et al., 2007). The need to manage non-native species is increasingly recognised as a necessity to minimise these impacts (Bryce, et al., 2011). In particular the impact of mink predation on ground nesting colonial seabirds can have a significant effect, on not only the breeding success of the species concerned but also the long term viability of the population (Craik, 1997; Craik, 1998). It is documented that mink at relatively low densities can also seriously affect salmonids (Areal & Roy 2006). Atlantic salmon (*Salmo salar*) is a species in decline, for which two Special Areas of Conservation have been established in the Outer Hebrides. The removal of mink can have significant beneficial consequences to a range of species, especially in island ecosystems (Nordström, et al., 2003).

In the Outer Hebrides the impacts of invasive mink over decades had become a significant concern and the most immediate effects were on the colonial nesting species such as tern which were being severely impacted both in terms of their productivity and also the loss of significant numbers of adult birds.

MATERIALS AND METHODS

The Outer Hebrides of Scotland are a highly complex archipelago of hundreds of islands which also includes the third biggest island in the UK, Lewis and Harris. It is characterised by vast expanses of moorland dissected

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 261–266. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

by numerous convoluted freshwater lochs that amount to approximately 24% of the freshwater linear edge of Scotland's total. Due to the remoteness of some areas, and the general coastal nature of the American mink's behaviour, much of the work required the use of rigid hull inflatable sea-going boats that were used extensively, as well as Canadian open canoes in the complex freshwater habitats.

The project design was first established during the application process for LIFE funding but from its earliest conception it was regarded as an innovative trial of eradication techniques and an experimental project that required continuous critical appraisal of the progress being made.

Phase I of the Hebridean Mink Project was to remove all mink from the southern isles of the Outer Hebrides; South Uist, Benbecula and North Uist. The plan was also to reduce the mink density on South Harris to create a buffer zone between North Harris and Lewis (Helyar, 2005), minimising re-immigration, see Fig. 1.

Live capture traps were chosen as the core removal method due to the perception that kill traps were too much of a risk in terms of by-catch. Later in the project it was recognised that with experience, training and robust protocols these risks could be reduced to extremely low levels. Traps were made using 3 mm gauge wire mesh 18 × 15 × 60 cm and had galvanised steel doors. Caught mink were despatched using a .22 calibre air pistol.

From November 2001, for a period of three months, a total of 2,545 traps were dug into the ground and dressed in order that they became part of the landscape, although no more than 10% were open at any time. This provided a large number of pre-located traps, which could be used in

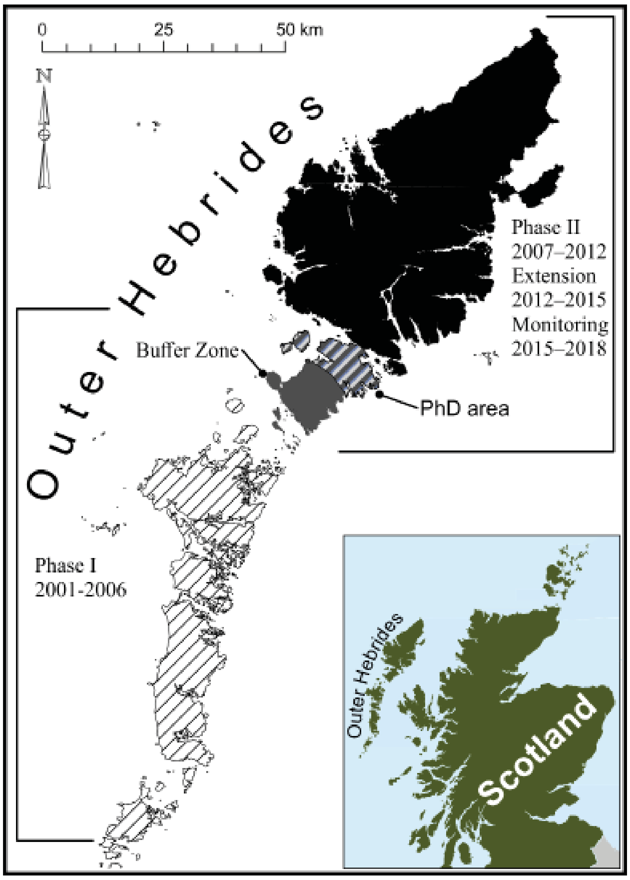

Fig. 1 The Outer Hebrides of Scotland showing the Hebridean Mink Project areas completed with timeframes.

rotation. The most efficient spacing of traps was established to be approximately 500 m apart, but with a higher trap density at individual den sites. Traps were initially baited with horse mackerel (*Trachurus trachurus*), that was later replaced or accompanied with anal gland lure which was more efficient (Roy, et al., 2006).

The team was comprised of a project co-ordinator, two trapper supervisors (one each on Harris and Uist), six permanent trappers, and seasonal/casual workers who assisted when required. The trappers worked a defined 37 hours per week, setting traps on a given route on a Monday and closing them on a Friday. This gave a weekly total of four trap nights per trap opened on any individual route. Traps were most efficient in the first few days of opening, see Fig. 2, and were left open for two weeks initially, reducing to one week in subsequent years.

During 2004 and 2005 the trapping was punctuated with high intensity trapping regimes. This involved co-ordinating a group of up to 25 individuals to trap simultaneously for a period of two to three weeks. The extra support was drawn from external organisational staff from DEFRA and the State Veterinary Service. The aim was to increase the likelihood of capturing any remaining, highly mobile mink.

Throughout Phase I, the most difficult areas to trap were the offshore islands. Two Rigid-Hulled Inflatable Boats (RHIB) were purchased and the associated training was given to trapping staff to enable them to reach all areas.

Dog searches were introduced as a technique during the summer denning period, when trapping is less efficient.

The final mink caught during Phase I was on 23rd March 2005 (see Fig. 2). This was followed by a further 5,567 trap nights and a 'summer' of dog searches with no further mink sighted or caught, bringing Phase I to an end in June 2006. In the interim between Phase I and II, two trappers were employed to keep the mink population low across the South Harris buffer zone.

Phase II of the project aimed to remove all mink from Harris and Lewis, to complete a full eradication from the entire Outer Hebrides. This project commenced in February 2007 and was initially due to end in March 2014, but at present is still ongoing.

Trap locations were pre-determined through the use of a GIS system. Trap positions were chosen by placing them at obvious intersections of linear riparian or coastal features, with 500 m buffer zones to ensure there were no geographical gaps. When in the field, staff were given a leeway of 50 m from the pre-positioned point to allow the

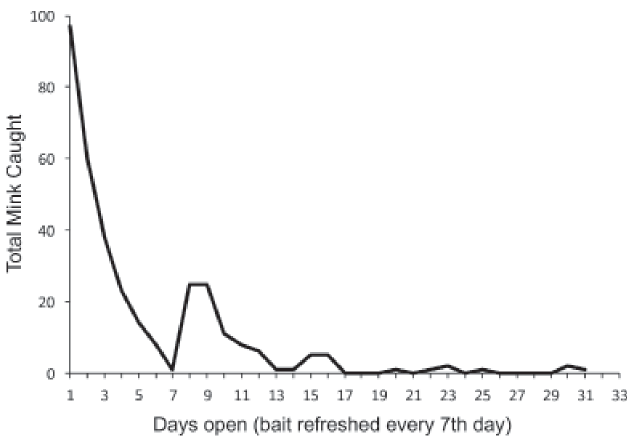

Fig. 2 The number of mink caught per length of time an individual trap remains open (SNH, 2006).

best position to be chosen in relation to the habitat. Once traps were installed, they were mapped on the GIS system to confirm absolute coverage of an area.

From 2007 there were 12 full-time trappers working 37 hours per week, reduced to six full-time trappers in 2012, and three in 2015. By 2008, 7,500 live capture traps had been permanently placed approximately 350–500 m apart, across Lewis and Harris. Traps within an area of approximately 100 km^2 were open at one time, for a period of four days. From 2008 to 2014, systematic trapping continued from the south-to-north, twice yearly. An exception was made in 2012 when the direction of trapping was altered to a north-to-south direction to ensure that specific areas were not always being trapped at the same time of year.

The mink population had been reduced to much lower densities by 2013 An assessment was carried out to ascertain whether the number of trap nights per 2.5 km^2 area was comparable, ensuring effort was distributed evenly across the entire project site. An extensive monitoring programme was set up in areas where there had previously been the highest mink densities, with 17 monitoring devices placed within 10 km^2 areas of interest. Monitoring devices included the use of footprint monitoring tunnels (clay and carbon plate), footprint monitoring rafts, camera traps and dog searches. These monitoring techniques were replaced with more efficient technology in the form of remote monitoring alarms (RMAs) which are activated when a trap is triggered. The monitoring devices are attached to a magnet which is pulled off when a trap is triggered, sending an SMS or email message to chosen team members. The devices were placed on traps situated in areas of good mobile phone coverage.

In 2014 the team reduced to three trappers. In order to maintain good monitoring coverage the live capture traps which had historically caught were replaced with 140 × 140 mm '116 Magnum bodygrip' spring traps contained in a bespoke designed wire mesh cage to exclude all non-target species. Over a period of two years almost 450 bodygrip traps were installed and 120 live capture traps were fitted with remote monitoring alarms.

Meanwhile on the Uist's, a few individual mink re-emerged in North Uist, which were immediately captured. In December 2014 another two mink were sighted in the northern end of North Uist, initiating another trapping project on the Uists. Staff from the Uist Wader project installed kill traps in a small area to detect any further mink. As more traps were installed, more mink were caught, and the trapping area was widened. From 2014 to the present there has been an increase in both trap nights and the number of mink caught on the Uists, with the trapping area now extending from North Uist down to Locheynort and due to be expanded to cover the entire Uists.

RESULTS

Phase I

A total of 532 mink from approximately 200,000 trap nights were caught during Phase I, see Table 1. Approximately half of those caught were on the Uists, compared with a similar number being caught in just the south of Harris (Fig. 3). This demonstrated that the mink population in the Uists had not yet reached carrying capacity, as south Harris has very similar terrain, and large areas of available habitat on South Uist had few captures. Between November 2004 and March 2005, only females were caught. This is likely a result of the trap density and the wider ranging behaviour of male mink. No mink were caught while trapping on the Uists between March 2005 and March 2006.

During the initial stages of Phase I it was quickly determined that the traps were most effective at catching during the first four days of being open. When opened for a further four days during the second week, the trap still caught mink but in far fewer numbers (Fig. 2).

In South Harris, due to a much higher trapper resource for the area available to trap, this number of trapping cycles per year was much higher, up to five times per year compared to just twice a year, and resulted in a very quick collapse in the territorial mink population. Thereafter, trapped animals were generally those immigrating, from the north, into the area, as indicated by a higher proportion of males caught during this period.

An important difference in the capture locations between the Uist's and South Harris became evident in the first few months of the project with the Uist's showing a significantly higher proportion of captures inland compared to coastal habitats. The difference was largely due to the

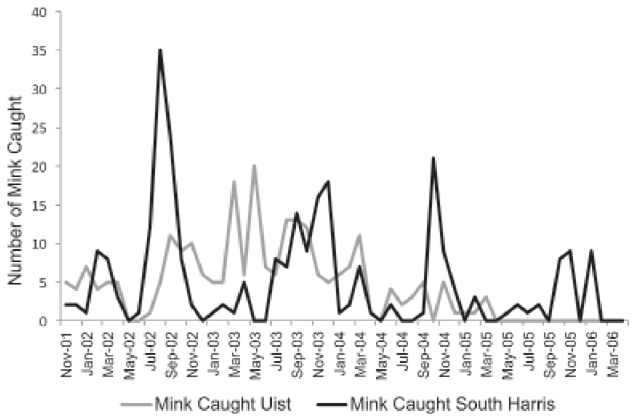

Fig. 3 Number of mink captured per month and year on both South Harris and the Uists during Phase I (SNH, 2006).

Year beginning	Trap nights		Mink captured by trapping		Mink captured per 1000 trap nights		Mink captured by dog searches (dependent young in brackets)

Sep-2004	20,037	2755	13	38	0.65	13.79	1	3 (1)
Sep-2005	1,114	76	0	1	0	13.15	0	0
Total	100,824	41,674	191	230	1.89	5.15	37	18

Table 1 The numbers of trap nights, mink captures and trap successes in the Uists and South Harris during Phase I (Roy, et al., 2015).

greater availability of food resources inland in the Uist's, including a large number of duck and wader species closely associated with the freshwater edge but, importantly, the presence of field voles in the moorland habitat that were absent from Lewis and Harris.

Phase II

Trapping took place over large areas, only moving on when a low mink density had been achieved. This resulted in a significant drop to the overall mink population, with 51% of the final captures so far, being caught in the first two years. The final total of mink captures by March 2012 was 91% of the current figure. From April 2012 a further 116 mink were caught over the next three years, equating to a further 6% of the current final total.

Initially there was a two week live trapping cycle carried out but this was reduced to a one week cycle to increase the efficiency of the knock down phase. Whilst initially unpopular with the trapping staff, as they felt they were leaving animals behind, the speed with which the project reduced the mink population over a wide area soon became apparent and the staff bought into the techniques employed.

From 2007 to the present a total of 1,666 mink have been caught from 527,431 trap nights, across Lewis and Harris.

The major result of moving from live traps to a kill trapping regime was an increase in the total trapping effort, despite being reduced to a trapping team of just three. This can be seen in Table 2, where up to 14,000 trap nights per month were being achieved compared to approximately 2,000–2,500 per month when 12 trappers were employed for live capture trapping.

The captures per unit effort have declined over time but reflect the seasonality related to the trapability of more mobile mink during the rut and the naivety of young animals during the dispersal period (Fig. 4). The striking issue, however, is the extremely long tail to the graph which describes the extreme difficulty in catching the final animals over such a large geographical area with a declining staff resource (see Fig. 5). Two modelling exercises were completed, (Shirley, et al., 2012) and the modelling exercise carried out by Aberdeen University (Lambin, et al., 2014) did predict that this would be the case: 80% of

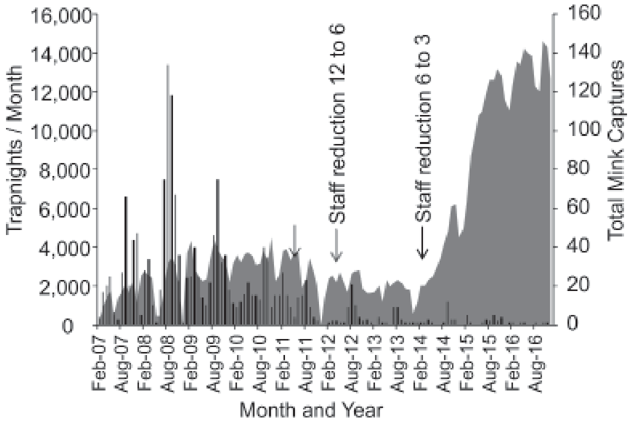

Fig. 4 Trap captures from Feb 2007–Nov 2016. Black bars are mink caught; grey area is the trapping effort.

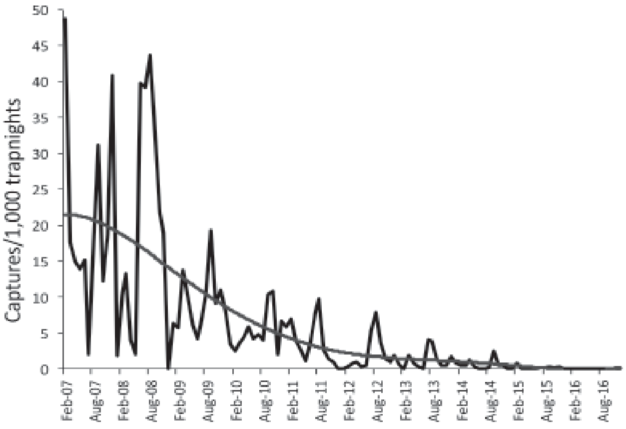

Fig. 5 Number of mink captures per 1,000 trap nights between February 2007 and December 2016.

iterations predicting eradication by 2017, using the data up to 2011 and a trapping regime based on live capture and a trapping regime of 12 trappers see Table 2.

During the final monitoring phase of the project in Lewis and Harris, the final 1.5% of the mink population was caught and functionally the population was eradicated with only isolated individuals, unable to find a mate and breed, left to track down. No juveniles have been caught in Lewis and Harris since August 2015

Through an increase in trapping effort and larger areas being monitored, there has been an increase in the number of mink being caught on the Uists since 2014 (Table 3). These animals are finally reducing in number as the same kill trapping regime used in Lewis and Harris takes effect.

Table 2 Actual trap nights and captures for all years of the project from 2007 onwards.

Year	Total trap nights	Total captures	Male	Female
2007	14,914	280	146	134

DISCUSSION

In 2001 when this project was initiated, there were few, if any, successful eradications that used trapping as the main technique for the removal of an invasive non-native mammal; the only UK example being the coypu eradication in Norfolk, (Gosling & Baker, 1989). In addition, there was a limited range of literature available providing examples of wildlife management project design and best practice to follow (IUCN, 2000). The EU LIFE fund recognised that the project would need to adapt as it progressed and agreed to provide funding based on the understanding that it was innovative in its concept, scale and design.

During Phase I, one of the main lessons learnt was the necessity to ensure trap distribution was coordinated by the supervisor. Initially trappers were relied upon to distribute traps in the field according to their own judgement, with only a specific distance between traps to guide them. This meant that traps were situated in ideal locations for catching mink, but trappers on the ground were unable to ensure that there were no gaps in the overall trap coverage, leading to irregular densities. Over time, the emergence of better GPS technology enabled trappers to be more efficient in the field and able to provide more accurate trap locations. Establishing the most effective trapping schedule was important as it was not possible to trap the entire area at once with the staff available. A twice yearly minimum trapping cycle of the entire trap network was vital to ensure that all areas maintained sufficient trap nights, while removing animals in a timely manner to avoid successful breeding.

Despite the ongoing learning process during the first phase, the project managed to achieve the removal of the majority of the mink from the project area in just under three and a half years, followed by a summer of monitoring. It was thought at this point that it was very unlikely that any mink remained in the Uists and Benbecula and that eradication from these islands had been achieved.

The second phase of the project was an absolute requirement if the gains of the first phase were to be secured over an even larger geographical area and the investment in the previous five years was to be protected. Scottish Natural Heritage demonstrated significant commitment in proceeding with Phase II, helped with funding from the Esmeè Fairbairn Foundation, but from the outset the budgetary constraints on the project were clear. The modelling work undertaken by the Central Science Laboratory (now Animal and Plant Health Agency) indicated that 16 trappers would be ideal (Moore, et al., 2003) but due to budgetary constraints, the project proceeded with just 12. Restricted resources continued into the project extension and the monitoring phases and required significant adaptive changes to strategy and efficiency in order to give the project the greatest chance of success. It is undoubtedly true that the project has taken longer due to these budgetary constraints and that, if fully funded for the entire requirement of 10 years plus two extra years to ensure eradication, significant savings could have accrued over this period. This type of consecutive long-term funding is simply not available in the UK, (Lambin, et al., 2014), as it does not fit with the funder's requirement to demonstrate success, generally within five years, and exceeds the acceptable commitment levels between political administrations.

Throughout the project, different methods were employed at various stages to overcome the challenges of limited resources. The addition of the bodygrip traps instead of solely live traps enabled a high level of trapping effort to be maintained with limited staff. Bodygrip traps meant that trappers did not have to respond to triggered traps immediately as the mink would be dead upon capture. The initial concern of accidental by-catch was reduced to an acceptable level through very strict protocol in the practical setting of the trap, including the bespoke tunnels which excluded all non-target species, and camouflage technique.

Monitoring such a huge geographical area with only six trappers was challenging and several monitoring devices and techniques were trialled. Footprint rafts were not able to withstand the extreme weather of winter months either through wind or high water spate events, the cameras had slow triggers and reset times which led to missed targets, while the clay/carbon footprint monitoring required careful set-up and protection from the elements to provide useful data. In addition, the time between detecting the mink and being able to initiate the trapping was too long to catch a highly mobile individual. The acquisition of trap RMAs were particularly useful for the monitoring period, giving a precise time stamp for when a trap caught and enabling further traps to be installed in the area immediately. This was immediately effective as the mink population had begun to cluster in their distribution, not only during the rutting period which would be expected, but animals would also set up territories next to existing ones rather than be isolated and alone. This helped greatly once an individual was trapped, as a localised trapping campaign could be mobilised to catch a few additional animals.

The Hebridean Mink Project is now into its 16th year, and has cost a total of £5.26M. The learning process has been difficult and expensive and these lessons should be passed on to others. There is a requirement for simple tools to be developed that will allow projects to recognise the key stages of eradication from the data they collect. These comprise: population crash completion (knock down), identification of groups of target species (cluster effect) and difficult to trap areas to allow targeted action (trap everywhere at the same intensity), detection of individuals and their rapid removal (find the right monitoring technique), effective and efficient long-term monitoring and biosecurity (ensure the last individuals are not left behind or re-introduced).

Clearly there are vast amounts of data associated with this project that could provide a lifetime of analysis opportunities of which only a tiny fraction has been used here. Some of the intuitive assumptions made within this paper need to be statistically analysed to provide definitive proof of behaviours such as clustering, which appear so obvious from mapping the capture data geographically over time.

CONCLUSIONS

Phase II of the Hebridean Mink Project commenced with a wealth of knowledge, practical scientific information, techniques and trapping scheme models, not to mention a core of well-trained staff. This no doubt contributed to the success in greatly reducing the population of American mink to near eradication. With the re-emergence of mink in the Uists, the main lesson that can be learnt from Phase I, is the importance of ensuring a sufficiently long monitoring period with a sustained level of effort is implemented once the last mink is thought to have been captured. Maintaining sufficient resources to continue monitoring during the final years following eradication is crucial to ensuring the project's success (Rout, et al., 2009). Any lapse in funding before eradication is declared could result in the mink being able to breed successfully and repopulate, leading to financial losses that are both immediate and exponential.

If eradication can be achieved in the Outer Hebrides this would represent the largest mammalian eradication initiative worldwide using just trapping techniques.

ACKNOWLEDGEMENTS

We would like to thank Charles Thompson and Rachel Cartwright for their help with initial drafts of this paper and Alasdair Macleod of the University of the Highlands and Islands for his help in producing and maintaining the database software beyond the contract requirements. Further thanks to the staff of Newcastle and Aberdeen Universities for their modelling, especially Xavier Lambin for his scientific input and constructive practical ideas.

Most of all, a huge thanks to all who have been involved with the project over the past 17 years. Too many to name individually, this has been a collective long-term achievement due to the hard work of hundreds of people: in particular the trapping staff, who have walked the equivalent of several times round the world in order to check the trapping network in the worst of weather that the west coast of Scotland could throw at them. Lastly, but not least, the people of the Outer Hebrides for their help and co-operation throughout the project. Thank you all.

Abstract Socorro Island is part of the Revillagigedo National Park, Mexico. At 132 km^2, it is the Mexican island with the highest level of endemism. It provides habitat for 117 vascular plant species, 26% of which are endemic. There is also an endemic blue lizard (*Urosaurus auriculatus*) and eight endemic terrestrial birds. Socorro's ecosystem had been heavily degraded by invasive mammals for the past 140 years. Feral sheep (*Ovis aries*) destroyed one third of the island's habitat and feral cats (*Felis catus*) severely impacted the island's avifauna and the Socorro blue lizard. Together, feral sheep and cats are responsible for the extinction in the wild of the Socorro dove (*Zenaida graysoni*) and the Socorro elf owl (*Micrathene whitneyi graysoni*) and have been a serious threat to other vulnerable species, particularly Townsend's shearwater (*Puffinus auricularis*). As such, the island's restoration is a high priority. We conducted a feral sheep eradication from 2009 to 2012, using aerial and terrestrial methods, aided by Judas sheep and trained dogs, to kill 1,762 animals. The vegetation recovery has been remarkable, as well as the improvement of soil properties such as compaction, nitrogen, organic carbon, phosphorus, and calcium. In 2011, we initiated a feral cat control programme, which soon became an eradication project. The ongoing feral cat eradication has been a challenge, due to Socorro's large size, vegetation and topographical complexity. By December 2016, 502 cats had been dispatched, using soft leg-hold traps equipped with telemetry transmitters and lethal traps: a total effort of 50,000 trap-nights. Cat abundance has decreased very significantly and catch per unit of effort indicates that the eradication is nearing completion. The abundance of the Socorro blue lizard and terrestrial birds has already increased. We estimate completing the feral cat eradication by the end of 2017, when we will shift to a verification of eradication phase.

Keywords: exotic mammals, habitat recovery, outcomes of eradications

INTRODUCTION

Mexican islands are known for their high biodiversity richness. They are home to many endemic species and are important breeding grounds for a variety of birds and marine mammals (Aguirre-Muñoz, et al., 2011). Unfortunately, these ecosystems are suffering serious impacts resulting from human activity. Exotic species are among the main causes of biodiversity loss and ecological disequilibrium in many environments (Courchamp, et al., 2003). Herbivores, like feral sheep (*Ovis aries*), have caused serious ecological impacts on insular ecosystems. In 1869, 100 sheep were introduced to Socorro Island, in Revillagigedo National Park, Mexico (Fig. 1) for ranching. Over time, they became feral, successfully adapting to island conditions (Levin & Moran, 1989; Álvarez-Cárdenas, et al., 1994; Brattstrom, 2015). In the absence of natural predators, the sheep population grew to be about 5,000 individuals by 1960 (Villa, 1960). This reduced to around 2,000 in 1988 as a result of increased hunting by the Mexican Navy (Walter & Levin, 2008), but they became the main cause of the island's poor ecological condition (Richards & Brattstrom, 1959; Veitch, 1989). Since their introduction, feral sheep have caused huge modifications to the natural habitat. Erosion rates and loss of vegetation caused by the presence of sheep were documented, along the southern-central region of the island (León de la Luz, et al., 1994; Maya-Delgado, et al., 1994; Rhea, 2000). Nearly 30% of the original soil and vegetation on Socorro Island was lost due to erosion caused by feral sheep (Ortega-Rubio, et al., 1992). Among the most significant changes to the original floral composition has been an increase in the presence of grasses and shrub species, as well as a reduction in the area covered by native flora. Sheep aid the propagation of introduced plant species, dispersing seeds in their coat and excrement. The change in native vegetation has been observed in every habitat that sheep occupied (SEMARNAT, 2004). Another serious threat is the feral cat (*Felis catus*), which have severely impacted the island's bird communities and the endemic Socorro tree lizard (*Urosaurus auriculatus*) (Arnaud, et al., 1993; Arnaud, et al., 1994). Together, feral sheep and cats are responsible for the extinction in the wild of the Socorro dove (*Zenaida graysoni*) and the Socorro elf owl (*Micrathene whitneyi graysoni*), and pose a serious threat to other vulnerable species, such as Townsend's shearwater (*Puffinus auricularis*) (Martinez-Gomez & Jacobsen 2004). The eradication of feral cats represented another serious challenge, as Socorro is a large and complex island, and little baseline information was available on the distribution and abundance of cats (Arnaud, et al., 1994). Fortunately, technologies have been developed on other islands of Mexico and the world to achieve the eradication of these predators (Bester, et al., 2002; Wood, et al., 2002; Algar, et al., 2010; Aguirre-Muñoz, et al., 2011; Luna-Mendoza, et al., 2011; Parkes, et al., 2014). The successful implementation of an eradication campaign of this type is essential to determine the basic aspects of the species, the impact of the methods applied on the native fauna, and the

development of an official eradication plan (Veitch 1989; Arnaud, et al., 1994; Donlan, et al., 2003; Dowding, et al., 2009).

MATERIALS AND METHODS

Study site

The volcanic Socorro Island is the largest and most diverse portion of the Revillagigedo Archipelago, a World Heritage site in Mexico that was listed by UNESCO in July 2016. It is located in the tropical eastern Pacific, 460 km from the Baja California Peninsula and 700 km from Manzanillo, Colima. It has an area of 132 km^2 and a maximum altitude of 1,040 m (18º 47´ N, 110º 58´ W). Due to its remoteness, the island is a strategic point for Mexico's military personnel (40–50 people) situated at a naval base located in the southernmost part of the island. Additionally, Socorro Island has critical biodiversity significance through a high level of endemism, due to its isolated position A remarkable number of its native biota are exclusively found in this part of the world. Approximately one third of the 118 species of native vascular plants inhabiting the island are endemic. The native fauna is comprised of one endemic reptile species and almost 101 species of birds, of which eight of the terrestrial birds are endemic (SEMARNAT, 2004).

Feral sheep eradication

Monitoring: To identify the main areas where sheep were distributed, several flights (on a Beechcraft Bonanza aircraft) were made over the island during October 2005. At the same time, Mexican Navy officers conducted land surveys on foot and in motorised vehicles (ATV´s).

Aerial hunting: The aerial hunting stage was carried out using a single turbine helicopter (model MD369D), between April 20 and 29, 2009; supported by a GPS to record the flight trajectories. Two hunters were shooting simultaneously during the flight, using semi-automatic rifles and shotguns. All flights took place between 07:00 and 11:00 h, and between 16:00 and 19:00 h; at an average speed of 42 km/h and average height of 35 m.

Judas sheep: During the aerial hunting, 12 live animals were captured, to be used as 'Judas' sheep (individuals that serve to help locate remaining herds; Taylor & Katahira, 1988). These animals were neutered and fitted with radio-telemetry collars (Telenax, Mexico). These Judas sheep were deployed back to the sites where they were captured.

Terrestrial hunting and trapping: From February 2010 to April 2012, 4–7 experienced hunters carried out terrestrial hunting. Each one was equipped with a handheld GPS to record their hunting tracks, rifles (calibre .222, .243 and .308) with telescopic sights, as well as a 12-gauge shotgun with cartridges. Supported by the Judas sheep, it was possible to identify sheep herds. Simultaneously, leg-hold traps (Oneida Victor Soft Catch # 3) and snare traps were used on previously identified sheep trails; both types of trap were checked daily.

Hunting dogs: for the last stage of the sheep eradication, we used two hunting dogs (beagle and foxhound) to track down the remaining sheep herds; the dogs were fitted with GPS collars to record their locations and movements (Ortiz, et al., 2016a).

Feral cat eradication

Trapping: The eradication method consisted mainly of catching cats using leg-hold traps (#1 ½) and lethal traps (Conibear Bodygrip traps 10": Rauzon, 1985; Twyford, et al., 2000; Phillips, et al., 2005; Rodríguez, et al., 2006; Rauzon, et al., 2008; Luna-Mendoza, et al., 2011). Leg-hold traps with pads were used in 220 sites over the duration of the expedition (21–51 days), baited with a commercial cat bait made of seafood, tuna or fried sardine (Brothers, 1982). Traps were checked daily from 7:00 to 10:00 h. Lethal and leg-hold traps were located in sites of difficult access, equipped with telemetry systems (ATS, mammal trap monitor Series M4000) to determine whether they had been activated from a distance (Will, et al., 2010). Once cats were captured, these were euthanised by intramuscular injection of an anaesthetic and lethal intracardiac injection (pentobarbital). As a secondary method, night hunting was conducted using .222 calibre rifles with telescopic sights, and lamps (Kohree 80,000 lux: Ortiz, et al., 2016a).

Soil quality assessment

Soil compaction: In 2013, soil penetration resistance measurements were taken using a penetrometer (Soil Compaction Tester Dickey-john®) within 20 vegetation transects (Fig. 1). Sites were categorised as: bare soil sites, those with 50% recovered vegetation and those with 100% recovered vegetation. Additionally, soil compaction measures were taken in sites with 100% vegetation coverage, not previously disturbed by the sheep (ND = not disturbed). Fifty replicates were obtained in each category, resulting in a total of 200 measurements. An analysis of variance and Tukey's honest significance test were performed to analyse the differences among the different categories of vegetation cover.

Physicochemical soil parameters: soil samples of approximately 1 kg each, were collected from each transect at a depth of 0–10 cm: 16 samples were obtained in each one of the soil categories (N= 64). Subsequently, the following physicochemical parameters were determined: pH and electrical conductivity, total nitrogen by the Dumas method in a LECO nitrogen analyser; organic matter by the method of Walkley-Black; phosphorus by colorimetric reading of a spectrophotometer, and calcium and magnesium by the EDTA method.

Vegetation recovery assessment

Field assessment: Prior to eradication, in 2009, vegetation data collection was started to obtain a baseline scenario of the degraded environment, with the aim of making subsequent comparisons possible, and to detect signs of recovery after sheep removal. The estimation of sheep overgrazing consequences on the island was determined by selecting 20 plot sites. Transects of 10 m × 100 m were established in the more disturbed areas, to identify pioneer species on eroded soils; all plants were identified and counted. Plot sites were categorised in: forest (six replicates), mixed scrub (six replicates) and eroded surface (seven replicates) (León de la Luz, et al., 1994). The vegetation monitoring continued from 2011 to 2016. Analysis of variance was performed (rANOVA) to analyse differences in vegetation cover and in the number of species over the years of the study (Ortiz, et al., 2016b).

Normalised Difference Vegetation Index (NDVI): To identify changes in vegetation cover the photosynthetic vegetation vigour of the island was obtained, quantified with the Normalized Difference Vegetation Index (NDVI). Supported with QGIS software, two maps were generated. A "pre-eradication" map, created using a QuickBird satellite image, dated on May 11, 2008; and a "post-eradication" map, generated with a WorldView 2 satellite image, dated on May 9, 2013. Finally, the change in vegetation cover between the two dates was determined by subtracting the 2008 image NDVI raster pixel image values from the image of 2013, considering only differences exceeding 0.2 (bare soil).

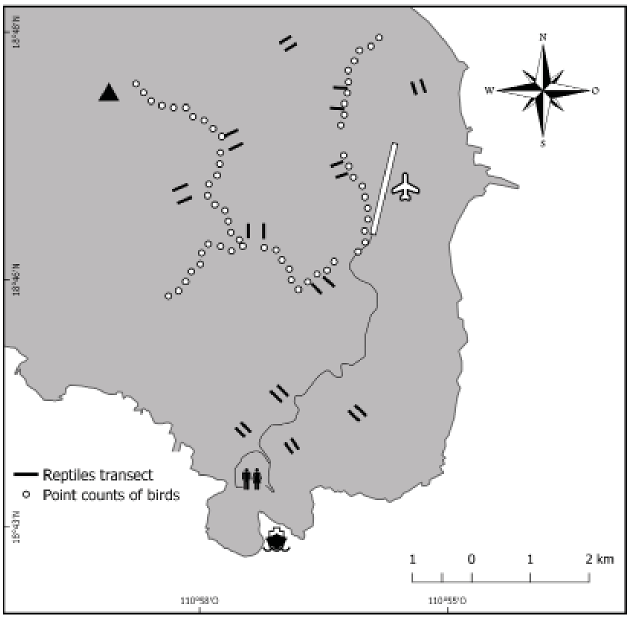

Fig. 2 Location of transects of Socorro tree lizard (lines) and count-points for birds (quadrats).

Monitoring of native fauna

Socorro Island tree lizard: To evaluate if the vegetation recovery was promoting any improvement of native animal populations, we monitored the Socorro Island tree lizard, during April and October, from 2012 to 2017. Twenty-four transects were set up in three different types of habitats (eight replicates per habitat type): forest, deciduous scrubland and eroded surfaces or areas impacted by sheep (León de la Luz, et al., 1994), each measuring 6 m × 100 m (Fig. 2). Transects were each visited on three consecutive days, between 10:00 and 12:00 h, during two different seasons (dry and rainy). Density (D) was estimated using the formula: $D = (n/2wL)$, where n is the number of individuals recorded, L is the total transect length, and w is the width of the transect on each side of the line (Gallina & López-González, 2011). A one-way repeated measure analysis of variance (rANOVA) was conducted to determine differences in seasonality and in habitat type on tree lizard density, the statistical software R (Version 3.2.2) was used for the analysis.

Terrestrial birds: Terrestrial birds were also monitored, using the point-count technique. Six transects were established during April and October (two seasons per year) from 2012 to 2017 (Fig. 2). The monitoring was carried out from 6:30 to 9:30 h and was repeated on three consecutive days, during the dry and rainy season, respectively. At each site, all birds observed within a radius of 25 m in a time span of five minutes were counted. Subsequently, the observer moved to the next counting point, located 250 m away, with a five-minute break before starting the next count. The statistical test rANOVA was run to determine the effect of season and habitat type on the total number of birds, plus Student t-tests for paired samples with a Bonferroni adjustment, to compare sightings during the different seasons.

RESULTS

Sheep eradication

Aerial hunting: a total of 35 flight hours was achieved in one week during the aerial hunting stage, in which most of the island was covered, with an average flight time of 1h 20 min per event; this resulted in removal of 1,257 individuals. The aerial hunting ceased when sheep became difficult to locate, and relatively few animals were being shot within a flight event. This method was selected due to its proven effectiveness in achieving rapid eradication (Campbell & Donlan, 2005) and was ideal on this island owing to its tropical conditions, which allowed the carcasses to decompose rapidly.

Ground hunting and trapping: 505 sheep were dispatched during the ground hunting stage, which comprised a nine-month period of hunting, over two years (March 2010–April 2012). Judas sheep were mostly effective when there were more remaining sheep, due to an increased probability of aggregation. Hunting dogs were used only at the final stage of eradication to locate the last ten remaining animals, which were difficult to locate for hunters. A total of 1,762 sheep were dispatched from Socorro Island in a three-year eradication campaign (Table 1).

Feral cat eradication

By December 2016, 502 cats had been removed, using soft leg-hold traps equipped with telemetry transmitters and lethal traps (body grip). Traps were placed in more than 250 sites on the island. Up to that date, there was an effort of more than 50,000 trap-nights. The success of cat capture during the trapping period fluctuated throughout the year (greater catch in January–May, dry season; and lower catch in June–October, rainy season). However, a clear trend to a smaller population was noted at a multi-year timescale (Fig. 3). In general terms, the success of capture is greater in the dry season and decreases during the rainy season. It is expected that cat eradication will cease in 2018; if that is the case, absence confirmation monitoring will be carried out in 2019.

Soil quality assessment

The results of the soil compaction assessment showed that eroded soils were the most compacted and a trend towards compaction reduction on areas with recovered

Table 1 Feral sheep dispatched on Socorro Island.

Year	Months	Personnel	Hunter hours	Distance (km)	Judas sheep	Trap nights	Captured sheep	Dog hours	Sheep removed
2009	May		35 (helicopter)						1,257
2010	Mar–Apr	7	1,323	815	53	900	41	-	355
	Jul	6	588	460	18	-	-	-	48

Total			3,811	2,953	86	1,550	49	49	1,762

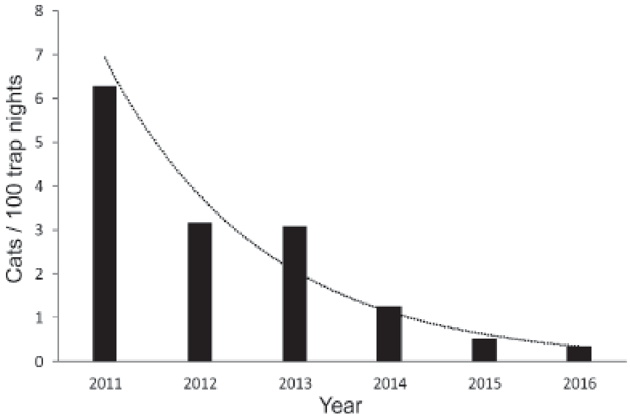

Fig. 3 Success of capture of feral cats.

vegetation was observed (50% and 100% recovered vegetation cover). Transects that retained eroded soils (0% vegetation) because of the sheep trampling, showed greater penetration resistance (>300 pounds-force per square inch, or psi, to 12 inches deep); at sites with 50% and 100% recovered vegetation cover, soils were also compacted and shallow (100–120 psi to three inches deep) and became more compacted at greater depths (300 psi to 24 inches deep); at sites with 100% coverage without disturbance (ND), the soil showed little variation (230–300 psi until 21 inches depth), which was in the optimal range for the growth of most plants (from 200–400 psi to 24 inches), which could be due to the constant, stable conditions. Significant differences ($p < 0.001$) were observed among sites with 0% and those with 50% and 100% recovered vegetation cover. The results of physicochemical analyses of soil samples showed increased nutrients: pH values remained close to neutral, showing a significant difference ($p < 0.021$) between sites without vegetation and 50% vegetation cover (results in Ortiz, et al., 2016b). Electrical conductivity, which is an indicator of salt presence in soil, was also significantly different ($p < 0.013$) between the eroded and 100% vegetation covered sites, although no difference was observed between eroded soils and those that were not disturbed. In the case of total nitrogen, organic carbon, phosphorus and calcium, sites with recovered vegetation were significantly different ($p < 0.001$) to those with erosion. Both nitrogen and organic carbon doubled, while phosphorus and calcium values almost tripled in places with increased vegetation cover compared to the eroded sites. Meanwhile, magnesium showed significant differences among the eroded sites (0%, 50%, and 100% recovered vegetation cover) and undisturbed sites (100% ND; Ortiz, et al. 2016b). The sites that were never altered by the presence of sheep exhibited a magnesium concentration twice that of disturbed sites.

Vegetation recovery assessment

Calculations (comparison of the images from 2008 and 2013) showed a difference of 1452 ha, which is equivalent to vegetation recovery of 11% of the island surface. The eastern part of the island was the area with the greatest habitat disturbance (Álvarez-Cárdenas, et al., 1994), and where the greatest vegetation recovery seemed to have occurred within the analysed period. Due to the presence of sheep, most of the evaluated sites lacked vegetation, and few species were present in 2009 (Fig. 4). Additionally, trails made by the sheep were observed to have compacted soils. Statistical tests showed significant differences from 2009 to 2013 in the number of species present in the eroded sites as well as in percentage cover. It was possible to record obvious recovery in all the habitats in 2013, i.e. the forest habitat with the highest values, followed by the mixed scrub, and then the eroded surface.

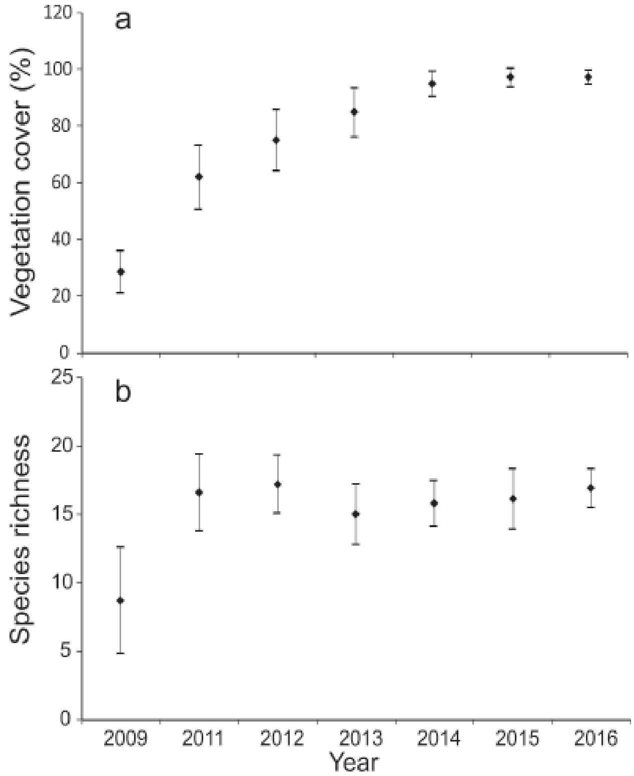

Fig. 4 Increase in vegetation cover (a) and species richness (b) on Socorro Island.

Monitoring of native fauna

The results of tree lizard monitoring reveal that the population is increasing, taking into consideration both the dry and rainy seasons (Fig. 5). Lizard density fluctuated significantly between seasons since the trapping of cats started on Socorro Island ($p = 0.014$). The number of birds sighted from 2012 to 2015 also showed significant differences between seasons ($p = 2.2 \times 10^{-4}$). Although population fluctuation is evident over the years of the study, there is an increase of birds in the dry seasons of 2014 and 2015 (Fig. 6). Significant differences were found between November 2012 and the rest of the monitoring time points (except November 2014). No significant differences were found between dry seasons during the years 2013 to 2015. The most abundant species was the Socorro tropical warbler (*Setophaga pitiayumi graysoni*), followed by the Socorro wren (*Troglodytes sissonii*), and the towhee (*Pipilo maculatus socorrensis*), all of them endemic to the island.

DISCUSSION

Compared with other islands where goats or sheep have been eradicated (Van Vuren, 1992), the Socorro Island feral sheep eradication can be considered highly effective as it was completed in three years, when similar projects have taken 3–5 years, and even decades, to conclude (Campbell & Donlan, et al., 2005). Moreover, the methods used reduced project cost, which was US$ 38/ha, while other sheep eradication projects, such as that developed on Santa Cruz Island, California, cost US$ 80/ha, due to capture and transport of sheep to the continent (Faulkner & Kessler, 2001).

The capture of cats increases during the dry season (January–May) and decreases in the rainy season (June–October). The results differ between wet and dry seasons, since moist land interferes with the installation of leg-hold traps, and dry substrate is unavailable to cover them. Rain also compacts and hardens the substrate covering the traps, hence restraining their activation. At the same time, another key factor that affects trapping in the rainy season is the higher abundance of land crabs (*Gecarcinus planatus*), which consume the bait placed in traps, or activate traps when attempting to reach the bait. The combination of lethal traps and telemetry devices is essential during trapping in the most remote areas of the island. In this way, traps do not have to be checked daily but every five to seven days any bait lost to insects (mainly ants) and crabs is replenished (Parkes, et al., 2012).

The changes in soil physicochemical properties on Socorro Island seem to be related to the gradual recovery of vegetation after the eradication of feral sheep. Prostrate *Chamaesyce* sp. and *Erigeron socorrensis* have been observed to have a great capacity to retain soil. *Hyptis pectinata* and *Pteridium caudatum* established in high densities; in addition to retaining soil, they have generated much organic matter. Possibly the most successful species to colonise disturbed areas has been *Dodonaea viscosa*, which has a great ability to germinate in eroded soil (Campa-Molina, 1989), generating organic matter and preventing the germination of other species (Castellano & Valone, 2007). In the absence of trampling, soil aggregate stability increases, which enhances permeation, reduces erosion, and may promote nutrient accumulation and soil retention (Allington & Valone, 2010). As pioneer plants began to establish, the ground became less compacted because the roots of plants, particularly annual grasses in this instance, act as biological perforators, also incorporating organic matter into the soil. Once the roots die and shrink, these pores are large enough to allow the roots of perennial shrubs to penetrate (Sellés, et al., 2012). Greater ease of water movement in the soil matrix, coupled with heavy rainfall, could be causing leaching and replacing cations with H+ ions, acidifying the soil.

Both the results obtained with the NDVI calculation and field observations suggested that some pioneer plants had the ability to germinate on eroded soils and were instrumental in the succession process by providing the right conditions for seeds of tree species to germinate. The progressive increase in vegetation cover reduces soil compaction and restores the biogeochemical cycles of essential nutrients, such as nitrogen, phosphorus, and calcium, which are essential for the recovery of communities and the ecosystem in general, as well as the incorporation of carbon on the ground, which is essential for the proper functioning of important microbiological components. Any change in the habitat that produces changes in litter production, soil aeration, or any other factor affecting microorganisms will be reflected in changes in biogeochemical cycles, such as those of carbon and nitrogen (Hartmann, et al., 1997).

We found differences in the number of species and vegetation cover in the sampling area between 2009 and 2013. The forests and mixed scrub areas showed the greatest recovery, probably favoured by their vegetal components and the permanence of seed banks, due to a more stable landscape, water availability, and precipitation patterns. The endemic tree species recovering were *Guettarda insularis* and *Psidium socorrense*. The smaller number of plant species found in the isolated patches of mixed scrub included in large expanses of erosion could be due to the steepness of slopes and wind exposure. Gravity also makes the permanence of naturally occurring soil seed banks difficult. Some species of exotic grasses have increased with sheep eradication because they are no longer grazed.

The Socorro Island tree lizard was found at higher densities in the deciduous scrubland, being less abundant in forests at higher altitudes. The results of this particular study show that the density of lizards on eroded surfaces was as high as 43 individuals/ha after cat abundance was reduced, however Galina et al. (1994) reported not having observed lizards in these areas. This may be due to a gradual recovery of the vegetation resulting from the recent eradication of sheep (Ortiz-Alcaraz, et al., 2016a; Ortiz-Alcaraz, et al., 2016b) and to the sustained trapping of cats in these areas. Lizard abundance was slightly higher during the rainy season, likely due to greater food availability. As the cat eradication programme in the eastern area of the island has progressed, the predation pressure of cats on the lizard population has decreased. Lizards are a major component of the cats' diet (50% of faecal samples of cats analysed contained lizard remains; Arnaud, et al., 1993). The vegetation type where the highest number of birds was observed was the forest (*Ficus-Guettarda-Ilex*), especially in the highest parts of the island, where the recovery of vegetation resulting from the absence of grazing sheep has led to greater availability of food and shelter against predators (Rodríguez-Estrella, et al., 1994). On the other hand, special efforts have also been made to eradicate cats in the forest, aiming to protect the native bird species, such as the Townsend´s shearwater (Ratcliffe, et al., 2009).

The plans developed by Veitch (1989), Arnaud, et al. (1993) and Parkes, et al. (2012) are all in agreement that feral cats can be eradicated using traditional techniques: trapping and night hunting. However, the experience on the island has shown the importance of using detection dogs to locate the remaining cats, either during the day, in their dens (placing traps to catch them), or at night, killed by hunting (Tortora, 1982; Veitch, 2001), as well as the statistical confirmation of absence (Ramsey, et al., 2011).

CONCLUSION

The aerial hunting method proved to be an ideal technique for the eradication of sheep from Socorro Island. It enabled the eradication team to dispatch a high number of animals in a few days of work, while allowing the hunters to access difficult terrain. The use of Judas sheep and hunting dogs was crucial for completing the eradication.

Removing the exotic herbivorous species from the island is a conservation tool, which is evident in recovery of the natural environment. Habitat fragmentation and degradation caused by the presence of sheep was evident on the island, where the main impact was on vegetation. The resistance of native species has been important, not only in the relatively rapid recovery of the vegetation cover, but also in offering the possibility of recovering the former island vegetation. The results reflect the important role of vegetation in erosion control, both for establishing mechanical support due to plant roots in the soil structure and in capturing water flow and nutrients, providing fresh organic matter to the soil and restoring biogeochemical cycles and ecosystem processes.

With habitat recovery and progress in the feral cat eradication, wildlife recovery is expected as food availability and resources for the native species of the island gradually increase and predation decreases. Socorro Island seems resilient enough to recover over a relatively small-time scale, after the removal of the pressures caused by exotic mammals.

Removing introduced hedgehogs from the Uists

R.C. Thompson and J.M. Ferguson

Scottish Natural Heritage, Stilligarry, South Uist, HS8 5RS. <Charles.Thompson@nature.scot>.

Abstract Hedgehogs (*Erinaceus europaeus*) are native to Great Britain but were introduced to the island of South Uist in 1974 and gradually colonised South Uist and Benbecula. In 1999 hedgehogs were confirmed in southern areas of North Uist. Hedgehogs eat the eggs and occasionally the chicks of waders, which breed at high densities in the Uists. Initial research by Royal Society for the Protection of Birds (RSPB) in 1998 suggested that predation by hedgehogs was having a significant effect on the wader populations in South Uist. In 2014, remote cameras were used on a sample of wader nests and found hedgehogs responsible for 52% of all predation in South Uist. The Uist Wader Project was set up in 2000 to remove hedgehogs from North Uist initially, but with a long-term aim to remove hedgehogs completely from the Uists. Various methods including lamping, trapping and the use of sniffer dogs were developed, trialled, and improved. We developed an Index of Abundance (IOA) of hedgehogs, using footprint monitoring tunnels. This IOA provides a means of confirming the impact of removal activities on the hedgehog population. In anticipation of scaling up, we carried out a removal trial on a two km² area at Drimore in South Uist. The trial demonstrated the effort required to reduce the abundance of hedgehogs from high density, 30 animals/km², to zero and enabled the project team to estimate the resources required to eradicate hedgehogs from Benbecula, North and South Uist. The North Uist phase should be complete by the beginning of 2018, with only eight hedgehogs caught in 2016 and just one in 2017. Two years of monitoring are planned between 2018 and 2020, to confirm eradication.

Keywords: dunlin, IOA, redshank, ringed plover, sniffer-dogs, translocation, trap, wader

INTRODUCTION

Wader surveys in the early 1980s showed that the Uists, off the west coast of Scotland, held high densities of breeding redshank (*Tringa totanus*), ringed plover (*Charadrius hiaticula*) and dunlin (*Calidris alpina*) (Fuller, et al., 1986). In recognition of the importance of the Uists, 14 Sites of Special Scientific Interest (SSSIs) and two Special Protection Areas (SPAs) for Birds were designated in the late 1990s. Shortly afterwards a decline was found in wader populations on the islands of South Uist and Benbecula that was largely due to egg predation by hedgehogs (Jackson, 2001; Jackson & Green, 2000; Jackson, et al., 2004). Hedgehogs (*Erinaceus europaeus*) are native to Great Britain but were introduced to South Uist in 1974–75 (Angus, 1993). In 1999, hedgehogs were starting to colonise southern areas of North Uist (Jackson & Green, 2000; Jackson, et al., 2004). Declines of waders recorded in South Uist between 1983 and 1998 were: ringed plover by -58%; dunlin by -65%; and redshank by -43% (Fuller & Jackson, 1999). In 2014, remote cameras were used on a sample of wader nests and found hedgehogs responsible for 52% of all predation in South Uist.

The hedgehog population on the United Kingdom mainland has been in decline since the1960s (Noble, et al., 2012). Hedgehogs are protected under Schedule 6 of the Wildlife and Countryside Act 1981 throughout the UK, but are classified as invasive non-natives in the Uists, as they are classified outwith their native range under section 14. Hedgehogs have no natural predators in the Uists, can breed five months out of the year, and can produce at least as many young per year as their population, as measured in the spring (Jackson, 2007). Initial research in South Uist on hedgehog behaviour and methods of locating them was carried out between 1997 and 2001 (Jackson, 2007). This work estimated the density of hedgehogs in different habitats in South Uist at 31.8 animals/km² for machair, 15.4 animals/km² for blackland and two animals/km² for moorland.

The Uist Wader Project was launched in 2000 as a partnership of Scottish Natural Heritage (SNH), Royal Society for the Protection of Birds (RSPB) and the Scottish Executive. The Project's objective was to safeguard the waders of the Uists from introduced hedgehogs. In order to achieve this it would be necessary to remove all the hedgehogs from the Uists, starting in North Uist.

MATERIALS AND METHODS

Study area

The Uists are part of the Outer Hebrides, located off the north-west coast of Scotland (Fig. 1). The Uists include six inhabited, low-lying islands, connected by causeways. The three main islands are North Uist (333 km²), Benbecula (81 km²) and South Uist (315 km²). The climate is wet and windy. Wind-blown shell sand has formed extensive machair habitats on the west side of these islands. These lime-rich coastal grasslands are grazed by livestock and cultivated with arable crops (oats, rye, barley and potatoes) on a traditional rotation (Angus, 2006). There are a few farms but most of the agricultural land is divided into small tenanted units, known as crofts, each with shares in larger common grazings. The other predominant habitat types in the Uists are moorland and blackland (an intermediate zone of mesotrophic grassland between machair and moorland).

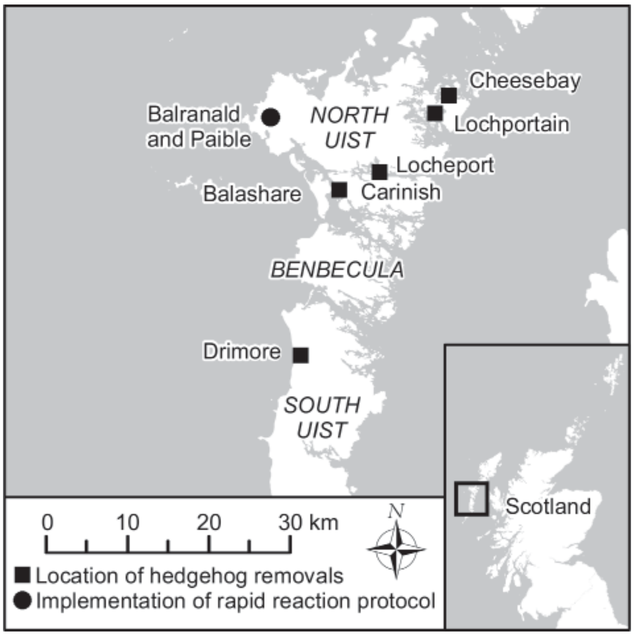

Fig. 1 Location map of the Uists in conjunction with mainland Scotland.

In order to carry out any type of fieldwork in the Uists it was essential to have the full support of the local community, land owners, crofters and residents. Project staff spent time working with these groups to secure access to land and receive information relating to hedgehogs. Although access permission was always granted, there were constraints placed on some of the removal methods described below.

Population model

Based on initial research by Jackson (2007), modellers at Newcastle University developed a hedgehog population model in two phases (Shirley, et al., pers. comm. 2007; Shirley, et al., 2010). These individual-based, simulation models of the hedgehog population indicated that trapping and lamping would achieve total eradication of hedgehogs from the Uists within 30 years, at best, which represents eradication by 2040. The hedgehog population in the Uists was estimated from a combination of field data and the model to be around 3,900 in 2010, whereas this was estimated to be about 3000 in 2007, (95% confidence limits ±800). This highlighted the shortcomings of our initial methods and led to a new approach, using sniffer dogs and all year round removal of hedgehogs.

Hedgehog removal

There are three key methods of removing hedgehogs; lamping (spot-lighting), live cage trapping and searching with sniffer dogs. Lamping at night was very effective on short cropped machair turf. It involves three to five people transecting areas of land operating in a straight line about five to 10 metres apart, each using a 10–50 watt, 12 volt halogen spot-lamp to survey the ground for hedgehogs. Lamping was not effective in longer vegetation and the night work caused disturbance to local residents. Lamping as a method of hedgehog removal was gradually phased out due to its intrusive nature with regard to light and noise disturbance at night.

Live cage trapping was tried in 2004 and proved very effective at removing a large proportion of the population: 80–90% of hedgehogs over an eight week period. Trapping worked well in all types of habitat and replaced lamping as the main method of removing hedgehogs. The live cage traps used for hedgehogs are 180 × 150 × 480 mm, with a spring-loaded door, activated by a treadle plate. Traps are installed in large trap grids, designed to intersect the home range of each potential hedgehog. Two different trapping densities are used. Low density trapping (30 traps/km^2) is used when initially establishing a trapping route, where the underlying hedgehog population is expected to be zero (i.e. monitoring suggests no hedgehogs) or when the underlying habitat is not particularly suitable for hedgehogs, such as moorland and bog. Higher density trapping (50 traps/km^2) is used where a known hedgehog population exists and the underlying habitat is suitable. The traps are baited with fish, which is placed behind the treadle plate, but not obstructing it. Once operational, traps are checked every day. Throughout the project, trap placement was continuously improved through experience and research with habitat, location, cover, bait and trap sensitivity being the most important factors. Trapping proved to be an effective means of capturing a large proportion of a population, but not every animal, suggesting that some were trap shy.

Sniffer dogs are also used to remove hedgehogs. The dogs are trained to indicate the location of a hedgehog without harming it and are rewarded with a short period of play time with a favourite toy when successful. A specialist trainer was brought in for six days each year to guide the training process, encourage best practice and work with each dog handler on a one to one basis. Sniffer dogs can work effectively for periods of three to four hours and an experienced sniffer dog and handler can cover up to two km^2 per week in most weather conditions and across diverse vegetation. Dense vegetation and calm conditions result in narrower, more condensed search transects, while wind speeds between eight and 55 kph and short vegetation allow wider more expansive transects and hence greater area covered per unit of time. Wind speeds in excess of 55 kph progressively reduce the efficiency of dog searching due to the scent being dispersed too widely. Sniffer dogs and trapping complement each other as hedgehog removal methods, because dogs are more effective in boggy ground where traps simply can't be set and traps are more effective in areas where dens are located deep underground and hedgehogs only re-emerge at night. There were sometimes more restrictions on using dogs than traps in fields at lambing time but sniffer dogs could locate hedgehogs during the winter, when trapping is ineffective. The use of dogs was suspended, early on in the project, following the introduction of legislation banning the hunting of wild mammals with dogs, The Protection of Wild Mammals (Scotland) Act 2002. This greatly reduced the efficiency of removing hedgehogs at lower densities and added additional time and cost to the Project. Following careful legal interpretation of how dogs could be used to locate and 'flush' hedgehogs, the use of sniffer dogs was reinstated in 2010.

Between 2003 and 2006 all captured hedgehogs were euthanised, based on the best information available at that time. Advice from the animal welfare organisation, the Scottish Society for the Prevention of Cruelty to Animals (SSPCA), rejected translocation on welfare grounds and advocated hedgehogs were euthanised. The SNH board in 2002 stated that there was no scientific evidence or overriding conservation imperative to justify translocation of hedgehogs from the Uists to the mainland. During this time, the Project came under increasing pressure from animal rights groups and special interest conservation groups to stop killing hedgehogs and consider moving them to the Scottish mainland instead. The British public perceives hedgehogs as an iconic species, which is the gardener's friend, and there was strong media and public pressure against the cull.

New research carried out at Bristol University (Molony, et al., 2006) showed that translocation of hedgehogs resulted in low mortality if certain levels of veterinary care, feeding and general welfare were provided. Based on this work, the SSPCA advised that the hedgehogs' welfare would not be adversely affected by being translocated to the Scottish mainland. SNH then entered into a partnership with the animal care sector to translocate hedgehogs. Fieldworkers pass hedgehogs onto a 'carer', based in South Uist, for onward transport to an animal rescue centre on the mainland for release under established protocols. In response to improvements in the ability to identify and care for pregnant females and to locate dependant young, it became possible in 2012 to remove hedgehogs throughout the season, rather than only during the non-breeding season of three and a half months as done previously.

Monitoring

Monitoring between 2009 and 2010 simply involved checking traps and lamping, which equates to extending the removal methods until a period of two years has elapsed where no capture of hedgehog has occurred.

From 2011 onwards, three monitoring techniques were deployed: footprint monitoring tunnels, sniffer dogs and motion-activated cameras.

The footprint monitoring tunnels were made out of 150 mm plastic drainage pipe, cut to 560 mm lengths. A rectangular section 100 × 190 mm was cut out of the middle of the pipe to accommodate a plastic tray, 110 × 50 × 200 mm. The tray was then filled with one of three different substrates; clay, sand or carbon plate. The tunnels were dug into the ground and covered with turf to make the tunnel as much like a natural burrow as possible. The inside of the tunnel was fashioned to allow a natural walk through for an animal over the tray. These tunnels were dug into the monitoring area at a density of five tunnels/km² and their positions recorded using GPS.

Trained sniffer dogs were deployed to search at least 25% of the monitoring area following methods similar to their use for hedgehog removal. Hedgehogs located in North Uist were removed as re-release was not an option, whereas hedgehogs located in South Uist were released, since their removal would have no real impact on the overall population, which had reached its maximum carrying capacity.

Motion-activated cameras (model: Bushnell Trophycam HD max) were deployed at a density of 1.25 cameras/km². We set them to record 60 second video clips (1280 × 720 px) onto a 32 GB SD card. The camera was focussed on a 120 g 'tuna tin' with perforations in its top, filled with fish and dug into the ground so the surface of the can was level with the ground. This acts as an attractant to hedgehogs and a host of other animals, yet prevents them from removing the fish. The SD card needs to be changed every two weeks and the rechargeable batteries have a variable lifespan, of two to three weeks, depending on the rate of triggering.

Six sample areas representing the whole of North Uist were monitored between 2013 and 2014 using at least two different monitoring methods. Monitoring highlighted the areas where hedgehogs were present and allowed a more strategic and selective approach to checking the total area of North Uist.

Occupancy model

In the early part of the Project, progress was measured as 'number of hedgehogs caught per 1000 trap nights'. When trapping effort was applied over time, this measure generally showed a decline. However, we were unsure if this measure reflected the actual impact of removal activities on the hedgehog population, or if a significant number of animals remained undetected due to trap avoidance. In 2013, a two-year monitoring trial was established to estimate occupancy and the relative index of abundance (IOA) of hedgehogs across the Uists, and evaluate the effectiveness of the removal methods.

Between 2013 and 2014, hedgehog populations were assessed in 19 locations in the key areas for breeding waders, using footprint monitoring tunnels. Attempts were also made to assess populations using motion-activated cameras and sniffer dogs, but insufficient cameras were available and the sniffer dog data proved too difficult to interpret due to a number of factors including experience of dog and handler, wind speed, and topology of land.

Each plot (route) covered an area of four km² with a minimum of five monitoring tunnels/km² and was checked twice per week.

Various occupancy models were tested, and the Royle-Nichols single season, abundance-induced heterogeneity model (Royle & Nichols, 2003) was chosen as the most appropriate single season occupancy model. This is a two-parameter model that derives occupancy (ψ) from estimates of detectability r (the probability of detection per tunnel) and population density λ (the mean of the Poisson distribution), thus estimating occupancy in a way that accounts for hedgehogs being easier to detect when there are more of them. The following formulas represent the Royle-Nichols model:

$$1)\ L(w) = \prod_{i=1}^{R} \left\{ \sum_{k=0}^{K} \binom{T}{w_i} p_k^{w_i} (1-p_k)^{T-w_i} f_k \right\}$$

$$2)\ p_k = 1 - (1-r)^k$$

$$3)\ f_k = \frac{e^{-\lambda}\lambda^k}{k!}$$

Formula (1) represents the likelihood of detections, where W represents detections, R represents sites, T represents (route) locations. Formula (2) represents the site detection probability and (3) represents the probability density formula for a Poisson distribution, where both (2) and (3) substitute into (1). Note also how r and λ are incorporated into this model.

The plots were grouped together by year and modelled with a constrained detectability and unconstrained population density. Detectability was estimated, along with individual population density, for each location and year.

Footprint monitoring results were used in preference to camera monitoring results due to the limited data sample from the cameras compared to tunnels (Paul Ross, pers. comm. 2014).

Hedgehog removal trial

In 2014, we undertook a hedgehog removal trial to evaluate the effectiveness of the hedgehog removal methods. A research area of 1.78 km² was selected on Drimore farm in South Uist, which represented typical machair habitat with a probable high population of hedgehogs. A perimeter area of 1.3 km² surrounding this research area was also created to reduce the effects of dispersion and migration of hedgehogs following removal from the research area.

The research area was monitored using footprint monitoring tunnels, motion-activated cameras and sniffer dogs for a four week period to establish an IOA. The monitoring tunnels were evenly distributed at a density of five tunnels/km², motion-activated cameras at a density of five cameras/km² and sniffer dogs were operated at a rate of two km² per week. Hedgehogs were then removed from both areas using 50 traps/km² on the research area only, and sniffer dogs on both areas, for an eight week period. The research area was monitored for a further four weeks in the same design as the pre-removal monitoring, to establish whether all hedgehogs had been removed.

Scaling up to North Uist

Recent hedgehog removal efforts in North Uist were guided by the results of the monitoring work; areas that showed presence of hedgehogs were searched using a combination of trapping and sniffer dogs. The search effort was set using the results of the Drimore trial.

The removal phase is expected to be completed by spring 2018, and will be followed by a further two years of monitoring to confirm absence of hedgehogs. If a hedgehog is encountered during the monitoring phase a rapid-reaction protocol will be initiated.

Rapid-reaction protocol

A one km radius buffer around the sighting of a hedgehog will be searched for four weeks with sniffer dogs and 50 traps/km². If further hedgehogs are found, this process will be repeated.

RESULTS

Activites implemented in 2003 to 2008

Sniffer dogs were used only in 2003 during this period. Lamping and trapping were used as the main methods of hedgehog removal. Monitoring between 2009 and 2010 confirmed successful eradication.

Initial hedgehog removal: 2003–2008

Hedgehog removal started in 2003 in Locheport and Carinish in the southern area of North Uist (129 km²) and was completed by 2008. A further two years of monitoring were carried out to verify a successful eradication, which was declared in 2010. Fig. 2 shows the removal of hedgehogs and effort applied in Carinish and Locheport. Believing that North Uist was clear, the Project expanded the removal methods into Benbecula to continue working southwards. Good progress was made initially, but further hedgehogs were reported from new areas of North Uist; from Balranald in 2009 and Lochportain in 2012. Work in Benbecula was postponed whilst the trapping team was re-deployed to eradicate hedgehogs from these new areas.

Monitoring results – occupancy estimates 2013–2014

As expected, the lowest occupancy (ψ) estimates were in North Uist and the highest ones in South Uist.

The North Uist IOA monitoring results for 2013 and 2014 are shown in Table 1 and Table 2, respectively. Note that the route names do not correspond to the same areas between the two years. In 2013, Baleshare (represented by H1 & H2) showed no occupancy of hedgehogs, and Balranald (F1) showed a low level of occupancy. In 2014, Balranald (F1, M1, andG2) showed further dispersal of hedgehogs.

The South Uist and Benbecula occupancy results for 2013 and 2014 are shown in Table 3 and Table 4, respectively. Note that the routes K1 and B2 correspond between Tables 3 and 4. Fig. 3 shows these results spatially. The occupancy estimate of hedgehogs is relatively high for almost all parts sampled in South Uist and Benbecula.

All other parts of North Uist, Benbecula and South Uist were monitored by sniffer dog but due to a range of confounding factors it proved impossible to convert these data into a meaningful occupancy estimate. However, the sniffer dog monitoring did give a good overview of the distribution of hedgehogs across the Uists to complement the formal occupancy estimate results.

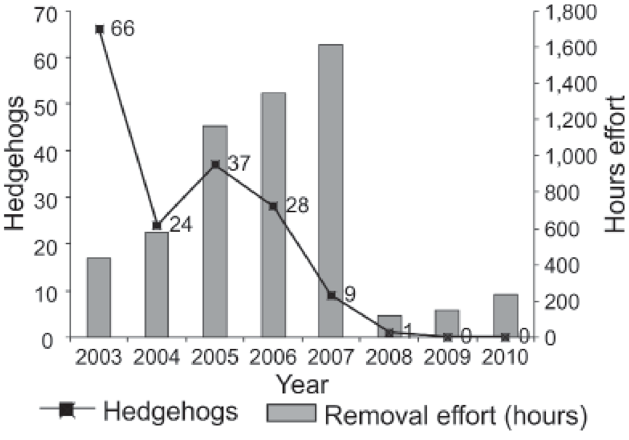

Fig. 2 Carinish and Locheport hedgehog removal and effort.

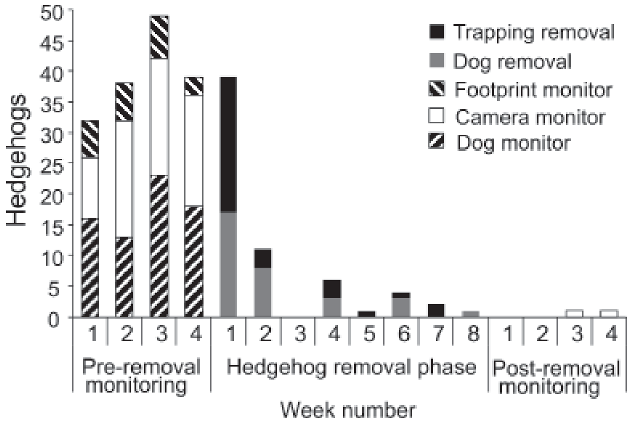

Fig. 3 Hedgehogs removed or detected, by method, for the Drimore trial.

Removal trial results (Drimore, 2014)

Pre-removal monitoring phase

Monitoring was carried out across the research area for four weeks between 7 April and 4 May. Table 5 shows the numbers of hedgehogs detected each week by footprint monitoring, camera monitoring and sniffer dogs. Using only the footprint monitoring data, it was possible to derive an occupancy estimate for this area of land during the four week monitoring phase, which is shown in row B2 in Table 3. In comparison to other sites monitored in the Uists, the Drimore site represented a high population of hedgehogs.

Removal of hedgehogs

This phase of operation involved removing hedgehogs from the research and perimeter areas using live cage traps and sniffer dogs over an eight week period between 5 May and 29 June. Two fieldworkers searched the area using sniffer dogs and operated 89 live cage traps. Table 6 shows that the same numbers of hedgehogs were removed from the research area by sniffer dogs as by trapping. Over the same period, hedgehogs were removed from the perimeter area by sniffer dogs alone, as shown in Table 7.

Post-removal monitoring

The final phase of the trial involved repeating the monitoring over another four week period between 30 June and 28 July to measure the IOA of the hedgehogs after the removal operation. Table 8 shows that only two hedgehogs showed up on camera during this period, both in the perimeter area. No hedgehogs were detected within the research area, providing an acceptable level of confidence that all of the hedgehogs had been removed. Fig. 3 summarises the numbers of hedgehogs detected by each monitoring method at all three stages.

Recent hedgehog removals in North Uist – scaling up to North Uist

Lochportain hedgehog removal

Lochportain, along with the neighbouring townships, is located on a peninsula on the east side of North Uist. In 2012 a hedgehog was found by a member of the public on the road close to Cheesebay (adjacent to Lochportain). Due to other commitments and limitations on staff resources the Project was only able to respond to this potential hedgehog population with a very limited removal effort in 2013, which yielded no hedgehog captures. The team returned to this area in 2015, with a concerted removal effort covering some 75 km^2, followed by monitoring in 2016. Fig. 4 shows the hedgehog removal and relative effort appliedin Lochportain.

Table 1 2013 – Royle-Nichols parameter estimates for hedgehogs in North Uist. Note: ψ represents the probability of occupancy, derived from (1 – f_k), r represents the probability of detection per hedgehog / tunnel, and l represents population density as the mean of the Poisson distribution. Route name refers to four km² plot areas.

Lochportain was effectively cleared of hedgehogs over a 10 week period, which matched very closely with the Drimore removal trial. Migration to and from Lochportain was minimised by being located on a peninsula with a narrow isthmus.

Fig. 5 compares the Drimore trial and Lochportain removal. There is a strong similarity in the pattern of hedgehog removal even though the starting populations of hedgehogs and the area of land covered are very different. Both locations represent declining sequences of weekly captures ending at one or less over eight to 10 weeks. Subsequent monitoring on both sites demonstrated that no further hedgehogs were immediately present.

Balranald & Paible hedgehog removal

In 2009 hedgehogs were sighted in Balranald and Paible in the west of North Uist by members of the public. Trapping began in 2009, and sniffer dogs were introduced gradually from 2010, so that by 2013 all fieldwork staff operated a dog.

Fig. 6 shows that the bulk of the hedgehog population was removed between 2013 and 2015, with just a small number of hedgehogs removed in 2016. It also shows the relationship between trapping effort and the number of hedgehogs removed for Balranald and Paible.

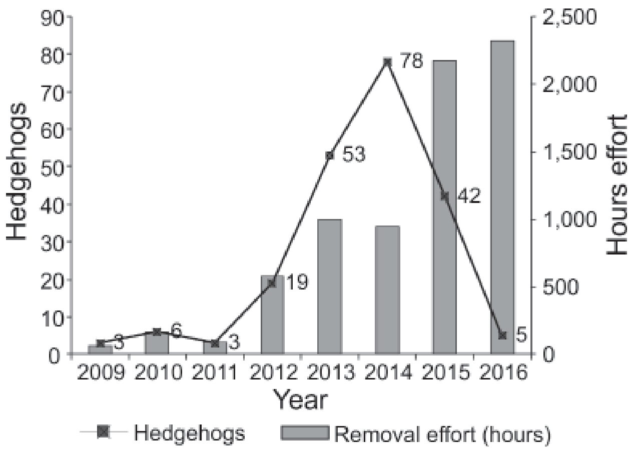

Fig. 6 Balranald and Paible removal and effort.

Table 5 Hedgehogs detected during the pre-removal monitoring phase at Drimore. Monitoring effort: two footprint monitoring checks per week per tunnel over 10 tunnels, five cameras running continuously and two sniffer dogs checking two km² per week.

Monitoring method	Week				Total
	1	2	3	4	
Footprint	6	6	7	3	22
Camera	10	19	19	18	66
Sniffer dog	16	13	23	18	70

Implementation of rapid-reaction protocol

The rapid-reaction protocol has been used only once. One hedgehog was located by a monitoring camera and then located and removed by a dog handler and sniffer dog in the area of east Balranald during April 2017. A search zone was established using a buffer of a radius of 1 km from the location of the hedgehog, as shown in Fig. 7. Four weeks searching using sniffer dogs and trap checks were carried out, but no further hedgehogs were located.

DISCUSSION

It is essential to have the support of the local community, not just to report sightings but also to persuade people not to move hedgehogs to new areas. Hedgehogs were clearly moved to discrete unconnected areas in North Uist, including Carinish, Locheport, Balranald and Lochportain. We had support from most land managers but we failed to reach all individuals within the wider community. Some people moved hedgehogs as they thought they would provide a helpful service such as controlling garden slugs or snails that host sheep fluke. Once we were able to discuss these introductions and the potential impacts with the individuals involved, they usually became more supportive. Any future removal project should include an education and promotion resource to assist with community engagement. There is also a need to secure full support and commitment right from the start of the project all the way through until eradication is confirmed.

The methods used in eradicating hedgehogs from Carinish and Locheport were limited by the absence of sniffer dogs and a lack of clarity on the abundance of hedgehogs in any given area. For animal welfare reasons, hedgehog removal was restricted to the three and a half month non-reproductive period. These limitations meant it took approximately eight years to clear the area and verify it as clear. Balranald and Paible were also initially limited to the non-reproductive season and sporadic, exploratory efforts prior to 2013. However from 2013 onwards Balranald and Paible had a fully operational team of sniffer dogs and hedgehog removal progressed relatively quickly, with captures tailing off by 2016. Lochportain also benefitted from the use of dogs and from being on a peninsula. The introduction of monitoring, refined control methods and strategies meant that removing the Lochportain hedgehog population took just two years, compared to eight at Carinish. If there are obstacles or barriers to removal activities then it will reduce the effectiveness of removal and it will take longer to reduce the population to zero. Being able to work all year round made the Project much more efficient, reducing the predicted minimum time required for eradication of hedgehogs from the Uists from 30 to five years.

The Drimore trial demonstrated that hedgehog population density within a discrete area can be effectively reduced to zero by trapping and sniffer dogs over a relatively short period of time. The removal phase reduced the IOA from a high level to zero. The two hedgehogs detected on camera in the latter weeks of the post-removal monitoring were located in the perimeter area and it is assumed these were migrating into the research area. Comparing the Drimore trial results to the Lochportain eradication shows that it took roughly the same effort to remove 64 hedgehogs as it did 14 hedgehogs from an equivalent area. This suggests that eradication effort is determined by area of suitable habitat more than hedgehog density.

Table 8 Hedgehogs monitored during the post-removal monitoring phase at Drimore.

Monitoring method	Week				
	1	2	3	4	Total
Footprint	0	0	0	0	0
Camera	0	0	1	1	2
Sniffer dog	0	0	0	0	0

The Project needed to estimate the effort required to reduce the hedgehog population to zero over a given area of land and prevent re-colonisation from surrounding areas. The Drimore removal trial enabled us to assess whether the resource had been sufficient on every bit of land at Balranald and where to put in additional resource.

The near complete removal of hedgehogs from North Uist was achieved using an agreed strategy with proven methods of removal, which were shown to be effective. Being able to measure the effectiveness of the hedgehog removal methods used, and the effort required to clear a given area of land, enables a fairly accurate estimation of what timescale would be required to clear a specific area of land. There also needs to be a method of confirming that the population has been reduced to zero (Russell, et al., 2016). The IOA has been extremely valuable in that respect, particularly on areas such as Balranald, with complicated land tenure and constraints on using dogs whilst livestock are in fields at certain times of year.

In the early days of the Project we coloured maps by hand and filled in paper data sheets, whereas now we use graphic GPS, integrated to GIS systems, connected to relational databases. This increased data flow has facilitated a more adaptive approach to managing project activity. Scientific advice from a wide range of sources has been extremely helpful but needs to be combined with practical considerations.

Ideally it would have been desirable to have cleared the hedgehogs from South Uist to allow the waders to recover faster, but clearing North Uist first and then moving south made more strategic sense. Having successfully removed all of the hedgehogs from North Uist, the next step is to continue southwards and remove hedgehogs from Benbecula and South Uist. This will require clearing an area of almost 400 km². Using the results from the Drimore trial and the current removal methods, we estimated that this will take between five and 10 years and will require a team of 18 staff. It is estimated that this will cost between £3.5 and £5.0 million and, at the time of writing, SNH is exploring funding options with partners.

ACKNOWLEDGEMENTS

We would like to acknowledge the pioneering wader survey and research work carried out by RSPB and BTO which provided the initial evidence for this project and for the ongoing support and involvement from both organisations, including financial assistance from RSPB. SNH took the lead in the project, and we would like to thank the many staff who were involved, including: the rest of the UWP project team, fieldworkers, graduate placements, volunteers, and the Scientific Advisory Committee. Special thanks are due to the land owners, crofters and residents of the Uists, who played a major role in supporting this project by granting access permission, taking part in fieldwork, and reporting sightings of hedgehogs.

Five eradications, three species, three islands: overview, insights and recommendations from invasive bird eradications in the Seychelles

N. Bunbury, P. Haverson, N. Page, J. Agricole, G. Angell, P. Banville, A. Constance, J. Friedlander, L. Leite, T. Mahoune, E. Melton-Durup, J. Moumou, K. Raines, J. van de Crommenacker and F. Fleischer-Dogley

Seychelles Islands Foundation, La Ciotat Building, Mont Fleuri, P.O. Box 853, Victoria, Mahé, Seychelles. <nancy@sif.sc>.

Abstract Management and eradication techniques for invasive alien birds remain in their infancy compared to invasive mammal control methods, and there are still relatively few examples of successful avian eradications. Since 2011, five separate eradication programmes for invasive birds have been conducted on three islands by the Seychelles Islands Foundation (SIF). Target species were prioritised according to their threat level to the native biodiversity of the UNESCO World Heritage Sites of the Seychelles, Aldabra Atoll and Vallée de Mai, which SIF is responsible for managing and protecting. Red-whiskered bulbuls (*Pycnonotus jocosus*) and Madagascar fodies (*Foudia madagascariensis*) occurred on Assumption, the closest island to Aldabra, which, at the time, had no known introduced bird species. The growing population of ring-necked parakeets (*Psittacula krameri*) on Mahé posed a threat to endemic Seychelles black parrots (*Coracopsis barklyi*) on Praslin where the Vallée de Mai forms their core breeding habitat. In 2012, red-whiskered bulbuls and Madagascar fodies were detected on Aldabra, so an additional eradication was started. All eradications used a combination of mist-netting and shooting. The intensive part of each eradication lasted three years or less. On Assumption, 5,279 red-whiskered bulbuls and 3,291 Madagascar fodies were culled; on Mahé, 545 parakeets were culled; and on Aldabra 262 Madagascar fodies and one red-whiskered bulbul were culled. Each programme underwent 1–2 years of follow-up monitoring before eradication was confirmed, and four of the five eradications have been successful so far. None of these species had previously been eradicated in large numbers from other islands so the successes substantially advance this field of invasive species management. The challenges and insights of these eradications also provide unique learning opportunities for other invasive avian eradications.

Keywords: Aldabra, Indian Ocean islands, invasive alien bird management and control, mist-netting, parakeets, passerines, shooting

INTRODUCTION

Birds are currently one of the least represented groups of terrestrial vertebrates in the field of invasive alien species research and management, and the development of successful eradication strategies for introduced birds remains in its infancy, especially when compared to well-established invasive mammal control techniques (see: Blackburn, et al., 2009; Feare, 2010; Bauer & Woog, 2011; Strubbe, et al., 2011; Baker, et al., 2014; and Menchetti & Mori, 2014; for potential reasons for the discrepancy). The relatively few examples of successful large-scale avian eradications include rock pigeons (*Columba livia*) from the Galápagos Islands (Brand Phillips, et al., 2012), which at the time was the largest successful eradication of an alien bird from an island system (with 1,477 birds removed), and several eradications of the common myna (*Acridotheres tristis*) (e.g. Saavedra, 2010; Canning, 2011; Feare, et al., 2017). There has, however, been little development of best practices or compilation of lessons learnt so far. Furthermore, we are not aware of any examples of pre-emptive invasive bird eradications from islands to protect native biodiversity on nearby islands.

Since 2011, five separate eradication programmes for invasive alien birds have been conducted on three islands in the Seychelles by the Seychelles Islands Foundation with the aim of protecting endemic biodiversity on Aldabra Atoll and Praslin from the potential impacts of these invasive bird species, should they become established. These eradications targeted: (1) red-whiskered bulbuls (*Pycnonotus jocosus*) on the island of Assumption; (2) Madagascar fodies (*Foudia madagascariensis*) on Assumption; (3) red-whiskered bulbuls on Aldabra; (4) Madagascar fodies on Aldabra; and (5) ring-necked parakeets (*Psittacula krameria*) on the main Seychelles island of Mahé. Red-whiskered bulbuls have a broad introduced range covering 15 countries (Global Invasive Species Database (GISD), 2017), and their impacts on native ecosystems and biodiversity (Clergeau & Mandon-Dalger, 2001; Linnebjerg, et al., 2010; GISD, 2017) have prompted control efforts and even small-scale eradications, but these efforts have not been upscaled in most places. Madagascar fodies are widely introduced across the Western Indian Ocean islands including many of the Seychelles islands, where they threaten native avifauna through hybridisation (Lucking, 1997), and transmission of pathogens (de Sales Lima, et al., 2015). Ring-necked parakeets have been introduced to over 35 countries outside their native range, making them one of the most successful avian invaders in the world, and are known to cause detrimental impacts on native wildlife (Strubbe & Matthysen, 2007; Strubbe & Matthysen, 2009; Strubbe, et al., 2010; GISD, 2017), but have not yet been eradicated or substantially reduced in numbers from any of them.

In this paper, we present a general overview of each eradication including: (i) the main methods applied in each phase; (ii) the relative success and numbers of birds culled with each method; and (iii) the difficulties encountered. Finally, we suggest 10 key insights and recommendations that can be applied to further eradication attempts and adopted for best practice, and offer a positive outlook for the future of introduced bird management.

METHODS

Location and background of project

The Seychelles archipelago consists of 115 islands across the Western Indian Ocean region (Fig. 1). The country has two UNESCO World Heritage sites; Aldabra Atoll, which was inscribed on the World Heritage list in 1982, and the Vallee de Mai, inscribed in 1983. Aldabra (15,250 ha; 9°24' S, 46°20' E; Fig. 1), one of the largest raised coral atolls in the world, is famous for its remarkable

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 282–288. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

biodiversity, including the largest giant tortoise population in the world, huge seabird colonies, pristine marine ecology and its relative lack of ecological disturbance. The Vallée de Mai (4°19′ S 55°44′ E), a 20 ha site on the island of Praslin (Fig. 1), is a mature palm forest dominated by the endangered endemic giant palm, the coco de mer (*Lodoicea maldivica*). A public trust, the Seychelles Islands Foundation (SIF), is responsible for managing and protecting both sites. The sites form crucial strongholds for many endemic and/or endangered species, and both sites host endemic bird species that face increasing threats from the invasive birds present on nearby islands. This context prompted SIF to consider and initiate pre-emptive management action of the introduced species in 2010, to ensure protection of the endemic species.

In the case of Aldabra, Assumption Island (1,171 ha, 9°44' S, 46°30' E; Fig. 1), only 27 km away, had populations of red-whiskered bulbuls and Madagascar fodies which were introduced in the 1970s. Aldabra's native avifauna, including the endemic Aldabra fody (*Foudia aldabrana*) and a native sub-species of Madagascar bulbul (*Hypsipetes madagascariensis rostratus*), had long been considered threatened by the proximity (*sensu* propagule pressure, Simberloff, 2009) of these introduced birds on Assumption (Roberts, 1988). The main threats posed by the potential spread of these introduced species to Aldabra were considered to be competition, hybridisation and transmission of novel pathogens. When the Assumption eradication of red-whiskered bulbuls and Madagascar fodies was being planned in 2010/2011, Aldabra was not known to have any introduced bird species and may have been the largest tropical island to be free of invasive birds. Unfortunately however, both of the introduced species from Assumption were identified on Aldabra in early 2012, soon after the start of the Assumption eradications. This was thought to be due to the increasing populations of both species on Assumption, so an additional eradication operation for these new populations on Aldabra was quickly planned.

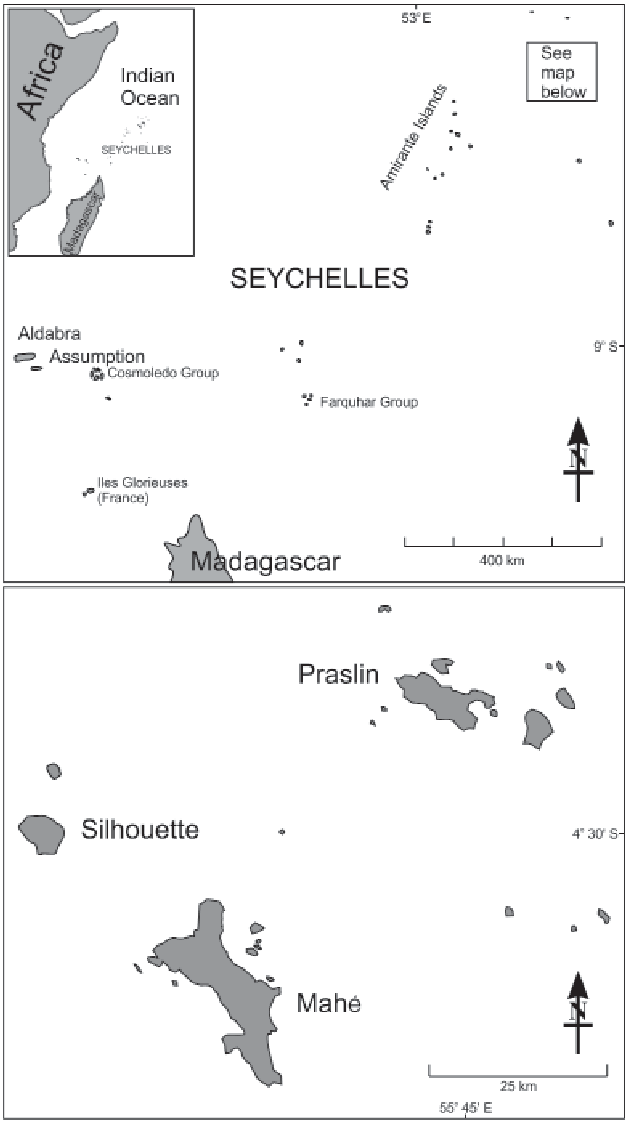

Fig. 1 Location of the Seychelles archipelago in the Indian Ocean (top, inset), the main islands and island groups of the Seychelles, including Aldabra and Assumption (top), and the inner Seychelles islands (bottom), showing Mahé, Silhouette and Praslin.

In the case of the Vallée de Mai, the mature coco de mer palm forest at this site forms the main breeding area for the Seychelles black parrot (*Coracopsis barklyi*), which is endemic to the island of Praslin and a flagship species for this island. The main Seychelles island of Mahé (Fig. 1), ca. 37 km away from Praslin, had a rapidly growing population of introduced ring-necked parakeets since the 1990s. The increasing probability of their establishment on Praslin, was accompanied by threats to the black parrot through competition and pathogen transmission. The presence of the parakeets on Mahé was thus considered the most pressing threat to these endemic parrots, which number only 520–900 birds on one island in the wild (Reuleaux, et al., 2013). In addition, long-term conservation plans for the black parrot include possible translocations of the species to other islands (Rocamora & Laboudallon, 2009) and such interventions could not be considered while ring-necked parakeets remained on Mahé.

Eradication time-frames and methods

All of the eradications were initiated in 2011/2012 and started with a 2–6 month initial phase, which included surveys to estimate the population size and distribution of the introduced bird populations, and trials to identify the most effective eradication methods.

Population estimates were carried out by island-wide distance sampling for Madagascar fodies and red-whiskered bulbuls on Assumption, grid-based surveys on Aldabra, and standardised roost counts for ring-necked parakeets on Mahé.

The choice of eradication methods trialled in the first phase of each project (see Table 1) was based on literature research, staff experience with the species, advice from experts, and experimentation. The trialled methods included trapping (using a number of types of trap, bait, trapping locations, decoys and playback), ground mist-netting, shooting and poisoning, as well as manual methods such as location and hand-capture of birds at nests and roosts. For the ring-necked parakeets, high-level (canopy) mist-netting was also trialled, which involved mist-nets set up in the canopy at 8–15 m from the ground using either bamboo poles or tree branches. The outcomes of these initial trials in terms of capture rates, efficiency, cost and labour intensiveness were then assessed and informed the choice of focal method(s) for the main phase of each eradication (Table 1). Thereby, the methods used for each eradication varied by island, species and phase of the project. Nevertheless, amendments needed to be made throughout the main eradication phase as the situation changed, so flexibility and adaptability in approach was essential.

The initial phase was followed by a second phase of intensive eradication efforts which lasted about three years for all of the eradications. During this phase the focus was on reducing the target bird population numbers to zero

Table 1 Trialled methods in phase 1 and focal methods in phase 2 for each of the eradications.

Island	Species	Methods trialled in phase 1	Phase 2 focal method(s)
Assumption	Red-whiskered bulbul	Trapping, shooting, poisoning, hand-capture at nests/roosts	Mist-netting, then shooting
Assumption	Madagascar fody	Trapping, shooting, poisoning, hand-capture at nests/roosts	Mist-netting, then shooting
Aldabra	Red-whiskered bulbul	Mist-netting, shooting	Mist-netting
Aldabra	Madagascar fody	Mist-netting, shooting, hand capture	Mist-netting, supplemented by shooting with air rifle & hand capture of fledglings
Mahé	Ring-necked parakeet	Trapping, canopy mist-netting, ground mist-netting, nest cavity targeting, shooting along flight lines and feeding areas	Shooting along flight lines and feeding areas with shotgun

as quickly and efficiently as possible using the methods identified in the trial phase. The second phase started in 2012 for Madagascar fodies and red-whiskered bulbuls on both islands, and in 2013 for the ring-necked parakeets after approval to use firearms was granted. It ended when no more birds could be detected.

Outreach was an important part of the ring-necked parakeet eradication in particular and efforts were made at the start of the intensive phase of this project to reach as many people as possible to encourage them to call the team with any information on sightings. We initially used all means available (including radio, TV, talks and presentations, newspaper and magazine articles, social media posts, website, newsletters, posters, stickers) to spread the message, and fine-tuned this according to responses over time.

The third and final phase consisted of monitoring (direct observations at all sites, island-wide point counts on Assumption; grid-based surveys in and surrounding the invaded area of Aldabra; roost and feeding tree checks at all known sites on Mahé) to confirm that no individuals of the target species remained. The monitoring was implemented in four 2–3 week periods with a team of 2–4 local scientific staff who had experience in one or more bird eradications, every 3–6 months.

RESULTS

Bird removal

Table 2 summarises pre-eradication population estimates and the total number of birds culled in each eradication, with estimates of the size of the introduced bird populations ranging from two to 4,300.

To date, four of the five eradications have been successful, with only the ring-necked parakeet eradication still in the monitoring phase. On Assumption and Aldabra, there were no sightings of either introduced bird species in two years of monitoring so both islands are again considered free of invasive birds.

Efficiency of control methods

The proportion of birds culled using different methods varied in each eradication (Fig. 2) and only a summary is provided here. The predominant and most effective methods for all campaigns were shooting and mist-netting (Table 1; Fig. 2).

For the ring-necked parakeets on Mahé, mist-netting caught 25 birds in the trials and first two months of the intensive phase of the campaign, but quickly became unfeasible as the birds learnt to avoid the nets even when set up in different places. Trapping caught no birds. The

Table 2 Summary of the pre-eradication population estimate and the number of birds culled for each of the target populations.

Island	Species	Pre-eradication population estimate	Number of birds culled	Population estimation method and reference
Assumption	Red-whiskered bulbul	4,300	5,279	Distance sampling; Feare & Fries-Linnebjerg, 2012
Assumption	Madagascar fody	1,600	3,291	Distance sampling; Feare & Fries-Linnebjerg, 2012
Aldabra	Red-whiskered bulbul	2–3	1	Direct observations; van de Crommenacker, 2012
Aldabra	Madagascar fody	150–200	262 (incl. hybrids)	Point counts; van de Crommenacker, 2012
Mahé	Ring-necked parakeet	288	545*	Roost counts; Birch, et al., 2012

* The 545 ring-necked parakeets included 543 from Mahé, one bird from Silhouette and one bird from Praslin. The single ring-necked parakeets culled on Praslin and Silhouette were assumed to have flown there from the Mahé population as there were no records of captive birds on either island.

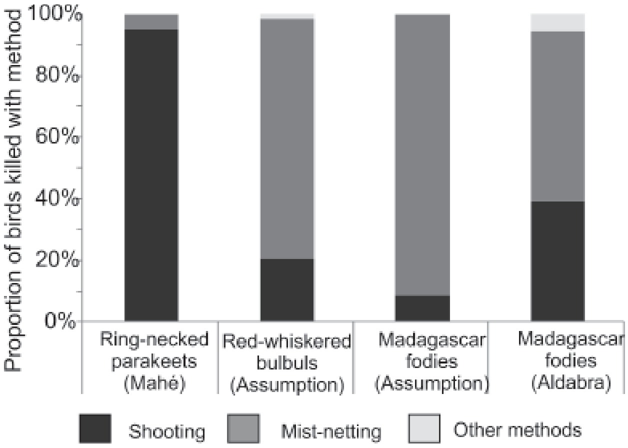

Fig. 2 The proportion (%) of birds culled on each introduced bird eradication (ring-necked parakeets [*Psittacula krameri*] from Mahé, red-whiskered bulbuls [*Pycnonotus jocosus*] and Madagascar fodies [*Foudia madagascariensis*] from Assumption; and Madagascar fodies from Aldabra) using the main eradication methods of shooting and mist-netting. 'Other methods' include trapping and manual capture. The red-whiskered bulbul eradication on Aldabra is not included in this figure because there was only one bird (mist-netted).

parakeet on Silhouette was culled by a member of the public using a catapult – a method not trialled on Mahé. The bird on Praslin was hand-caught.

Ring-necked parakeet eradication outreach

Television adverts were found to have prompted ca. 70% of all callers with information on sightings of the parakeets, with less than 10% of responders prompted by newspaper and magazine articles and the remainder from presentations, social media and having seen the posters.

DISCUSSION

Difficulties encountered

For each island and species, there was a particular set of challenges to overcome. On Aldabra, Madagascar fodies very closely resembled the endemic Aldabra fodies. This caused problems with capture of non-target species, and identification of introduced vs endemic species at a distance. The two species also quickly hybridised (van de Crommenacker, et al., 2015), making the eradication decisions more complex. Most birds targeted therefore needed to be identified at very close range to ensure that no Aldabra fodies were culled. Aldabra's physical challenges also included impenetrable vegetation, treacherous terrain and extremely demanding logistics. The invaded area was in the most remote part of Aldabra, initially had no field station, freshwater or facilities, and is only accessible via boat on a high tide, followed by a one-hour hike. Establishing basic infrastructure was therefore an essential pre-requisite for this eradication to proceed.

On Assumption the main challenges were higher than estimated population sizes of both target species, and the fact that neither species behaved as predicted from previous observations elsewhere. For example, trapping was initially anticipated to be an important and relatively simple capture method throughout the eradication, but this method appeared almost completely ineffective in extensive trials of the first phase. The failure of birds to accept bait (without traps) or to enter traps, combined with the high densities of both species, meant that mist-netting was by far the most effective capture method in the early part of the intensive eradication phase. This was labour-intensive and most successful when targeted at flight lines to and from nocturnal communal roosts. The propensity for communal roosting varied seasonally and the location of flight lines required constant monitoring to maximise mist-net captures. As numbers of target birds fell and mist-netting became less effective, shooting became the dominant method in the last year of the eradication. Both bird species on Assumption also appeared to be extremely wary of humans, even before the start of the project, and this became more marked as the eradication progressed. The originally planned methods therefore had to be re-assessed early in the project and underwent continual assessment as the eradication progressed.

On Mahé, mist-netting and trapping of ring-necked parakeets proved ineffective or inefficient – the birds were found to fly and roost usually too high for mist-netting, and several specialised trap designs (including the use of decoys) were unsuccessful. Poisoning could not be considered on Mahé because of possible effects on humans and non-target species. This left shooting as the only viable alternative, which was a politically and socially difficult method to adopt. Mahé is an inhabited island, with a population of ca. 80,000 people, and eradication activities had to occur in inhabited areas as the birds were predominantly observed in agricultural and cultivated areas with crops and fruit trees. The Seychelles is, for historical and security reasons, highly sensitive about the use of firearms and this resulted in a delay of two years before firearms were approved for use on the project. Shooting was then permitted to external hunters, provided they were accompanied by a military escort at all times and used only shot-gun and air rifle. Ring-necked parakeets are also highly intelligent birds and became 'educated' and wary very quickly. For example, we think they learnt to recognise and avoid the project car and staff uniforms. Shooting therefore had to be done with extreme caution (e.g. from cryptic locations, wearing camouflage gear, only shooting at groups of one or two birds, and shooting only when the hunter was very confident of a strike). A final critical issue with working on an inhabited island was public perceptions concerning the project, especially with such a charismatic target species and because the success of any eradication partly depends on public support and contribution (Mack, et al., 2000). SIF tackled this potential problem from the outset by conducting intensive outreach campaigns to try to ensure that as many people on Mahé as possible were aware of the eradication and the reasons for it. Lack of support did cause occasional problems with access to private land and misinformation. Fortunately, the parakeets were a known pest and commonly viewed as a threat to farming and endemic wildlife, so the majority of people encountered were in favour of the project and very supportive.

Ten key insights and recommendations

Here is a list of 10 key insights from these eradications, which can serve as a basis for recommendations for practitioners who are considering invasive alien bird eradications. The eradications presented here cover islands from both ends of the ecological disturbance spectrum, from the most ecologically depauperate (Assumption), to the least disturbed and most biodiversity-rich (Aldabra) making the lessons relevant to a broad suite of islands.

1. Large-scale invasive bird eradications are feasible

Red-whiskered bulbuls in the Seychelles occurred only on Assumption, plus the single bird on Aldabra, so the outcome of these eradications has been national elimination of the species. With the parakeet's range on the Seychelles encompassing only Mahé, if this eradication is successful, it will mark a second national eradication of an invasive bird species of high concern. Madagascar fodies remain established in high numbers on many islands of the Seychelles, but their eradication from two very different islands confirms the feasibility of this approach, should there be a need to consider their eradication elsewhere. Therefore, our first key message is that eradications of invasive alien birds from islands are feasible, even if the population of the target species exceeds 5,000 birds.

2. Pre-emptive action should be considered as a means to remove perceived threats

The three initial eradications of red-whiskered bulbuls and Madagascar fodies on Assumption, and ring-necked parakeets on Mahé, were based on the precautionary principle, i.e. the aim was to protect threatened endemic biodiversity pre-emptively based on perceived threats. This was justified in the case of the red-whiskered bulbul and the ring-necked parakeet, which have known detrimental impacts in their introduced ranges. However, even in the case of the Madagascar fody, the impacts of which on endemic birds have been questioned (Garrett, et al., 2007), the perceived threats were verified during the course of the eradications: (i) all three target species reached the islands of concern and at least one of these species established a breeding population (Madagascar fodies on Aldabra); (ii) hybridisation was confirmed to occur between introduced and endemic fodies on Aldabra (van de Crommenacker, et al., 2015); and (iii) several potentially novel pathogens were identified in the invasive species (SIF, unpubl. data).

3. Don't assume what you know of a species from other locations will apply in a new area – plan to conduct initial trials

Based on experience of the same species elsewhere, we expected a main method for catching Madagascar fodies and red-whiskered bulbuls to be trapping, and planned accordingly with respect to equipment and logistics. Trapping can be an effective capture method elsewhere for these species (N.B. & P.H., pers. obs.; C.G. Jones, pers. comm., all in Mauritius), but was found to be almost completely ineffective on Assumption for reasons that are unclear, and the birds never became accustomed to baited areas. This was despite several members of staff working on the project who had extensive experience successfully trapping these species in other locations. This caused delays at the beginning of the eradication while methods were re-assessed and other equipment sourced. A similar problem was encountered with the ring-necked parakeets, which have been successfully trapped in other countries (e.g. Bashir, 1979; Hussain, et al., 1992), but could not be trapped using the same or similar trap designs on Mahé, although these problems were less significant, as trapping parakeets had not been assumed as a main method of capture. It is important to note that we are not ruling out any particular method for targeting these species elsewhere. Trapping may still be a highly effective capture technique in other places for these species, so our advice here is simply that initial small-scale trials should be conducted to determine the feasibility of several different methods and save time and funding.

4. One size doesn't fit all birds

Shooting was by far the most effective method for ring-necked parakeets in the Seychelles, while mist-netting proved to be generally more effective for passerines (although this depended on the phase of the eradication). However, a flexible approach and willingness to modify the strategy was critical for the success of these eradications. Even within the same species and island, our techniques needed to be assessed and 'tweaked' frequently (and often substantially) to maintain efficient capture rates. For example, on Assumption, there was a switch in the final year of the intensive phase of the eradication, from using mist-nets as the main method of capture to firearms (this switch also applies to mynas; Feare, et al., 2017). This was decided when catch rates in mist-nets (i.e. the density of target population) had dropped too low for continued progress with the eradication (i.e. population recruitment rates were thought likely to be equal to or higher than capture rates).

5. Don't count your eggs before they hatch

For all three species, there were more birds present than had been estimated by survey methods. This was the case regardless of which estimation method was used. The higher numbers are likely to have been primarily due to recruitment of young birds into the populations since distance sampling is based on classical closed population sampling (Cassey & McArdle, 1999) but the survey methods (roost counts, distance sampling) could also have produced underestimates. The higher figures had implications for the planning and especially the costs of completing the eradications.

6. Identify the weak points of your target species

Each target species was found to have at least one trait or habit which either increased their vulnerability at certain times or to certain methods, or could be used to improve eradication effectiveness. The communal roosting sites of ring-necked parakeets enabled regular standardised counts to be conducted, which initially provided a valuable way to monitor the population numbers, flight lines and the impacts of the eradication efforts and later formed an essential location for targeting the remaining birds. These sites proved so useful that parakeets were not targeted at roosts until close to the end of the project to ensure that the roost sites were not disturbed or compromised. Red-whiskered bulbuls also roosted communally in the early stages of the project and could be targeted with mist-nets along their flight lines towards roosts, which maximised the mist-net catch. Later in the eradication, their habit of vocalising from prominent perches meant that they could be reliably located from several hundred metres away, which greatly helped in the search for and targeting of the last few birds. Madagascar fodies were found to have a tendency to form large foraging groups, especially in the non-breeding season, which, when spotted, provided key areas for mist-netting.

7. Use research to aid management decisions on the ground

A scientific and research-based approach was an important aspect of the eradications and greatly facilitated management decisions on the ground. This included collecting comprehensive data and samples from all birds caught, regularly analysing the effectiveness of methods and approaches, and setting up external research partnerships for analysis which could not be done on site. The strongest example of this was the case of the Madagascar fody introduction to Aldabra, for which SIF was able to quickly establish a collaboration with university researchers, ensuring that the samples and data collected could be rapidly and effectively analysed. The resulting research outputs included analysis of origin (Assumption) and timing (recent, but probably pre-dating the start of the eradication) of the invasion, as well as confirmation of hybridisation between the endemic and introduced species and more insights into this process (van de Crommenacker, et al., 2015). A collaboration was also established for disease-screening of ring-necked parakeet and black parrot blood samples to provide information on the pathogen status of each species.

8. Training of local staff is essential for project success

Few people with the necessary technical skills needed for the eradications existed in the Seychelles when the project started, so more than 30 local staff were intensively trained on the job throughout the eradications. Five of these staff members subsequently led parts of the eradications and were crucial to their success. Several of the staff members have subsequently been recruited in other invasive species management positions within SIF and elsewhere, so the eradications have increased in-country capacity in this field. Indeed, local staff training is seen as one of the biggest achievements of the eradications and has had the additional benefit of providing a strong sense of national ownership to the eradications.

9. Assess effectiveness of publicity and focus on the most appropriate means

Outreach activities are important in any eradication but in some, they are an essential means of achieving success. For the ring-necked parakeet eradication, on assessing where callers had heard about the project we found that the vast majority were prompted by the TV advert so we were able to focus on this for the rest of the project, which reduced costs and time without compromising the information received. In addition to public outreach, we found it was essential to liaise with other stakeholders in the environmental sector about the importance of the eradications. We noticed that the eradications tended to bring out strong feelings either for or against the project, and most people appreciated an opportunity to ask questions and understand the reasons for it. Our impression was that the outreach and education carried out for these projects went a long way to increase public support although we have no way of quantifying this

10. The early bird catches the worm

In the case of these eradications, we are certain that pre-emptive action has been a more effective and cost-efficient strategy to protect endemic species than would have been the case had we waited for the introduced species to spread to Aldabra and the Vallée de Mai (or other islands in the Seychelles) and establish populations. Indeed, this had already started to happen with all three species and, had we waited much longer, eradication may have proved an impossible task. Finally, at least one and potentially two of these invasive bird species are now nationally eradicated from the Seychelles and there is minimal risk of them being reintroduced to the sites in the future. We therefore consider the biodiversity and ecological integrity of the Seychelles World Heritage sites to have been safeguarded from these particular threats by these eradications.

CONCLUSION

Although all three species targeted here are known invasive species, and control efforts have been made or are underway in several places, there were no previous records of them being removed in such large numbers, or their complete eradication from any other islands or countries. The challenges and successes of these eradications provide a unique learning opportunity and offer a positive outlook for the future of introduced bird eradications. The fact that these eradication successes (or near successes) in the Seychelles are the first of their kind suggests that a change in approach and mindset to invasive bird eradications is timely. We believe that insights gained from these programmes can be used as a basis to significantly advance the field of invasive bird management and to initiate the development of best practices for eradication attempts.

ACKNOWLEDGMENTS

We thank the Seychelles Ministry for Environment, Energy and Climate Change for their support and facilitation of all of these eradications. We are also very grateful to our key partners – the Islands Development Company, the Police Special Services Wing, the Seychelles People's Defence Force, and the Seychelles National Parks Authority. The red-whiskered bulbul and Madagascar fody eradications on Assumption, and the ring-necked parakeet eradication on Mahé were carried out under an EU-funded project (project DCIENV/2010/220-252: "*Mainstreaming the management of invasive alien species to preserve the ecological integrity and enhance the resilience of Seychelles World Heritage Sites*") implemented by SIF between 2011 and 2015. Later financial support for the ring-necked parakeet eradication was kindly provided by the Environment Trust Fund Seychelles and the Global Environmental Faculty. The red-whiskered bulbul and Madagascar fody eradications on Aldabra were initiated under an Emergency Assistance project funded by UNESCO. We thank all of our funders for their essential support of these eradication programmes. This paper includes as co-authors all staff who have worked directly on the eradication programmes on two or more of the three eradication locations (Assumption, Aldabra, Mahé) for at least a year. For the Assumption eradications, Chris Feare and Jannie Linnebjerg developed and led the initial research into the eradication and monitoring methodology and conducted the pre-eradication population estimates. Phase 1 of the Mahé eradication of ring-necked parakeets was led by Darryl Birch and Pete Haverson. In addition, all of the many consultants and staff who have worked hard on one or more of the eradications to make them a success are thanked, including Wilna Accouche, Nyara Anacoura, Lina Barbe, Samuel Bassett, Paul Benoit, Jude Brice, Unels Bristol, April Burt, Sheril de Commarmond, Stan Denis, Steve Denis, Martin van Dinther, Marcus Dubel, Roland Duval, Rebecca Fillipin, Ronny Gabriel, Frankie Gamble, Rosanna Gordon, Murvin Green, Arjan de Groene, Oskar Guy, Helga Hoareau, Jakawan Hoareau, Lauren Koehler, Israel Labrosse, Ronny Marie, Stephanie Marie, Jamie McAuley, Alex McDougall, Pete McIntosh, Glenn McKinlay, Adam Mitchell, Julio Moustache, Reza Moustache, Catherina Onezia, Hendrick Quatre, Terance Payet, Jeremy Raguain, Lotte Reiter, Heather Richards, Marvin Roseline, Jovani Simeon, Abel Sorry, Joel Souyave, Chris Tagg, Rowana Walton, Jeremy Waters and Jack West. Thanks to Carl Jones for his expertise on the trapping of Madagascar fodies and red-whiskered bulbuls. Finally, we would like to thank the II17 organisers and Dick Veitch for the opportunity to present and submit this manuscript.

Abstract House sparrows (*Passer domesticus*) compete with native bird species, consume crops, and are vectors for diseases in areas where they have been introduced. Sparrow eradication attempts aimed at eliminating these negative effects highlight the importance of deploying multiple alternative methods to remove individuals while maintaining the remaining population naïve to techniques. House sparrow eradication was attempted from Robinson Crusoe Island, Chile, in the austral winter of 2012 using an experimental approach sequencing passive multi-catch traps, passive single-catch traps, and then active multi-catch methods, and finally active single-catch methods. In parallel, multiple detection methods were employed and local stakeholders were engaged. The majority of removals were via passive trapping, and individuals were successfully targeted with active methods (mist nets and shooting). Automated acoustic recording, point counts and camera traps declined in power to detect individual sparrows as the population size decreased; however, we continued to detect sparrows at all population densities using visual observations, underscoring the importance of local residents' participation in monitoring. Four surviving sparrows were known to persist at the conclusion of efforts in 2012. Given the lack of formal biosecurity measures within the Juan Fernández archipelago, reinvasion is possible. A local network of citizen observers is the best tool available to detect house sparrows at low density, however ongoing, dedicated eradication funding does not exist. Opportunistic removals via shooting have been possible from 2013–2016, but elusive individual sparrows were seen during a small number of days each year suggesting remnant group(s) exist in yet unknown forest locations.

Keywords: invasive bird, management, *Passer domesticus*, trapping

INTRODUCTION

House sparrows (*Passer domesticus*) have a wide range of negative impacts in areas where they have been introduced. They affect native bird species, pushing eggs and nestlings from nests and chasing adults (McGillivray, 1980; Gowaty, 1984); they consume crops and ornamental plants; and are vectors of at least 29 diseases affecting people, livestock and wildlife (Clergeau, et al., 2004; Fagerstone, 2007). This species is an effective invader owing to its generalist diet; rapid rate of increase, facilitated by colonial-communal nesting, large clutch sizes and extended breeding seasons; effective range expansion in human-altered landscapes; and aggression against similar and smaller sized birds (MacGregor-Fors, et al., 2010). The risks of house sparrows are often underestimated and delays in rapid responses to incipient or small localised populations can result in much more complex and costly future actions for their management once population growth and negative impacts on native species are documented (Clergeau, et al., 2004). Complete removal of invasive house sparrow populations should be considered to eliminate risk for negative impacts arising from the species' invasion.

House sparrow eradication attempts on other islands have demonstrated that the effectiveness of some methods may decline over time, if sparrows learn to avoid them (Bednarczuk, et al., 2010) emphasising the importance of using a variety of techniques in an adaptive management approach. Campaigns for house sparrow eradication should employ multiple methods and aim to remove the entire population within as short a time as possible. Otherwise, given the species' reproductive potential, there is a risk that house sparrows will breed faster than they are removed. To maintain naïveté of the population to methods for as long as possible and reduce the likelihood of house sparrows dispersing in response, methods should be implemented strategically. The detection and removal of the last individuals must be considered in planning the deployment of the multiple alternative methods available (Morrison, et al., 2007). To increase likelihood of successful eradication, some methods should be deployed consecutively and others sequentially with attention to maintaining sparrows naïve to methods.

The Juan Fernández Archipelago in Chile is comprised of three islands (Robinson Crusoe (4,790 ha), Alexander Selkirk (4,950 ha),) and Santa Clara (220 ha)) with globally significant biodiversity and endemism due to its isolation and topographic variation. However, invasive species continue to drive catastrophic changes to these unique natural values including species extinctions and massive erosion, as well as precipitous declines in plant and animal species and loss of native vegetation cover (Sanders, et al., 1982; Bourne, et al., 1992; Arroyo, 1999; Hahn & Römer, 2002). Feasibility of the complete removal of invasive species has been explored and participatory planning with the islands' inhabitants and varied stakeholders continues to advance as benefits of invasive species removals and restoration are prioritised (Saunders, et al., 2011; Glen, et al., 2013; Ministerio del Medioambiente, 2017).

House sparrows have been present on Robinson Crusoe Island (RC) since 1943 as a wild population (Hahn, et al., 2006) and none are kept as pets. The population appeared stable at around 80 individuals and to be restricted to the island's only human settlement of San Juan Bautista (Hahn, et al., 2006; Hagen pers. obs.); however, observations in 2011–2012 indicated population expansion within San Juan Bautista into new home construction areas following a tsunami in February 2010. The potential increased risk from this species to single-island endemic birds and local food production prompted a review of control and eradication options within a local multi-stakeholder group focused on animal issues related to conservation and local development.

The study reports on an attempt to eradicate the local house sparrow population within an experimental framework to examine the efficacy of methods for house sparrow eradications and protect local biodiversity. The

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 289–294. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

objectives of the study were to keep house sparrows naïve and eliminate the potential for survivors to learn to avoid methods (e.g. escape from traps).

METHODS

A range of potential methods for use in house sparrow eradication from RC were considered (see Table 22 of Saunders, et al., 2011). Removal techniques were evaluated and prioritised based on previous success in bird removals, permissibility in this urban setting, and likelihood to contribute to sparrow learning. Toxicants were assessed, but none were considered suitable for house sparrow eradication (Fisher, et al., 2012). Trapping was identified as having the greatest potential to provide a large reduction in the house sparrow population on RC while minimising risks to native birds and poultry. Pre-baiting was initiated one month before removals began (15 June 2012) at 10 sites to allow house sparrows to become accustomed to feeding at a given location on provided crushed maize (1.6–3.2 mm diameter) and to confirm minimal attraction of non-target species to these sites.

Passive removal techniques were employed in the first phase of this trial, to minimise education of house sparrows to future methods (10 July 2012–14 September 2012). Active removal techniques were added to the trial beginning 27 July 2012.

Passive removal techniques

To minimise education of house sparrows in the population, passive traps were employed in the initial phase of removals.

Elevator multi-catch traps have demonstrated good capture and low escape rates (Fitzwater, 1981). House sparrows enter a compartment alone to feed on bait, their body weight causes an "elevator" to lower the individual to its "escape" into a closed cage. Without the bird's weight, the counterbalanced "elevator" springs back into the original position ready for another passenger. Birds trapped in the closed cage act as live decoys. We purchased traps without the central mesh body for ease of transport, and then assembled the mesh over a plywood base forming the holding cage once on the island. Trap dimensions were 60 × 40 × 20 cm (<http://www.sparrowtraps.net/index.htm>). Elevator traps were placed on an elevated platform, approximately 2 m in height, to reduce the potential for trap interference by domestic animals and private citizens. We added a covered plywood compartment with a perch within each elevator trap's holding cage to provide protection from the elements for live decoys. Decoys had primary flight feathers on one wing clipped so that they couldn't fly in the event of escape. Food and water were provided.

Trio multi-catch traps are comprised of two compartments which each function as a single-catch trap, whose sprung doors must be manually reset after each catch (Nature-House ST1 Trio house sparrow trap http://www.amazon.com/Nature-House-ST1-Trio-Sparrow/dp/B001GIP2MG). The bird drops into the compartment, onto a perch over the feed tray which triggers the compartment door to close. Captured individuals can freely move into the third compartment, where they act as live decoys. Three trio traps were deployed, mounted at least 1.5 m above the ground to reduce potential for trap interference by domestic animals and private citizens. We provided flooring in each compartment to increase bait retention and partial roofs to decrease interference from natural elements.

Modified Australian crow (MAC) traps function when birds drop into the MAC trap to access bait and are unable to fly through the trap entrance to escape as their wingspan exceeds the diameter of the entrance. Captured individuals alight on perches in the higher parts of this trap (Clark & Hygnstrom, 1994). Exclusive use of a 'mini' MAC trap has enabled local populations of house sparrows to be entirely removed (McGregor & McGregor, 2008). We constructed two mini MAC traps, retaining traditional width of slats and height of centre board to avoid birds jumping to escape, reducing overall length (82 × 137 × 71 cm). MAC traps were placed on the ground given their robust size.

Nest box traps were made from nest boxes which were converted into single-catch traps (http://www.vanerttraps.com/urban.htm) to capture house sparrows investigating nest cavities. In areas where house sparrows were seen entering and exiting cavities, known cavities were covered to exclude sparrows and nest box traps were deployed with small feathers and fine nesting material added to the entrances to encourage investigation.

Traps were placed within open areas where birds could easily see them, and near frequented flyways, perches and feeding areas. For 2–3 days before arming traps, wired-open traps were placed at pre-baiting sites, with crushed maize on and around the open traps, to permit birds to explore them without risk of capture. When birds were trapped, the trap would be covered with a bed sheet to assist calming the birds during transport and reducing visibility to the general public. Covered traps were then transported to a room where any escapees could be recaptured, prohibiting escape. Within this facility birds were removed from traps and either selected for use as live decoys, or euthanised. Euthanasia was via cervical dislocation; possibly the easiest means for this species and a practical means for mass euthanasia (Sharp & Saunders, 2005; AVMA, 2007).

Active removal techniques

As capture rates declined with passive traps, active removal techniques were added to the trial. We continued using passive traps simultaneously with active removal techniques.

Walk in cage traps were used to target individual sparrows unable to be trapped in other trap types. A wooden box with mesh sides was set up as a walk-in cage trap by propping open a door that opens from the bottom. When the prop is pulled out by a nearby observer (Sharp & Saunders, 2005), bungee cords add to downward force to close the door quickly.

Clap traps utilise a spring-loaded throw net triggered remotely by the trapper, which is placed on the ground and pre-baited with crushed maize (<http://pestbarrier.com/store/itemdesc.asp?xCc=8u4u3>). The trap was not triggered unless all birds in a flock were able to be captured.

Mist nets are a common ornithological capture technique for small birds and were deployed on flyways to capture house sparrows that had avoided traps. Continual monitoring was required to quickly remove any house sparrows or non-target species.

Nest destruction can be used during the breeding season to slow or halt recruitment, and may make adult birds more susceptible to other techniques such as clap traps baited with nest material (Fitzwater, 1994). Eggs are crushed and nestlings euthanised (Sharp & Saunders, 2005). Nest destruction, although planned, was not needed in our trial.

Shooting was employed in specific scenarios where traps were proving ineffective. A 0.177 caliber air rifle with 4–12 times magnification scope (Beeman R9, Weirauch, Germany) was utilised, targeting only individuals alone or in pairs, to avoid wariness. Adult females were targeted first, to limit potential growth of the local population. After 2012, shooting was employed opportunistically.

Detection techniques

Eradication campaigns rely on effective detection of the target species to indicate when individuals of the target species no longer exist and the campaign can conclude. We assessed potential detection techniques for house sparrows throughout the trial, to examine their efficacy at varying house sparrow population densities. We anticipated that some detection methods may become innefective at low population densities as changes in flocking, calling and movements may result from individuals. Therefore we deployed multiple detection techniques simultaneously in order to ensure at least one technique was effective at even low population densities.

Autonomous recording units (ARUs) were deployed at 15 sites within San Juan Bautista. Ten ARUs were co-located with pre-baiting locations while the remaining units were in locations without pre-baiting. We programmed ARUs to record every other day for a 4-hour period around dawn (starting 30 minutes before sunrise) when house sparrows are known to be acoustically active. In addition, each sensor was programmed to record one of every 10 minutes throughout the rest of the day until 30 minutes after sundown. Data from these recordings was available only after post-processing in a sound laboratory. Automated analysis of all field recordings was carried out with the eXtensible BioAcoustic Tool (XBAT, <http://www.xbat.org>) using an image processing technique known as spectrogram cross correlation to detect and classify sounds on our field recordings that were correlated with the spectral qualities of typical house sparrow calls. Sensitivity in the detection analysis was increased to improve the probability of detecting house sparrow calls when few individuals remained, which led to manual review of all events to confirm accuracy of detecting true house sparrow calls (McKown, 2013).

Visual observations were conducted over the same period to provide alternative detection methods in the case that a given method failed to detect individuals even though a population remains present. Fixed radius point counts (Bibby, 2000; Buckland, et al., 2001) were conducted weekly beginning 15 June 2012. Project personnel conducted point counts 14 times throughout the trial period at 21 locations throughout San Juan Bautista, 15 of these locations were co-located with ARU deployment sites and six of which were not located with acoustic sensors or pre-baiting locations. Point counts were analysed using the fixed-radius point count equation as detailed by Buckland, et al. (2001), generating density estimates by habitat type, based on the estimated total surface area of coverage class occupied by sparrows (settlement and cultivated *Eucalyptus, Cupressus* and *Pinus* per Greimler, et al., 2002). Point count density estimates were compared to recorded call rates and sparrow removals each week.

In addition to point counts, citizens were encouraged to report opportunistic sightings of house sparrows, which were all investigated by project staff. Multiple reports of the same individuals, as well as uncorroborated reports prevented clear calculations of the number of individuals remaining.

Camera traps (Reconyx, Holmen WI) were deployed opportunistically at pre-baiting and passive trapping locations. Camera traps were used as an additional technique for visual confirmation of surviving individuals.

After the intensive 2012 campaign, an early observer's network attempting to harness the interest and participation of island residents was developed. This network has grown, and has become a formalised early detection network for invasive species, with individuals' observations of invasive species combined with a common smartphone application (WhatsApp) which allows researchers to capture reports within a database.

Stakeholder communications

Throughout the project, a communications campaign was undertaken to highlight the threats that house sparrows pose to local endemic species. Announcements via radio, signs, fliers, and a booth at a children's day event, were complemented with active participation in the local conservation committee, opportunistic presentations for local institutions and a nest box design contest for local endemic bird species. We also promoted the needs for biosecurity and a municipal ordinance to be established to regulate entry and possession of invasive species.

RESULTS

Methods to maximise personnel efficiency were deployed while reducing the risk of educating animals. Passive multi-catch traps (elevator, trio and mini-MAC traps) were deployed first. As nest-building behaviour was observed, passive single-catch nest box traps were deployed. As the number of individual sparrows was reduced, specific individuals were targeted with more time-intensive active multi-catch traps (mist net, clap trap and walk-in trap). Shooting (active, single-catch technique) was reserved for specific scenarios once other methods appeared ineffective.

Personnel contributed a total of 2,600 person hours across two months of sustained effort. A total of 814 trap days were conducted during the trial, resulting in 89 house sparrows removed. The majority of removals resulted from elevator traps (46 individuals, 275 trap days), followed by mist nets (22 individuals, 22 trap days) and trio traps (15 individuals, 70 trap days). Additional methods did not capture birds (modified MAC, walk-in cage, and clap traps) or were used in specific situations, after the population was reduced, and thus removed fewer birds (nest box trap, 1; shooting, 5). At the conclusion of the trial, four house sparrows were known to remain on the island (two males and two females).

Mist nets and shooting were the most effective removal techniques when effectiveness is assessed as the number of individual sparrows removed as a function of the days the technique was deployed. However, both of these active methods can educate individuals in the target population and require much higher personnel effort as compared to passive trap deployment (for example elevator traps and trio traps), demonstrating that this calculation of effectiveness is incomplete. Also, house sparrows captured in traps appeared to be useful as decoys; however, data specific to differential capture rates is not available.

Detection techniques

Both point counts and automated surveys detected a decline of house sparrows after house sparrow removals occurred. Point count density estimates showed abrupt declines after 60 individuals had been removed from the population, while call rates estimated from ARUs varied more gradually over the trial period (McKown, 2013; Fig. 1). Point count observers did not detect house sparrows

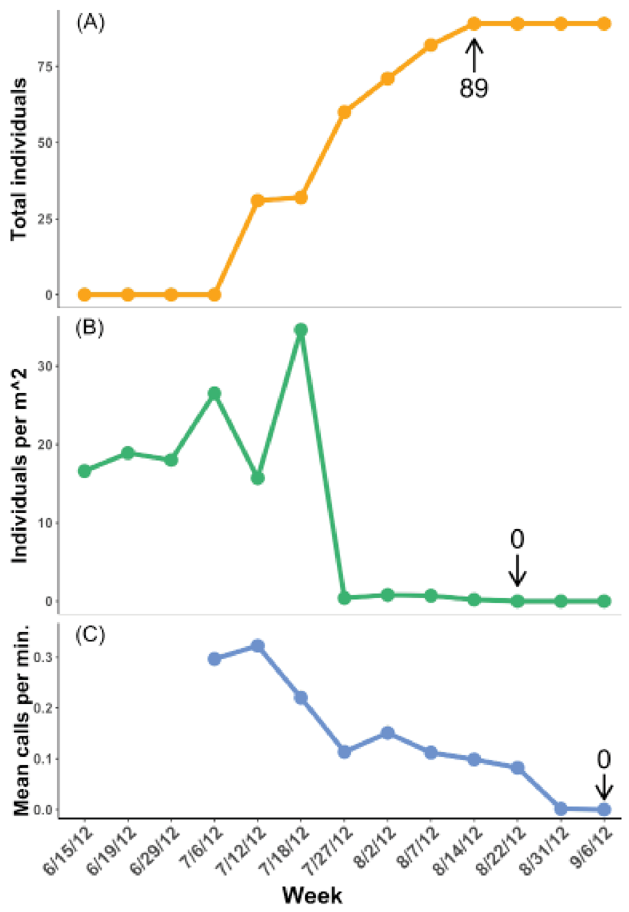

Fig. 1 Results of house sparrow removals over time (month/day/year), as well as detections from point count estimates and acoustic recordings. The cumulative total of house sparrows removed is presented (A) over the same time period that weekly density estimates were calculated from point count observations (B) and mean call rates by house sparrows (C), reported as averages over the previous survey week (McKown, 2013).

after 15 August 2012, while ARUs continued to detect house sparrow activity for 10 additional days. Both point counts and automated surveys failed to detect individual house sparrows known to be present by opportunistic observations on the island in early September 2012; neither point counts nor automated acoustic surveys were effective detection methods at low sparrow densities. Reports and observations made by community members were initiated in July 2012 and continue to date. These observations are a critical component of visual observations as they increase the effective coverage of the dedicated eradication team in area as well as time. In 2014 observations were also being made through the smartphone network, as well as through personal communications.

A total of 1,179 hours of acoustic recordings were collected and analysed from July to September 2012. All 79,822 events detected as potential house sparrow vocalisations were manually reviewed to confirm accuracy. Mean house sparrow acoustic activity, at all surveyed sites with data, declined from an average of 0.3 calls per minute in July 2012 to no calls by the end of August when a low number of individual house sparrows remained on the island (McKown, 2013).

Camera traps effectively captured images of house sparrows visiting known food sources. Given the trial setting in San Juan Bautista, some sites were inefficient for house sparrow detections via camera given that domestic animals, people, and objects moving in the wind would trigger the camera traps resulting in a significant number of images without the target species present. Camera traps did not capture images of individuals when population density was lowered by removals (after 15 August 2012), demonstrating ineffectiveness as a detection method for sparrows at low population densities.

The remnant house sparrows were infrequently detected within the town area between 2012 and 2016 and were reported by residents. Observations were limited to isolated localities and dates (20–23 June 2013, one individual detected and removed; 14 and 23 November 2015, one individual detected; 1 November 2016, five individuals detected; 19–30 October 2016, six individuals detected, three removed). Remaining house sparrows successfully avoided removal techniques and, based on inability to detect them, are thought to spend most of the year outside of the town area. It is uncertain whether or not house sparrows have continued to arrive via cargo ships from mainland Chile.

In addition to house sparrow detections, shiny cowbirds (*Molothrus bonariensis*) have been detected through the citizen observers network (15 March 2016, two individuals detected and removed; 20–24 April 2017, two individuals detected, one removed; Hagen, unpublished data).

Stakeholder communications

Dedicated efforts for regular, personalised and transparent communications about the trial and its goal to benefit native biodiversity were invested before, during and after the trial. Emphasis was given towards communications with homeowners at or near removal sites, as well as broad community-wide communications to minimise misinformation. Project personnel questioned while working always provided community members their attention, answering questions and continuing conversations as needed. A dedicated outreach coordinator led interactions with site owners and local institutions, served as primary point of contact for stakeholder concerns and provided regular updates to stakeholders regarding trial status and advances.

DISCUSSION

The house sparrow has aggressive foraging and nesting behaviour towards native bird species and is one of the most widespread invasive bird species throughout the world (Anderson, 2006). The house sparrow population expansion on Robinson Crusoe Island caused concerns for impacting vulnerable island endemic birds such as the Juan Fernández firecrown (*Sephanoides fernandensis*) and the Juan Fernández tit-tyrant (*Anairetes fernandezianus*), species which already co-occur with house sparrows (Hahn, et al., 2005). Given that house sparrows were pro-actively eliminated from neighbouring Alejandro Selkirk Island in 1994 (Hahn, et al., 2009), there was local interest in their removal from Robinson Crusoe Island while they were still restricted to one area of the island.

Worldwide, invasive bird eradications have received criticism for perhaps not being the highest need or having substantial evidence related to their impacts (Strubbe, et al., 2011). The precautionary principle may be invoked in decisions of eradicating potential threats before ecological damage is documented and the invasive bird establishes a population; in fact, this early action may be the only option for removing highly mobile bird species in some places and can definitely be the most economical option (IUCN, 2000; Baker, et al., 2014; Martin-Albarracin, et al., 2015). On Robinson Crusoe Island, house sparrow eradication and related activities as a community engagement and invasive species awareness-building technique for a broader invasive species programme (Glen, et al., 2013) were used. By working within the island's only town and with dedicated transparent communications focused on native species conservation, a coalition of homeowners was built that not only actively asked questions about invasive species management, but also contributed observations regularly to an early observer's network. This network has grown and today is formalised as an early detection network, continuing to rely on individuals' observations of invasive species by word of mouth, phone and smartphone application as a critical part of invasive species management (Ministerio del Medioambiente, 2017).

At the conclusion of the trial in late 2012, local decision-makers were interested in completing the house sparrow eradication, however the only detection techniques effective at low population densities are opportunistic visual observations. A wide network of citizen observers has successfully indicated presence and locations of house sparrows on Robinson Crusoe in following years; however detailed observations that lead to successful removals require effort-intensive follow-up by specialized personnel. Follow-up trapping has not been successful, however removals by shooting have occurred. It is unclear how many individuals remain, however they tend to be reported in the period from October to January. Multiple methods were ineffective at detecting the presence of remaining house sparrows at low population density, complicating the ability to assess eradication success probability without considerable observer effort across the island. Statstical frameworks developed to assess the probability of eradication confirmation success for other species may lend themselves to adjustments for invasive bird eradications and should continue to be explored (Ramsey, et al., 2011; Samaniego-Herrera, et al., 2013). There is no local institution able to dedicate staff to responding to observations, and so reported sparrow sightings and opportunistic removals are recorded in an exotic species database, including detections and removals from Alejandro Selkirk Island in 2016. The complete removal of house sparrows from the Juan Fernández Archipelago is possible with continued observations and removals; however, the arrival of additional individuals from continental sources via cargo boats is likely as no formal biosecurity measures exist and established municipal ordinances cannot restrict these movements. Persistent threats to native avifauna from introduced species continue to exist in the absence of formal biosecurity and environmental protection legislation.

Worldwide we are aware of at least 23 documented bird eradication attempts (DIISE, 2016, using data classified as good or satisfactory quality, and whole island eradications only). Bird eradication projects are more challenging compared to mammal eradications because volant birds fly more readily between adjacent islands, leading to higher rates of reinvasion (thus necessitating definition of eradication units for eradication planning, e.g. Robertson & Gemmell, 2004; Abdelkrim, et al., 2005) and it is often harder to define if treatment of the whole island or only part of the island is required. Recently, six successful bird eradications in the Seychelles were implemented (Bunbury, et al., 2019) adding to the global knowledge pool for planning and implementing invasive bird eradications. We are aware of only two other attempts to eradicate invasive house sparrows from island habitats, an unsuccessful attempt on Round Island in Mauritius (Bednarczuk, et al., 2010), and a successful attempt of a restricted range population on Mahe in the Seychelles, where repeated invasions (due to international ship traffic) are treated on an ongoing basis (Beaver & Mougal, 2009).

ACKNOWLEDGEMENTS

Thanks to J.L. Herrera, W. Jolley, A. de Rodt, D. Arredondo, R. Recabarren, M. Pérez, E. Oberg, U. Partarrieu, C. López, P. González and S. de Rodt for assisting in planning, logistics, and the field work conducted to implement this project. I. Leiva and the park guards at Parque Nacional Archipiélago Juan Fernández, especially B. López, M. Recabarren and D. Arredondo, provided support throughout the work described here. Island Conservation's eradication advisory team provided peer review of plans. Matthew McKown and Conservation Metrics provided excellent support with detection analysis. Permits were provided by Servicio Agrícola y Ganadero as well as the Corporación Nacional Forestal. Thanks also to residents of the Juan Fernández Islands who provided information on sparrow sightings, and landowners within San Juan Bautista who provided access to their land. We are grateful for the support and interest from the Municipality of Juan Fernández. This project received financial support from Island Conservation, The David and Lucile Packard Foundation, and National Fish & Wildlife Foundation. Thanks to two anonymous reviewers for constructive feedback on an earlier draft of this manuscript.

Predation pressures on sooty terns by cats, rats and common mynas on Ascension Island in the South Atlantic

Abstract Despite the presence of invasive black rats (*Rattus rattus*), common mynas (*Acridotheres tristis*), and feral domestic cats (*Felis catus*), sooty terns (*Onychoprion fuscatus*) breed in large numbers on Ascension Island in the tropical South Atlantic Ocean. These introduced predators impact the terns by destroying eggs or interrupting incubation (mynas), eating eggs (mynas and rats), eating chicks (rats and cats), or eating adults (cats). Between 1990 and 2015, 26 censuses of sooty terns and five of mynas were completed and myna predation was monitored on 10 occasions. Rat relative abundance indices were determined through trapping around the tern colonies and rat predation was monitored by counting chick carcasses. Cat predation was quantified by recording freshly killed terns. Prior to their eradication in 2003, cats had the greatest impact on sooty terns and were depredating 5,800 adults and 3,600 near-fledging chicks (equivalent to the loss of 71,000 eggs) each breeding season. We estimated that 26,000 sooty tern eggs (13% of all those laid) were depredated by approximately 1,000 mynas. Rats were not known to depredate sooty terns prior to cat eradication but in 2005, 131 of 596 ringed (monitored) chicks (22%) were depredated by rats. In 2009 chick carcass density was 0.16 per m^2. Predation by rats hugely increased in the absence of cats and was the equivalent of 69,000 eggs. Care is needed when applying our findings to seabirds globally. The scarcity of alternative food sources and seasonally high density of easily available prey in the sooty tern colony may have magnified predation by cats, rats and mynas.

INTRODUCTION

Comparative studies of global declines in faunal biodiversity have concluded that harvesting, habitat loss and introduced invasive species are leading causes (see refs in Young, et al., 2016). Of extinction events for which causes have been investigated, 54% have been attributed in part to invasive species (Clavero & Garcia-Berthou, 2005). Globally, terrestrial invertebrate invaders have reduced faunal diversity by 29% (Cameron, et al., 2016). Lowe, et al. (2000) compared the severity of alien species on animal and plant diversity by compiling a list entitled "100 of the world's worst invasive alien species". The list includes invasive predators that are commensal with man; they pose major threats to seabirds and they persist following anthropogenic introduction to 90% of all island archipelagos (Towns, et al., 2006). Global seabird population size has declined by 70% between 1950 and 2010 (Paleczny, et al., 2015) with introduced commensal predators being one of the major proposed causes of such declines (Moors & Atkinson, 1984).

Of introduced predators, feral domestic cats (*Felis catus*) (Medina, et al., 2011) and black rats (*Rattus rattus*) (Jones, et al., 2008) inflict the most severe impacts on native avifauna. Common mynas (*Acridotheres tristis*) (hereafter referred to as 'mynas') also have significant negative impacts on native avifauna through competition for food and nest sites (Grarock, et al., 2012). When cats, rats and mynas invade islands on which seabirds are breeding, cats have a direct effect on the size of the seabird population through predation of adults (van Aarde, 1983) while rats and mynas have a less immediate, but a more indirect, effect through predation of eggs or chicks (Jones, et al., 2008). Therefore, rats and mynas reduce breeding success and inflict downstream impacts on seabird demography through reduced recruitment to the breeding population (Harper & Bunbury, 2015). The direct impacts of cats on breeding seabirds are more readily observed than the indirect effects of rats and mynas that are more difficult to quantify because rat and myna predation is less obvious and is confounded by rats scavenging on chicks that have died from causes other than direct predation (e.g. starvation).

Alien invasive predators are the potential cause of precipitous declines in the population size of breeding sooty terns (*Onychoprion fuscatus*) on Ascension Island during the 20th century (Hughes, et al., 2017a). Sooty terns are the most numerous avian species in tropical waters and Ascension Island accommodates the largest breeding population in the Atlantic (Schreiber, et al., 2002). Three of the world's 'worst' invasive predators are found in the seabird colonies on Ascension Island. Black rats probably arrived when HMS Roebuck was abandoned close to the island in 1701 (Ashmole & Ashmole, 2000), and by 1725 rats were so numerous that a castaway on the island lived in fear of being eaten alive (Ritsema, 2006). In 1815 domestic cats were introduced to control the rat population. Mynas were introduced in the 1880s to reduce damage to crops by black cutworms (*Agrotis ipsilon*) (Duffey, 1964). Common mynas in their home range (i.e. India) are regarded as a beneficial species (BirdLife International, 2015) because typically more than 80% of their food mass comprises insects regarded as pests (e.g. cutworms – larvae of Noctuidae). Since the arrival of these invasive species on the island, the once vast colonies of seabirds, estimated to contain > 10 million birds (Ashmole & Ashmole, 2000), have dwindled to less than half a million birds (Bell & Ashmole, 1995). Of the 11 seabird species that breed on Ascension Island, only sooty terns now breed in large numbers on the main island. Numerically, 97% of all seabirds breeding on the main island are sooty terns (Hughes, 2014). Remnant populations of other seabird species nest on cat- and rat-free offshore stacks and Boatswainbird Islet (Ratcliffe, et al., 2009).

In 1958 and 1959, cats were the only non-native predatory species known to depredate seabirds and an aspiration for their eradication was conceived (Ashmole, 1963). During a feasibility study for cat eradication in 1992, rats were also considered a major threat to seabirds (Ashmole, et al., 1992) but the threat that mynas posed was not recognised at that time. More recently, in the Seychelles, Feare, et al. (2015) recorded mynas inflicting intense predation on seabird eggs. On Ascension Island cats were eradicated in 2003 (Bell & Boyle, 2004) and

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 295–301. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

rat control measures (Pickup, 1999) were implemented. The eradication of apex predators is generally associated with an increase in the abundance of smaller predators with this trophic interaction referred to as 'mesopredator release' (Prugh, et al., 2009). However, Russell, et al. (2009) modelled the effects of mesopredator release and concluded that the negative impact of more mesopredators is outweighed by the benefit of apex predator removal, allowing recovery of prey populations. If we apply their conclusions to Ascension Island then cat eradication should have resulted in an increase in the population size of sooty terns but, to date, no such effect has been detected (Hughes, et al., 2017a).

Here, we have collated data from published outputs and from a 25-year Army Ornithological Society (AOS) dataset on introduced species to calculate the relative impacts of cat, rat and myna predation on the sooty tern breeding population.

METHODS

Study area and period

Ascension (07º57′S, 14º24′W, 97 km²) is one of the volcanic islands that make up the UK Overseas Territory (UKOT) of St Helena, Ascension and Tristan da Cunha, and is isolated in the tropical South Atlantic Ocean midway between South America and Africa (Fig. 1; Hughes, et al., 2010). Its nearest neighbour is the island of St Helena some 1,300 km to the south-east. The territory is an Important Bird Area (IBA reference number SH009; BirdLife International, 2017). More than half of its surface consists of cinder plains, ash cones and basaltic lava flows. The average annual rainfall is 144.0 mm (Anon., 1998) and plant species richness on the plain is < 11 species (Duffey, 1964). The dry coastal plain is the traditional nesting site for seabirds and sooty terns nest at Mars Bay and Waterside in the south-west corner of the island (Fig. 1).

Fieldwork lasted two weeks per breeding season and was timed to coincide with the peak of the sooty tern breeding season (see further details in Reynolds, et al., 2014). Time in the field amounted to 1,691 person-days.

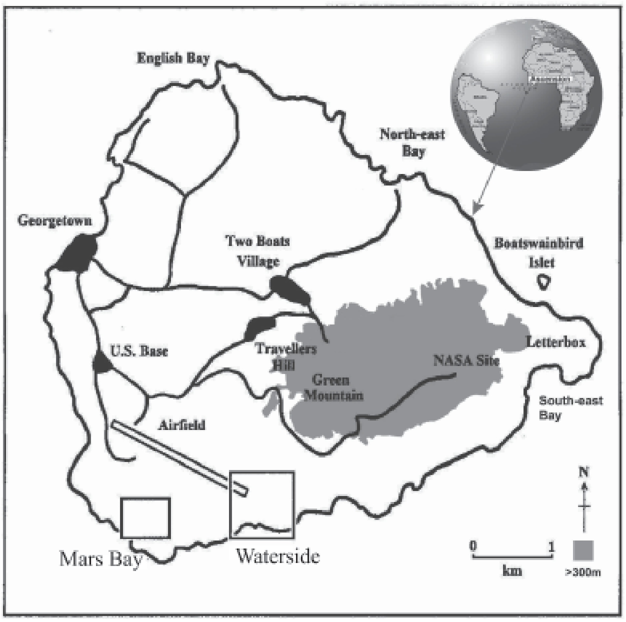

Fig. 1 Map of Ascension Island in the South Atlantic showing sites of human habitation and ground above 300 m (shaded). Sooty terns nest in the south-west corner of the island in the areas marked as 'Mars Bay' and 'Waterside'.

Prey population size

Sooty terns, the primary avian prey species of rats, cats and mynas, are a migratory species and are absent from Ascension Island for approximately three in every 9.6 months that constitute the sub-annual cycle of the species (Reynolds, et al., 2014). Modal clutch size of sooty terns is one (Schreiber, et al., 2002). The population was censused on 26 occasions between 1990 and 2015. We calculated the number of eggs laid by measuring the area of the two breeding colonies using conventional land survey techniques and determined egg density by counting eggs in quadrats (see full details in Hughes, et al., 2008).

Myna population size and their predation pressure on sooty terns

Censuses of the myna population were obtained from a consolidation of counts in 1994, 2004, 2005, 2006 and 2015 and included counts of birds feeding on the two rubbish tips, in 116 1-km grid squares covering the whole island, and at night-roosts.

Rates of predation were estimated by marking focal sooty tern eggs and following their fates. In each sooty tern breeding season, egg predation by mynas was measured for approximately seven days (i.e. for 25% of the incubation period of 28.8 days; Ashmole, 1963) and mean egg failure rates for the core and periphery of the colony (Hughes, et al., 2008) were calculated using the Mayfield method (Johnson & Shaffer, 1990). Causes of egg failure were categorised according to egg damage likely caused by mynas: 'consumption' was defined as the opening of a viable egg and feeding on some (usually < 10%) of the contents, and 'puncturing' was defined as the creation of a single small hole that destroyed egg integrity. The ratio of consumed:punctured sooty tern eggs was obtained from quadrat counts of depredated eggs. To establish causation of egg desertion, sets of focal eggs that contained deserted eggs were separated into two categories: those containing eggs consumed or punctured by mynas, and those that did not. We had previously found that the apparent association between these egg fates was significant (see full details in Hughes, et al., 2017b).

Cat population size and their predation pressure on sooty terns

On Ascension Island the cat population size in 1958 was estimated to be in the hundreds (Ashmole, 1963). Of the 1,100 feral cats that were removed from the island in the eradication programme of 2002, approximately 50 were removed from the tern colonies (Bell & Boyle, 2004).

Predation of adult sooty terns was monitored by removing all corpses of terns from the breeding area and then re-visiting the colonies to record the number of freshly killed birds. The mortality data gathered over two weeks may sometimes under-estimate the level of predation. Ashmole (1963) found that towards the end of each season cats began to take large chicks as well as adults. To compensate for this unknown level of chick predation, cats were assumed to take equal numbers of adults and chicks for 110 days (i.e. the period when some adults incubate while others feed chicks close to fledging; see full details in Hughes, et al., 2008). Because cats have been observed consuming seabird eggs elsewhere, albeit on rare occasions (Plantinga, et al., 2011), we also assessed this source of egg loss by inspecting cat middens for cat-predated eggs.

Rat population size and their predation pressure on sooty terns

The size of the rat population on Ascension Island has not been estimated but anecdotal data indicate that it has been (and remains) large. For example, 70,148 rats were killed between 1878 and 1887 (Hart-Davis, 1972). Relative abundance of rats in the tern colonies was estimated using a simple index calculated as the number of rat captures per 100 trap-nights (C/100TN) corrected for traps tripped (after Cunningham & Moors, 1983). During field seasons 50 'Victor' break-back rat traps baited with peanut butter and cornflakes were set out in pairs along the edge of both tern breeding colonies. Nest density was too high to allow traps to be set within the colonies without significantly disturbing breeding birds. Trapping occurred over two consecutive nights.

We studied the rate of chick predation by rats by counting chick carcasses (Towns, et al., 2006). We eliminated the possibility that starvation was the ultimate cause of chick mortality by recording the muscle score and body mass of live chicks in the same parts of the colonies as carcass surveys. The shape of the pectoral muscles was scored between 0 and 2 according to the prominence of the keel as described in Gosler (1991). A muscle score of 0 on this scale is indicative of low body condition most likely caused by malnourishment. Body mass of live chicks was recorded to the nearest 1 g with a Pesola spring balance. Chicks aged 28–30 days that were underweight weighed approximately 80 g and those that were in higher condition were > 150 g (Ashmole, 1963).

Prior to cat eradication in 2002 we found two cavities in rocks on the perimeter of the tern colonies that contained many broken sooty tern eggs but only later did we attribute the find to rat predation. Rats will roll eggs away from avian nests to a place of safety where they can open them (Zarzoso-Lacoste, et al., 2011). After cat eradication, we studied the rate of egg predation by rats by marking focal eggs and recording their losses. The rate of egg losses to rats was calculated as for that to mynas. We calculated the level of egg predation by rats prior to cat eradication by scaling up our findings from the above focal study. We used rat indices to generate relative rat abundance estimates before and after cat eradication.

Comparison of the three predation pressures

To evaluate the impact of chick and egg losses on the size of the breeding population of sooty terns, ratios of adults to chicks, and adults to eggs were required. In other words, on average, how many eggs need to hatch, and thus how many chicks need to survive until recruitment, to replace one adult in the breeding population? Furthermore, cats depredate near-fledging chicks while rats take half-grown chicks and thus we also required a ratio of eggs to both cat- and rat-depredated chicks.

The ratio of near-fledging chicks to adults was obtained from demographic data and estimates of adult and juvenile survival rates were calculated from ringing-re-capture data of adults and near-fledging chicks that were ringed during the same breeding seasons and re-captured in subsequent seasons (see further details in Reynolds, et al., 2014). Adult and juvenile survival rates, age at first breeding and mean age of birds in the breeding population were determined each breeding season by the re-capture from each cohort of adults and new recruits, and a mean with a 95% confidence limit (CL) calculated using the program MARK (White & Burnham, 1999).

The ratio of eggs to near-fledging chicks (i.e. those depredated by cats) was calculated from density counts of eggs and near-fledging chicks in quadrats (Bibby, et al., 2000; Schreiber & Burger, 2002). The ratio of eggs to half-grown chicks (i.e. those depredated by rats) was calculated by taking the average of near-fledging chick survival (see above) and nestling survival rates. The age at which nestlings leave the nest was approximately five days (Schreiber, et al., 2002). We calculated nestling survival rate for the five days by applying a hatchability rate of 0.91 (i.e. the number of eggs that hatched at the end of the incubation period; after Koenig, 1982) and a predation rate from Ascension frigatebirds (*Fregata aquila*) of 0.98 (i.e. the number of nestlings that escape frigatebird predation; BJH, unpubl. data) to the incubation success rate.

RESULTS

Sooty tern population size

Each season between 1990 and 2015, sooty terns laid on average 180,000 ± 8,000 (1 standard error [SE]) eggs (range: 70,000–270,000 eggs, n = 26 censuses). The mean number of nestlings in the tern colony each season was 94,000 ± 14,000 (n = 12 breeding seasons). The mean size of the breeding population was 360,000 ± 14,000 (95% CL) birds (Fig. 2).

Myna population size and their predation pressure on sooty terns

Between 1992 and 2015 the mean size of the myna population was 935 ± 265 (95% CL) birds (Fig. 3a). We found no evidence to suggest that mynas killed tern chicks. Mynas were recorded every field season in the tern colonies. Between 2000 and 2008 we monitored 1,238 eggs (935 on the periphery and 303 in the core). Of the 331 nest failures at the periphery of the colonies, 87 (26.3%) failed as a direct result of mynas. We calculated the mean egg failure rate at the periphery of the colonies as being 0.35 ± 0.07 (± 1 SE) eggs per season (n = 10 breeding seasons). The core of each colony appeared largely free from egg predation by mynas. The mean rate of egg loss to mynas in the two colonies was 0.19 ± 0.04 eggs per pair of terns (range: 0.02–0.37 eggs per pair, n = 1,238 breeding pairs over 10 breeding seasons). The ratio of consumed:punctured sooty tern eggs was 1:1.83 (n > 500 eggs in five sample quadrats across three breeding seasons). In summary, of all sooty tern eggs lost to mynas, 21% were consumed, 39% were punctured and 40% were deserted. We calculated that sooty tern mean egg losses to myna predation per season amounted to 26,000 ± 12,000 eggs (range: 4,000–50,000 eggs) that represented an average of 13% of all eggs laid (n = 10 breeding seasons).

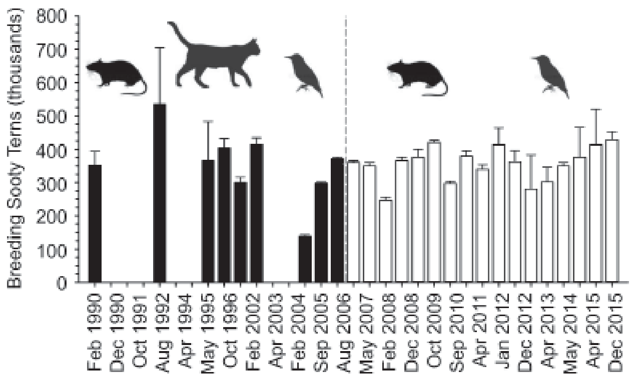

Fig. 2 Estimated size of the sooty tern breeding population (mean + 95% confidence limits) on Ascension Island between 1990 and 2015. Filled columns are censuses carried out during the cat-rat-myna (three) predator regime while open columns are those conducted during the rat-myna (dual) predator regime. Note that the sub-annual breeding cycle results in birds breeding twice in 1996, 2004, 2008, 2012 and 2015.

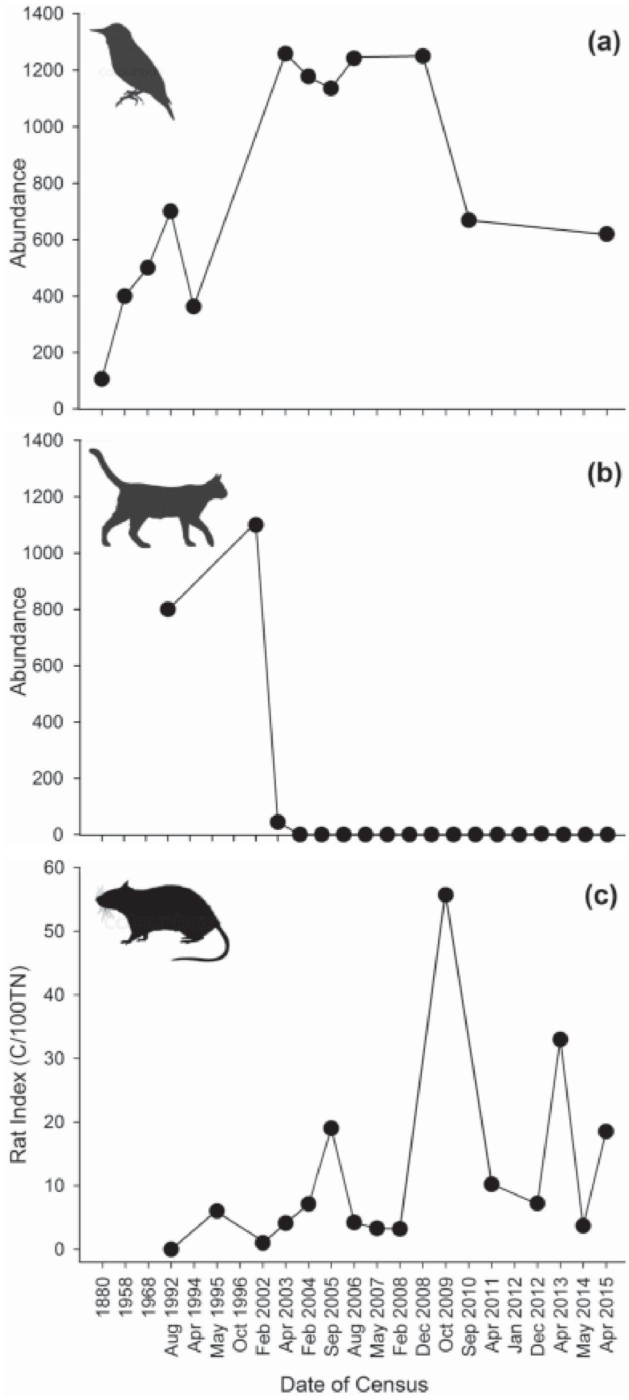

Fig. 3 Population sizes of the three introduced species that prey on various life stages of sooty terns breeding on Ascension Island in the South Atlantic: (a) common mynas, (b) domestic cats, and (c) black rats. Note that in (a) and (b) population estimates are based upon whole-island counts while (c) provides a relative abundance index calculated as the mean number of rats captured (C) per 100 trap-nights (TN) at both colonies (see further details in the Methods).

Cat population size and their predation pressure on sooty terns

We were unable to quantify cat numbers in the sooty tern colonies. Estimates of the size of the feral cat population across the whole island are shown in Fig. 3b. The number of adult sooty terns killed by cats from collection of corpses in 1990, 1992 and 1994 amounted to 2,996, 340 and 310, respectively. The mean number of adults killed by cats in the two colonies was 29 per night (n = 32 nights over three breeding seasons). Towards the end of the sooty tern breeding season cats were killing near-fledging chicks as well as adults. If cat predation continued at the same intensity in the second half of the season as in the first, the overall percentage of the adult population depredated by cats would have been 1.8% (or 5,800 birds on average, n = 3 breeding seasons). Predation of chicks was not monitored but we estimated that the overall percentage of chicks that were depredated or died of starvation because a parent was killed by cats, was 3,600 chicks (i.e. 29 cat kills per night for the four months that chicks were in the colony, yielding a total of 3,600 chicks, 3.8% of the chick population of 94,000). We found no evidence that feral cats were taking any sooty tern eggs.

Rat population size and their predation pressure on sooty terns

During 473 days of fieldwork prior to the eradication of cats, no rat predation of tern chicks was observed. Between 1992 and 2002 the mean relative abundance of rats pre-cat eradication on the dry coastal plain close to the two tern colonies was 1.3 ± 1.0 (± 1 SE) C/100TN (range: 0–6.0 C/100TN, n = 6 trap-lines over three breeding seasons). Between 2005 and 2015 after the cat eradication the mean relative abundance of rats was 15.2 ± 3.8 C/100TN (range: 0–74.5 C/100TN, n = 25 trap-lines over 12 breeding seasons) (Fig. 3c).

Carcasses of chicks depredated by rats were first observed in 2005 when 131 of 596 ringed chicks (22.0%) were depredated. In 2009 mean carcass density in quadrats was 0.16 (range: 0–0.9 per m^2, n = 68 quadrats). The area of the colony was 12.21 ha and thus it contained an estimated 19,500 ± 27,000 carcasses (20%) of the chick population. We found no evidence of mass starvation as live chicks had a mean muscle score of 1.05 ± 0.31 (range: 0–2, n = 998 chicks) and a mean body mass of 157.5 ± 29.2 g (range: 54.8–220.0 g, n = 946 chicks). In 2005 and 2009 the mean number of chicks depredated by rats was 20,000 (21% of the chick population).

During nine sooty tern breeding seasons between 2003 and 2012, we monitored 1,067 single egg clutches (792 on the periphery and 275 in the core) for rat predation. Of the 327 nest failures, 314 were on the periphery and 13 were in the core of the colonies. Of the 327 that failed, 51 (15.6%) were missing eggs and these were attributed to rat predation. The mean rate of egg loss to rats was 0.17 ± 0.06 (± 1 SE) eggs per pair of terns (range: 0.00–0.49 eggs per pair, n = 1,067 breeding pairs over nine breeding seasons). Assuming rats only depredated eggs at the periphery of the colonies as so few eggs failed in the core, the overall percentage of the eggs depredated in the tern colony by rats was 4.8% representing an egg total of 9,000 (n = 9 breeding seasons).

From a comparison of mean relative abundances of rats pre- (1.3 C/100TN, n = 3 breeding seasons) and post-cat eradication (15.2 C/100TN, n = 12 breeding seasons), we estimated that the rat population was only 8.6% as large prior to, compared with after, the cat eradication. We also estimated that rats depredated 800 eggs per season prior to cat eradication.

Comparison of the three predation pressures

A summary of the comparative predation pressures in terms of egg losses (i.e. the lowest currency to represent all tern life stages) is provided in Fig. 4. We generated ratios to eggs laid of survival estimates at various life stages using life-history data in Hughes (2014). The ratios generated were eggs preyed upon by mynas (1:1); chicks succumbing to rat predation (2.99:1); chicks preyed upon by cats (4.13:1); and adults preyed upon by cats (9.67:1).

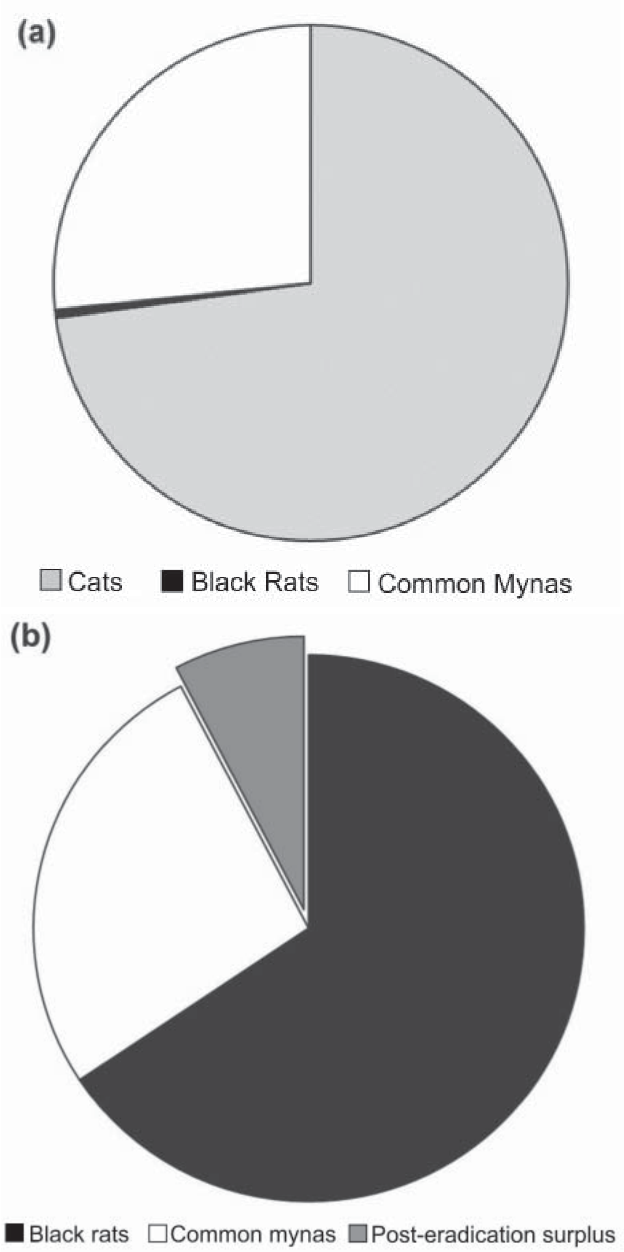

Fig. 4 (a) Pre- and (b) post-cat eradication losses of sooty tern egg equivalents (i.e. eggs and post-hatching chick and adult life stages) to three introduced predator species on Ascension Island in the South Atlantic. The average number of eggs laid was 180,000. Note that in (b) there are only two predators contributing to losses of egg equivalents while the third category represents the benefit to the tern population of cat eradication, equating to 2,000 eggs (see further details in the Results).

The mean number of eggs lost to myna predation per sooty tern breeding season was 26,000. We calculated that losses of chicks to rats translated into the 'loss' of 60,000 eggs (i.e. 20,000 chicks × 2.99). Rats also directly removed 9,000 eggs from the breeding colony. The sum of rat predation translated into the 'loss' of 69,000 eggs. Cats depredated 5,800 adults and 3,600 near-fledging chicks translating into egg losses of 56,000 (i.e. 5,800 adults × 9.67) and 15,000 (i.e. 3,600 near-fledging chicks × 4.13), respectively. Therefore, the sum of cat predation translated into the 'loss' of 71,000 eggs.

DISCUSSION

We compared carcass counts of adults killed by cats with those of chicks killed by rats to assess their relative impacts on the tern population. Carcass density of chicks killed by rats was likely to provide an under-estimate of chick losses as decomposition of corpses was rapid and rough ground made it easy to overlook them. Carcass counts of adults and near-fledging chicks killed by cats (and adjusted by the adult:chick ratio), and those of chicks solely killed by rats, were similar to each other, varying by 18%. If we take into account that rats also depredated 9,000 eggs then the variation between rat and cat predation is just 3%. Of the three sources of predation on the tern population, cats had the greatest impact on the tern population but following their eradication, rats replaced them as the primary source of predation pressure (Fig. 4).

The third source of predation on the island was mynas that depredated 26,000 eggs every sooty tern breeding season but their overall impact on the population size of sooty terns was less than half that of cats or rats. Mynas depredated more tern eggs than did rats (i.e. 26,000 *versus* 9,000) and very many more than did cats. Bell and Boyle (2004) found egg remains in stomachs of one of five cats culled close to the tern colony. We found no evidence that mynas depredated chicks or adults. Mynas depredated more tern eggs than rats or cats depredated chicks and before cat eradication (i.e. pre-2002) mynas had a greater detrimental impact on the size of the breeding tern population than did rats. There were large variations between sooty tern breeding seasons in the relative abundance of rats in the tern colonies (Fig. 3c) and in the extent of egg losses to mynas (i.e. 0.02–0.37 eggs per pair) suggesting that sooty terns were not the main driver of the population dynamics of these two omnivorous predators (Towns, et al., 2006).

Other comparative studies

A meta-analysis by Baker, et al. (2013) of threats to native avian species posed by introduced ones concluded that introduced invasive avian species are not a major threat. However, we found that mynas posed a major threat to native sooty terns on the island (Hughes, et al., 2017b). For every egg that mynas consumed, they punctured or caused desertion of four others. The only quantitative comparative study of seabird egg predation by mynas was of 350 wedge-tailed shearwaters (*Puffinis pacificus cuneatus*) on Hawaii where mynas punctured 74 (21%) of all eggs laid during one season (Byrd, 1979).

Ashmole (1963) estimated that on Ascension Island cats were killing approximately 10,000–20,000 sooty tern adults (i.e. 0.5 to 1.0% of the adult population) and up to 40% of chicks in 1958 and 1959. On Juan de Nova Island in the Mozambique Channel in the western Indian Ocean where predator/prey constituent members were similar to those on Ascension Island, Peck, et al. (2008) found that cats were killing 2,205 sooty terns per week (0.1% of the breeding population).

Prior to cat eradication, we saw no live rats in the tern colony and we did not suspect any rat predation of tern life stages. Similarly, Ashmole (1963) saw no such incidents of predation by rats during numerous day and night visits to the tern colonies in 1958 and 1959. On Juan de Nova Island where black rats co-exist with cats, and both depredate sooty terns, Ringler, et al. (2015) reported that losses of sooty terns to rats were relatively low. On Ascension Island losses of sooty terns to rats increased dramatically when cats were eradicated (Fig. 4). The severity of the predation post-eradication was similar to that found by Jones, et al. (2008) in their meta-analysis of the severity of rat predation.

Mesopredation

We found that the intensity of predation by rats varied depending on whether rats were the apex predator. Under the cat-rat-myna predator regime, rats exerted the least predation pressure on the tern population (Fig. 4a) but following apex predator (cat) removal, they exerted the greater predation pressure in the dual predator regime (Fig. 4b). Cats were eradicated from the tern colony in 2002 (Bell & Boyle, 2004) and the rat population increased seven-fold in size following their eradication as determined from the relative abundance index (Fig. 3c). The eradication of cats is seen as particularly beneficial to seabirds (Nogales, et al., 2013) but, to the best of our knowledge, this only applies to islands without rats in the first place (e.g. Natividad Island, Marion Island in the sub-Antarctic and Baker Island in the Pacific). We found clear evidence that when black rats are 'released' by apex predator removal the size of the rat population increased and rats started to depredate tern chicks. Rats as apex predators exerted a predation pressure on terns that was 97% of that in the regime of cats and rats. Our findings are at odds with those of Ringler, et al. (2015) who predicted that cat eradication would be beneficial to sooty terns. They also oppose McCreless, et al. (2016) who found that the potential for extirpation of seabird populations was greater in the twin predator regime of cats and rats and they also disagree with Ratcliffe, et al. (2009) who reported that on Ascension Island five seabird species had re-colonized the mainland following the eradication of cats. There are three possible explanations for this disparity: 1) despite major changes in predator population sizes (Fig. 3), there has been little fluctuation in that of breeding sooty terns on the island (Fig. 2) which suggests that predation may not be the primary driver of the tern's population size; 2) a change in the habitat on the tern colonies on Ascension Island occurred concurrently with cat eradication which rats, with their catholic diets, took advantage of by switching to alternative food sources such as seeds of the invasive plant mesquite (*Prosopis juliflora*) (Pickup, 1999); and 3) the sub-annual breeding cycle of sooty terns on Ascension Island may provide rats with more opportunities to breed than if sooty terns were breeding annually as they do elsewhere in their range (Reynolds, et al., 2014).

CONCLUSIONS

Care is needed when applying our findings related to predation pressures on Ascension Island sooty terns to other seabird species on the island and to other places in the world. When sooty terns are present, the super-abundance of prey as represented by eggs, chicks and adults may magnify predation pressures. As far as we are aware, our study is the first to provide a comparison of predation pressures by cats, rats and mynas on seabirds. Such empirical evidence of invasive species' impacts on native avifauna is critical for the prioritization of management options directed towards introduced species (Jeschke, et al., 2014; McCreless, et al., 2016). Here, we present strong evidence that mynas can be major egg predators of seabirds. We have quantified changes in predation pressures resulting from the eradication of cats and we have highlighted that rats in the absence of cats have impacted upon breeding success of sooty terns sufficiently to bring into serious question the benefits of cat eradication to the recovery of the sooty tern breeding population on Ascension Island. Conversely, pressures on sooty terns from predators have declined by 3% following the removal of cats. How rats have largely replaced the predation pressure posed by cats following their removal and why the population of sooty terns on Ascension Island has not recovered in response to seabird conservation efforts to date are questions that require considerable future investigation.

ACKNOWLEDGEMENTS

This study could not have taken place without the enthusiasm, energy and industry of more than 50 members of the Army Ornithological Society (AOS). We owe Colin Wearn a large debt of gratitude for ringing and re-capturing sooty terns and Ali Johnson at the British Trust for Ornithology (BTO) for calculation of the sooty tern juvenile and adult survival rates. We are also grateful to Chris Feare for his help and advice during the 2006 breeding season. BJH is particularly grateful to his five children who forfeited their inheritance so that he could follow his passion for seabirds on Ascension Island. We are grateful to the Royal Society for the Protection of Birds (RSPB) for their encouragement and for providing flights for one of our team and to the staff at the Ascension Island Government Conservation and Fisheries Department for their ongoing assistance. We thank two anonymous referees and the editor for their constructive comments on previous drafts of the manuscript.

Eradication and control programmes for invasive mynas (*Acridotheres* spp.) and bulbuls (*Pycnonotus* spp.): defining best practice in managing invasive bird populations on oceanic islands

S. Saavedra Cruz[1] *and S.J. Reynolds*[2,3]

Abstract Invasive plants and animals inflict much damage on native species and this is particularly the case on isolated oceanic islands with high degrees of endemism. Such islands commonly are important refugia for species of high conservation value. Some of the most pervasive and potent of invasive animal species are birds of the myna (*Acridotheres*) and bulbul (*Pycnonotus*) genera that historically were introduced to isolated islands as biological control agents for the management of insect pest species that can cause considerable economic damage to agricultural crops and wider ecosystems. In this paper we consider a number of 'successful' eradication and control programmes targeting mynas and bulbuls. We review the locations and taxa where 17 such programmes took place and report that the common myna *(Acridotheres tristis)* has been the most heavily targeted species in eradication efforts followed by the red-whiskered bulbul *(Pycnonotus jocosus)*. Common mynas were also at the focus of control programmes as were jungle mynas *(Acridotheres fuscus)* and red-vented bulbuls *(Pycnonotus cafer)*. By far the most favoured method of eradication and control was trapping whereas mist-netting was employed rarely. We discuss 'best practice' in planning and executing such eradication and control programmes on oceanic islands so as to maximise their benefits to local human communities. We outline measures that must be adopted pre-, during and post-intervention in both programme types. They include adequate resourcing, local engagement and the integration of both traditional ecological knowledge and established conservation theory.

Keywords: engagement, ethno-ornithology, invasive bird management, local community, multispecies approach

INTRODUCTION

The modern world is experiencing unprecedented anthropogenic inputs that are resulting in the sixth global wildlife extinction (Foley, et al., 2013) with concomitant phenomena such as accelerating climate change (Crowley, 2000) and increased frequencies of invasions of alien species (Vitousek, et al., 1997; Dukes & Mooney, 1999), resulting in losses of biodiversity (Lowe, et al., 2000).

The establishment of early human societies resulted in the trade of goods and services (Zeder, 2008), and the accompanying development of transport modes and infrastructure, such as roads and other trading routes, resulted in commodities traded over greater distances (Earle, 1994). Inevitably, this resulted in the movement of species out of their native ranges into areas where they were alien (exotic). Today, we continue to trade goods and services internationally and in so doing we move thousands of exotic species, approximately 10% of which will become established as invasive (Williamson & Fitter, 1996; Westphal, et al., 2008). By definition, an alien species occurs outside of its natural (past or present) range and it has dispersal potential, including any part of it (e.g. propagules, gametes) surviving and subsequently reproducing (Lowe, et al., 2000). Invasive species are targeted for conservation actions because they are alien species that become established in natural or semi-natural ecosystems or habitats where they present problems to native species (Colautti & MacIsaac, 2004). The impacts of avian invasive species on ecosystems are pervasive and enduring; they include, for example, competitive exclusion and predation of native species, disease transmission and dilution of native gene pools through hybridisation (reviewed in Blackburn, et al., 2009).

Oceanic islands are known to be more susceptible to negative impacts of exotic species compared with continental land masses because of their increased endemism as a result of their geographical isolation (Coblentz, 1990; Reaser, et al., 2007; Feare, 2017). Furthermore, their ecological fragility is magnified on smaller islands that accommodate more simple native ecological communities than larger ones (Donlan & Wilcox, 2008). Therefore, conservation priorities for insular environments are often defined by the need for effective eradication and/or control programmes of invasive species (e.g. Dulloo, et al., 2002; Donlan & Wilcox, 2008).

In this study we focus on two invasive avian genera (i.e. mynas *Acridotheres* and bulbuls *Pycnonotus*), consisting of six different species. These two genera are both represented on the list of '100 of the World's Worst Invasive Alien Species' (Lowe, et al., 2000), a subset of the Global Invasive Species Database, by common mynas (*Acridotheres tristis*) and red-whiskered bulbuls (*Pycnonotus jocosus*). The 18th and 19th centuries saw a series of introductions of mynas to oceanic islands as biocontrol agents to counter insect pests that threatened agricultural production. They were also transported to oceanic islands as cage birds. On Tutuila in American Samoa, for example, common mynas arrived in 1980 and jungle mynas (*Acridotheres fuscus*) in 1985 (SSC, unpubl. data) while on Ascension Island (Hughes, et al., 2017) and St Helena (Burns, 2011) they were introduced in the 19th century. Bulbuls were kept widely as caged birds but escaped captivity on islands such as Tahiti in 1925, Assumption in the 1970s and Tenerife and Fuerteventura at the turn of the 21st century.

The aim of our study is to provide an account of the characteristics of successful eradication and control programmes and then to discuss how they can be used to define 'best practice'. Through material presented in the discussion, we indicate how the conservation community can take effective measures to combat avian invasive species on remote oceanic islands.

METHODS

We used the following keywords – 'common myna', 'bulbul', '*Acridotheres*', '*Pycnonotus*', 'trapping', 'control', 'shooting', 'island*', and 'eradication' – in searches of several bibliographic databases including Webspire, Web

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 302–308. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

of Knowledge, Ovid SP, Inist, Blackwell Publishing and Science Direct to identify primary scientific literature about management programmes for avian invasive species on islands. References in literature cited/bibliography sections of the resulting sources were also considered for inclusion in our study. Whether programmes were considered further as successful eradications or controls, or rejected followed correspondence with programme managers to obtain further details about the interventions (Table 1). At the time of writing all programme managers have been contacted and we have received responses from all but one of them. Following inclusion in the study, the information obtained from these programme managers combined with that in publications was examined to assess a number of factors determining the effectiveness of programmes: the target species; and the numbers of birds of each species and the methods used as part of the intervention.

RESULTS

Literature searches

We did not consider every programme where eradication or control of avian invasive species had been attempted because after apparently successful removal of invasive birds, they reappeared on some islands (Table 1). The publications that were not considered further are detailed in Table 2. Following exclusions of these published studies we were left with 17 programmes (Table 3); their locations are shown in Fig. 1.

Invasive species targeted

Common mynas have been successfully eradicated from eight islands (Tenerife, Gran Canaria, Mallorca, Fuerteventura, Fregate, Denis, Tarawa and Atiu), and red-whiskered bulbuls from two islands (Tenerife and Assumption; Table 4). Control efforts targeting common mynas are ongoing on North Island in Seychelles (Table 4). Short-term isolated control programmes targeting common mynas were carried out twice on Ascension Island and once on St Helena, each being conducted in late 2009 (Table 4). An ongoing project on Tahiti is carrying out long-term control of common mynas and red-vented bulbuls (*Pycnonotus cafer*). In the Tarawa eradication two *Acridotheres* species were targeted and they were the common myna and the jungle myna. The only multi-species long-term control programme running today is in American Samoa where the two aforementioned myna species and the red-vented bulbul are being successfully targeted through trapping, with approximately 9,600 birds being captured in two consecutive trapping campaigns.

Total numbers of birds of each species by island

Table 4 provides details of the numbers of birds of each species that have been targets of population eradication and control programmes in the 17 projects (see also Table 3). In total, over 57,000 invasive birds have been captured. With ongoing projects such as the work on, for example, Tahiti and Tutuila (long-term control programmes) and North Island (an eradication programme), numbers are predicted to climb steeply in the near future. The vast majority of birds were common mynas and most were captured in Atiu in the Cook Islands (officially 'eradicated' but one remaining bird currently being tracked; SSC, unpubl. data), and on Tahiti in the control programme (Table 4). All but one of the 4,606 jungle mynas were caught in the ongoing control programme on Tutuila. The majority of red-whiskered bulbuls were caught as part of the eradication programme on Assumption, while most red-vented bulbuls were caught in the control programme on Tahiti (Table 4).

Table 1 Inclusive sets of categorisation criteria that allowed us to exclude (reject) or include published studies as successful eradication and control programmes targeting avian invasive species on oceanic islands as a result of questioning programme managers (see Methods for further details).

Reject	Eradication	Control
Birds were present as of April 2017	Birds were absent as of April 2017	Birds were present as of April 2017
No post-intervention monitoring	Post-intervention monitoring found no birds	Post-intervention monitoring found reproductive birds
No defined milestones during intervention	Defined milestones during intervention	Defined milestones during intervention
Pathways of invasion remain open	Pathways of invasion closed	Pathways of invasion remain open
No defined period of quarantine	Defined period of quarantine	No defined period of quarantine

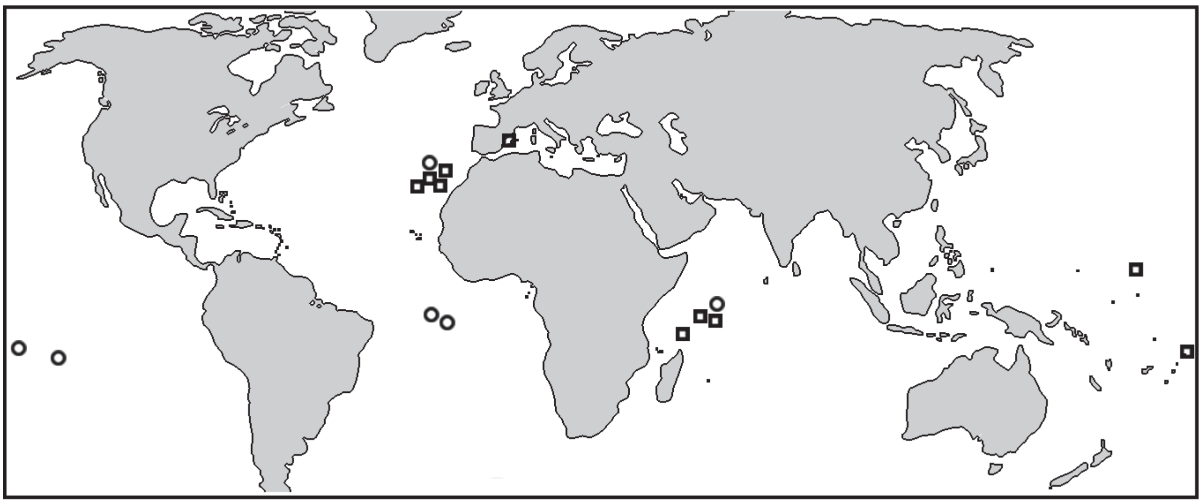

Fig. 1 Locations of islands where eradication (square symbols), and control (round symbols) programmes have been carried out to address problems of invasive myna and bulbul genera (see Tables 3 & 4 for further details).

Table 2 Details of eradication and control programmes on islands involving myna and bulbul genera, including the location, focal species, the number of birds eradicated/controlled (where known), and notes (including references) to explain why programmes were excluded from further consideration in our study.

Location	Species	No of birds	Notes (including references where available)
Ascension Island, Atlantic Ocean	Common myna *Acridotheres tristis*	40	Trapped birds were non-target species during feral domestic cat (*Felis silvestris catus*) removal in 2004 (Hughes, et al., 2008)
Seychelles, Indian Ocean	Common myna	-	Some birds remained after the eradication project ended (Canning, 2011). Eradication was abandoned when rats were discovered on site on Denis (Millett, et al., 2005)
Fakaofo (Tokelau), Pacific Ocean	Common myna	40	Birds targeted in 2006 with their egg and nest destruction resulting in no further sightings in 2011, but in early 2012 birds were seen on Nukunonu Atoll, 64 km north of Fakaofo (Parkes, 2012)
Western Samoa, Pacific Ocean	Bulbul *Pycnonotus* spp. and myna *Acridotheres* spp.	6,000	Feeding of ©DCR-1339 (3-chloro-p-toluidine hydrochloride) has been effective but to date no strategy to control avian invasive species has been formalised and consistently implemented island-wide
Mainland Australia	Common myna	>69,000	The Canberra Indian Myna Action Group (CIMAG) work, removing birds over 11 years using volunteer trappers, has taken place on a continental land mass and is of limited applicability to oceanic islands
Moturoa Island, Bay of Islands, New Zealand	Common myna	45	No detailed results were reported from trapping which has been criticised as an inappropriate method to control this species (Parkes, 2012)

Table 3 Island groups and islands where eradication and control programmes targeting myna and bulbul genera were carried out and the year when they ended and started, respectively.

Eradication			Control		
Island group	Island	Year	Island group	Island	Year

[a]Eradication of one target genus (i.e. red-whiskered bulbul) and one non-target genus (i.e. red fody *Foudia madagascariensis*) was achieved
[b]A control programme carried out by SSC by trapping
[c]A separate one carried out by C.J. Feare by poisoning, in the same year

Methods employed on projects

Methods used in eradication and control programmes included trapping, shooting, poisoning and mist-netting (Table 5). The method of choice for both programme types was live-trapping of invasive birds using live decoys and edible baits such as bread, fruit, pet food and tinned fish. Few programmes used shooting, with four out of five programmes employing firearms being conducted for population eradication purposes. Three out of the four programmes using poisoning were controlling (as opposed to eradicating) populations of invasive species. Only two eradication (but no control) programmes employed mist-netting to capture birds.

DISCUSSION

It was clear when we reviewed published studies and contacted programme managers that some programmes described as eradications should have been categorised as ongoing control programmes, according to our classification criteria outlined in Table 1. For those that did not carry out post-intervention monitoring, had not defined milestones during the intervention, had not identified invasion pathways or had not stipulated a period of quarantine post-intervention, we suggest that they should not be considered successful control programmes. We also request that programme managers consider carefully the contents of Table 1 as they plan and execute their intervention. Many studies were published before 2000 and they were unsuccessful in the case of eradication programmes because pathways of invasion were not closed and/or programme managers failed to remove all targeted birds (Tables 1 and 2). Remaining populations therefore recovered in numbers and, as a result, they expanded their ranges once again on islands. Such an example was provided by Millett, et al., (2005).

Table 4 Total number of mynas and bulbuls of six different invasive species caught on islands (see Table 3 for further details) as part of eradication and control programmes. Note that red-vented bulbul has been split into two subspecies – *cafer* and *bengalensis* – for historical reasons.

Island (year)	Invasive species (*A.*= *Acridotheres*; *P.*= *Pycnonotus*)					
	Common myna *A. tristis*	Jungle myna *A. fuscus*	*A.* hybrid	Red-whiskered bulbul *P. jocosus*	Red-vented bulbul *P. cafer cafer*	Red-vented bulbul *P. c. bengalensis*

Our empirical results document the species, the numbers of birds of each taxon and the methods employed during the targeting of birds in eradication and control programmes. It is clear that traps should be favoured to ‘capture’ invasive birds as we understand more about the biology of the target species and because trap design has markedly improved over recent years. From a practical perspective, the construction and establishment of traps on the ground are more preferable to applying continuously for permits from authorities on isolated islands to import and use firearms and poison. This said, national governmental agencies would be well advised to facilitate the use of complementary and effective management methods that can be combined with trapping to allow programme staff to progress invasive bird management on these islands and others in the future. As an example, the experience from Assumption suggests that combining mist-netting with shooting can result in removal of large numbers of red-whiskered bulbuls (now eradicated) and red fodies (*Foudia madagascariensis*).

As a result of considerations of both excluded (Table 2) and included studies (Tables 3 and 4) documenting eradication and control programmes, we briefly discuss below some of the fundamental considerations that should be undertaken in their future planning, execution and reporting. The outcome should be the adoption of processes that lead to best practice in managing invasive bird populations on oceanic islands.

Community engagement

Many programme managers historically argued that it was impossible to rely on local people to instigate actions on the ground, to remain committed to the programme and thus to constitute the main task force addressing the problems posed by the invasive species, as the programme will be destined to fail because of local apathy (SSC, pers. obs.). Nowadays, programme managers often assume that the programme’s aims will thrive mediated by the locals’ sense of community and shared aspirations for the programme. Success comes through the development of simple ‘tools’ that can be employed by the local community to manage invasive species for the benefit of the whole community. While people who want to become volunteers (whether trapping or otherwise) in any invasive species management programme have their own motivations for doing so, the success of any such intervention lies in the effective coordination of human power directed towards an achievable and beneficial community goal. This sustains commitment to the programme, especially from the community itself.

A successful programme will not only engage with the local community but also with wider audiences, requiring widespread availability of well-designed and well-delivered education campaigns, and comprehensive media coverage. The Canberra Indian Myna Action Group (CIMAG) provides an excellent example (albeit a mainland one) of a society-driven movement of volunteer

community trappers that has removed >69,000 common mynas and 8,900 common starlings (*Sturnus vulgaris*) through trapping over the last 11 years (CIMAG, pers. comm.). Their programme started in 2006 and it has achieved unprecedented successes in controlling birds on a continental scale, thereby demonstrating the effectiveness of well-coordinated volunteer efforts. Invasive birds have been managed effectively on Tahiti for the last seven years and on Tutuila for nearly the last three years.

Programme resourcing

We make a few general points about resourcing, based upon experiences of SSC gained from the control programme carried out on Tahiti in 2012 (Tables 3 and 4). This programme was driven by the need for urgent conservation action to promote the survival of the critically endangered Tahiti monarch (*Pomarea nigra*) (Blanvillain, et al., 2003; Ghestemme, 2011). It was a success because the programme engaged fully with the local community, and maintained high levels of motivation among local community members by sustaining frequent and dynamic communication between the local community and the programme's management team. It provided many insights that could be transferred to other such programmes. Contractors should provide an upfront realistic budget to meet the costs incurred in mobilising materials and having personnel in post at the start of actions on the ground. Mobilisation requires transport logistics, appropriate personnel to be available and fuel costs to be met at the start of the programme. Materials can include components for trap construction, mist-nets and their associated poles, firearms and ammunition, bait stations, bait and poisons, and storage facilities. Often equipment like traps has been used for centuries but knowledge about the appropriate deployment of them has been lost trans-generationally. Money spent on re-education and re-training to address the deployment of single traps and of coordinated networks of traps is particularly well received, especially in locations such as the Pacific islands (SSC, pers. obs.) where remote communities rely upon subsistence agriculture for food security and invasive bird species in part threaten their very existence.

There are costs associated with employing appropriate (i.e. informed) staff on such programmes (e.g. advertising, interviewing) and submitting applications for permits to relevant on- or off-island authorities for activities such as the use of mist-nets and traps, the handling of hazardous chemicals and the safe disposal of managed birds. Funding is also needed to maintain surveillance efforts to ensure that invasive birds have not returned (eradication programmes) or exist in low numbers as a result of sustained trapping efforts (control programmes).

Perceptions of invasive (and native) species

In many locations outside of their native ranges invasive species may be the first birds that locals observe and become familiar with (CIMAG, pers. comm.; SSC, pers. obs.). Their overwhelming presence can result in native species becoming 'invisible' in local communities both in terms of reduced numbers of birds on the ground and a loss of natural history knowledge through education and personal experiences. This erosion of so-called 'traditional ecological knowledge' (TEK) is a widespread phenomenon (Sinclair, et al., 2010) and is not just restricted to remote oceanic islands. Children often tend to consider invasive species as 'normal' because they observe them constantly throughout their formative years. In local community-based management projects, public awareness of native species for aesthetic, as well as ecosystem service, benefits is crucial in gaining public support, resulting in potent public engagement with invasive eradication and control programmes. Local people become highly motivated rapidly, especially if provided with effective management 'tools' to control invasive bird species. The challenge to the conservation manager is to promote native species' survival as a positive outcome of effective invasive species management in addition to other benefits to the local community. Whether this generates a conservation ethic in local peoples beyond that of their livelihoods remains aspirational but realistic, given experiences of SSC in the last seven years of control in Tahiti and three years in Tutuila.

Expertise networks

If invasive species are to be targeted successfully we must develop networks of expertise that are constituted not just by species experts (e.g. invasive species managers, professional ornithologists, avian pest controllers), but also by local experts who have developed detailed knowledge of the target species on the ground after training. Networks can thereby provide a detailed knowledge of the species' biological traits such as flocking patterns (Sinu, 2011), responses to novel foods (Martin & Fitzgerald, 2005), changes in food preference in relation to their location in their distributional range (Liebl & Martin, 2014), and trap shyness (Camacho, et al., 2017). For example, common mynas can be trapped for long periods of time without developing 'trap shyness' (SSC, pers. obs.), but only if trappers follow the recommended protocols.

Usually, local people have some biological knowledge of targeted invasive species, but on rare occasions some have detailed local knowledge about birds. All such knowledge can be obtained from full engagement with the local community who may have attempted eradication and control methods albeit in an uncoordinated manner that invariably results in unsuccessful outcomes. Knowledge can relate to where birds roost, favoured routes between roost and foraging sites, where they drink, their preferred foods and even how they behave in response to presentation of novel foods (e.g. Lermite, et al., 2017, SSC, pers. obs.). In some cases, ethno-ornithological knowledge (Tidemann & Gosler, 2010) could prove to be fundamental in the successful deployment of methods on the ground but to the best of our knowledge it has failed to inform eradication and control programmes to date.

Creating and sustaining networks of trappers on single islands and on chains of islands are fundamental in targeting high numbers of birds to be removed. Full engagement in terms of commitment and motivation by programme managers is key to retaining network integrity. Communication is the principal way to enlist assistance from trap builders and volunteer trappers, to inform the island population, to recruit local people to the programme, to educate the community about its benefits, and to update local people about the results of the programme to date. It is not just the general public that needs to be updated but, just as importantly, members of the trapper network itself. Sharing positive results from the ongoing programme motivates everyone and if a problem in the network is described in sufficient detail, a solution can be found rapidly because of shared experience and capacity in problem solving. Of course, a sustained line of communication also engages with stakeholders beyond the programme's location such as international agencies who might be partially funding the work.

The reality of most programmes is that training of staff takes the form of native biodiversity conservation but that of volunteers is focussed on local habitat protection, whether cash crop, farmland or otherwise. The practical training to build and deploy traps should be similar for both of the above groups, but is often viewed as being less exigent for volunteers. However, if local people are trained in partnership with programme staff through an established expertise network, often trap design and deployment can

be improved through inputs of local knowledge (Tidemann & Gosler, 2010). Part of such training should include emphasising the importance of record keeping. Recording data is key to a programme's success but can sometimes be problematic when carried out by local trappers without an appreciation for its importance. The transmission of data between trappers, programme managers and their staff can result in the loss of data when resources such as standardised datasheets, time, computer hardware and software etc. are lacking. Data collection should run smoothly with full commitment of participants on such programmes if training has been effective and expertise networks are maintained.

What constitutes best practice in control and eradication programmes targeted at invasive bird populations on oceanic islands?

To conclude, we refer the reader to Table 6 where we summarise the main attributes of effective control and eradication programmes. These attributes should be considered alongside others that we have discussed in this study. In conclusion, we have provided an account of the most common invasive avian species that have been targets for conservation action on oceanic islands where they threaten native species and the livelihoods of local human communities. Mynas and bulbuls still pose major threats to local economies and to native biodiversity, and we must find ways to plan and execute their eradication and control that engage with local communities while guaranteeing that programme outcomes are attained. Above, we have discussed effective planning through full engagement with and between the local community, programme managers and team members (whether volunteers or otherwise) to capacity build through education and training. This results in the construction and maintenance of expertise networks that are built on the ideas of local people, harnessing their local knowledge about the target species and on an appreciation of the benefits of the proposed actions to the local community. Executing plans involves coordinated action on the ground between programme managers, their staff and local volunteers that arises from sustained communication and motivation in meeting all of the programme's goals. Success involves far more than simply providing financial resources to cover various elements of a programme. If we were to propose one overarching recommendation it would be that programmes share information using standardised reporting protocols as everyone strives to adopt best practice.

ACKNOWLEDGEMENTS

We thank all of the programme managers who have so kindly answered our queries relating to finer details of their work. Their names are withheld because of the sensitivities surrounding such invasive species management. Félix M. Medina and two anonymous referees provided helpful comments that significantly improved the manuscript. We extend a special thanks to the Editor of the conference proceedings for his patience and encouragement as the manuscript was prepared for submission.

Abstract New Caledonia is a tropical archipelago of the South Pacific Ocean, and is one of the 36 world biodiversity hotspots. However, its unique biodiversity is increasingly threatened by habitat fragmentation and introductions of invasive alien species. Among these invaders, the red-vented bulbul (*Pycnonotus cafer*) is currently expanding towards the north of the main island. This passerine features in the IUCN-ISSG list of the 100 worst invasive species of the world because of impacts caused by its diet. Thirty-five years after its introduction, we present an overview of data from recent studies conducted in New Caledonia that describe the local status of the red-vented bulbul, its range expansion, and potential impacts on both the local biodiversity and agriculture. Biannual monitoring of the distribution coupled with surveillance at the edges of native forests highlighted a tight association of the bulbul with man-modified habitats. Using a distance sampling method, we estimated that bulbul densities within the distribution core varied from a peak of 200 individuals/km^2 in the main city of Nouméa, where the species has been introduced, to 30 individuals/km^2 in rural habitats located 50 km away from Nouméa. We conducted a diet analysis on 40 bulbul corpses and found that 82% and 55% of individuals had consumed plant and animal items, respectively. We identified plant and insect species that may be of concern in the contexts of seed dispersal and predation by the red-vented bulbul. Finally, a food colour selection experiment and an open field test showed that the red-vented bulbul had a significant preference for red and sweet fruits. We estimated the economic loss caused by bulbuls to a tomato grower and discuss the result with respect to the development of an adapted management strategy, to prevent further impacts of the red-vented bulbul on the biodiversity and agriculture in the tropical island hotspot of New Caledonia.

Keywords: density, diet, distribution, impacts, invasive bird, *Pycnonotus cafer*

INTRODUCTION

New Caledonia is a tropical archipelago located to the east of Australia, in the SouthPacific Ocean. The archipelago has been classified as one of the world's 36 biodiversity hotspots because of its high levels of endemism in such a small territory (Williams, et al., 2011). Among notable features of local biodiversity in New Caledonia, Myers, et al. (2000) highlighted five endemic families and 112 endemic genera of plants, and one endemic family and three endemic genera of birds. However, a significant proportion of this biological richness is increasingly threatened by human activities and global changes, as is the case for most of the world's biodiversity hotspots (Bellard, et al., 2014). Among factors that foster these changes, habitat fragmentation and climate change are widely recognized (Garcia, et al., 2014; Haddad, et al., 2015), although the best response from scientists and managers to species' introductions is still a matter of debate (Russell & Blackburn, 2017; Davis & Chew, 2017).

The effects of invasive species have been widely documented (Early, et al., 2016). Impacts are accentuated in island ecosystems (Russell, et al., 2017), often because of the naivety of insular species (Gerard, et al., 2016) and environmental, ecological and evolutionary factors associated with geographic isolation (Cabral, et al., 2017). Humans play a key role in the transportation of plant and animal species worldwide (Ricciardi, et al., 2017). Trade in animals (Cardador, et al., 2017; Su, et al., 2016) and the release or escape of cage birds are frequently identified as the main mechanisms for alien bird introductions and the dispersal of wild birds outside of their native ranges (Dyer, et al., 2017).

Tropical bird species, particularly those from South-east Asia, occupy an important place in global bird trade (Nijman, 2010), with bulbuls, starlings, mynas and robins figuring amongst the most traded species from this region (Harris, et al., 2015). As a result, two out of three species considered in the IUCN-ISSG list of 100 worst invasive species are native to Southern Asia: the red-vented bulbul (*Pycnonotus cafer*) and the common myna (*Acridotheres tristis*) (Lowe, et al., 2000). These two species historically were widely transported from India to Pacific Islands (Watling, 1978) and both are now established in New Caledonia (Brochier, et al., 2010). Our global review on the impact and management of alien red-vented bulbuls identified 37 islands in the alien distribution of this species (Thibault, et al., 2018a). This study also highlighted the lack of quantitative data and evidence-based assessments of the impacts associated with this invasive species. The red-vented bulbul was introduced into New Caledonia in 1983 (Gill, et al., 1995) and its local distribution range is currently expanding from Nouméa toward the north and south of the main island. For 25 years following its introduction into Nouméa, no studies were conducted to investigate the ecology, distribution or impacts of the species at a local scale. This lack of information has precluded any detailed assessment of the threats posed by the establishment of the red-vented bulbul in New Caledonia. Consequently, it has not thus far been possible to implement an evidence-based management strategy.

The goal of this paper is to present an overview of data from recent studies conducted in New Caledonia to describe the local status of the red-vented bulbul, its

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 309–316. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

range expansion, and potential impacts on both the local biodiversity and agriculture. We firstly report the local distribution range of the species, the rate and nature of its range expansion, and its habitat selection and densities in different habitats. We then use diet analysis to explore potential negative effects of the red-vented bulbul on natural and agricultural systems. We present original data on an ongoing invasion process in a tropical island biodiversity hotspot and highlight priority areas for local red-vented bulbul research and risk management.

METHODS

Red-vented bulbul range expansion

Red-vented bulbul dispersal was monitored over time using static 10-min point counts combined with 2-min playback of recorded calls to increase detection probability (Ralph, et al., 1995). Points were sampled within the four hours following sunrise, between November and December in 2008, 2012, 2014 and 2016. Each point was geo-referenced, and the observers accounted for seen and heard individuals. In 2008, 136 points were sampled that covered Nouméa and suburbs as well as borders of the two main roads going to the north and south. Random points were also located in major urban areas along these roads to search for potential pioneering individuals. The method was replicated in 2012, 2014 and 2016, covering 203, 96 and 99 points respectively. Data were compiled and plotted in Qgis software version 2.18.1 (Quantum GIS Development Team, 2016).

In April 2016, we selected six additional sites across native and man-modified habitats to explore the future establishment of the red-vented bulbul in forests. We chose three sites across urban and dry forest habitats, and three across urban and wet forest habitats. These sites were located close to the core of the distribution range, where red-vented bulbul densities were highest. We placed 10 points spaced at least 250 m apart at each site (five points per habitat) and counted red-vented bulbul individuals seen and heard. The method used was the same as for distribution monitoring. Data were compiled in Qgis software version 2.18.1 (Quantum GIS Development Team, 2016) and plotted in R software version 3.4.0 (R Core Team, 2017).

Red-vented bulbul densities

Red-vented bulbul density was measured using a distance sampling method (Thomas, et al., 2010) in four sites located within the core of the red-vented bulbul distribution range. This method relies on three key assumptions: i) individuals at zero metres distance are detected with certainty, ii) individuals are detected once and at their initial location, and iii) distance measurements are exact.

Sites were selected in man-modified habitats, along a distance gradient from Nouméa to Tomo, a village located about 50 km farther north. Three transects of 1 km were established at each site and sampled between October and December 2015. A pair of observers walked along each transect for 30 minutes and counted the number of individuals seen on both sides. The distance of observed individuals from each transect was recorded with a laser telemeter. Transects were sampled three times between 0500 and 0900 hours and data from the three sessions were used independently and pooled to prevent a potential bias due to time of day.

Data were analysed with the "Distance" package (Miller, 2016) using R software version 3.4.0 (R Core Team, 2017). This method considers potential missed observations in the estimated bird densities thanks to the calculation of a detection probability curve. We first estimated the bird density at each site using data from the three sessions separately. Then, we estimated densities at each site using data of the three sessions together, considering the nine transects at each site as independent. Finally, we chose to present the estimates from the pooled dataset as it provided a smoothed estimation of densities regarding the influence of time of day on bird detection.

Red-vented bulbul diet analysis

Gut content analysis was conducted on 40 dead red-vented bulbuls provided by local hunters. There is no morphological dimorphism between male and female red-vented bulbul, so we were only able to determine the sex of sexually mature individuals, using anatomical analysis. Gastrointestinal tracts were excised and the contents removed and washed with tap water through a 0.2 mm sieve. The retained contents were placed in a Petri dish filled with 70% alcohol and examined under a dissecting microscope at 10× magnification (Olympus SZ61). Items were photographed (Toupcam UCMOS camera and Toupview software) for subsequent identification (Lopes, et al., 2005).

Fruit colour selection

According to the literature, damage to cultivated plants is the most frequently reported impact of the red-vented bulbul in its alien range (Thibault, et al., 2018a). This is also the impact category most often reported locally both by professionals (Caplong & Barjon, 2010) and non-professionals. We tackled this issue through two distinct experiments, a colour preference test and an open-field test.

We conducted an experiment on fruit colour selection to test whether the red-vented bulbul was attracted by some fruit colours more than others. We trapped eight adult individuals, maintained them in an aviary for at least a month, and in individual cages for three days. We created false-coloured fruits of four distinct colours, following the method presented in Duan & Quan, (2013). Artificial fruits were made of banana, chicken grain and water, and three quarters of the fruits were coloured with red, green and yellow food colouring. Ten fruits of each colour were placed in four different petri dishes in cages with bulbuls held individually and observed for 25 minutes from a hidden position. Each bird was tested once during five consecutive days, following either two hours or six hours of fasting. For each repetition, the colour of the first fruit eaten as well as the total number of fruit eaten per colour were recorded. ANOVA tests were conducted in R software version 3.4.0 (R Core Team, 2017) with hypothesis H0 being that each fruit colour had the same probability of being eaten first.

Damage to crops

In 2016, we conducted an open field test to explore the range of damage caused by red-vented bulbuls to tomato crops. We planted eight tomato plants inside each of 20 square plots spaced by one metre, and randomly covered half of the plots with bird netting during the flowering stage. During the fruiting period in August and September, each plot was monitored twice a week. Ripe and damaged fruit were harvested and separated in three categories; i) marketable; ii) pecked fruits; and iii) other damage. For each category, the colour, size, and sugar levels (in Brix degrees; Bates, 1942) of fruit were recorded. Tomatoes that were pecked by the birds were easily recognizable by beak marks, and the mark's size together with direct observations were used to determine the fruits that were damaged by red-vented bulbuls. The relative economic loss in marketable tomatoes due to bulbul damage was then calculated as the total weight of pecked tomatoes divided by the total weight of tomatoes harvested in 'unprotected plots'. This percentage was then extrapolated to the national production recorded during the month of our experiment. Data were analysed with the "nlme" package (Pinheiro, et al., 2017) using in R software version 3.4.0 (R Core Team, 2017).

RESULTS

Red-vented bulbul range expansion

The 2008–2016 red-vented bulbul biannual distribution map (Fig. 1) shows a continuous increase in the distribution range occupied by the red-vented bulbul in New Caledonia. Coloured polygons contain all points where red-vented bulbul individuals were observed in 2008, 2012, 2014 and 2016. Conversely, green dots represent all points where red-vented bulbul were not detected either during point-counts or during playback calls. The green triangles and diamonds represent, respectively, absence points located in natural dry forest patches within the city of Nouméa, and in humid forest, which represents the northern border of the capital and its suburbs. This absence data suggests that the species is not yet spreading into natural forest. Indeed, over the 60 point counts conducted at frontiers between urban and forest habitats, we detected red-vented bulbul individuals at 16 points in urban habitats and one point in dry forest habitat. We also received testimonies from local people about red-vented bulbul sightings. These testimonies were rarely confirmed by further observations but sometimes led to new detections. Figure 1 shows a continuous distribution of the red-vented bulbuls with range expansion particularly along main roads. It also presents absence data from another study (Thibault, et al., 2018b) which are consistent with this hypothesis. The two road axes from Nouméa to La Foa (100 km north) and Yaté (95 km south) appeared to be the main dispersal pathways. In 2012, 25 years after its introduction in the city of Nouméa, the red-vented bulbul had reached Tontouta, 42 kilometres north. From 2012 to 2016 the species travelled 35 kilometres north (Fig. 2). Nowadays the red-vented bulbul occupies at least 1,350 km^2 (8% of the New Caledonia territory), mostly restricted to the west coast of the southern province.

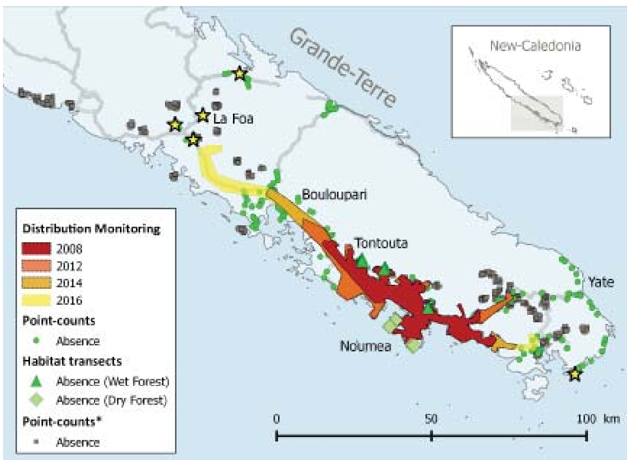

Fig. 1 Map of the expanding distribution of the red-vented bulbul between 2008 and 2016 according to the biannual monitoring. Stars represent observations from local people. Green dots represent point absence data (point counts) from the distribution monitoring. Green triangles and diamonds represent absence data (point counts along transects) in natural forests surrounding the distribution core. Grey dots show absence data (point counts) from another study (Thibault, et al., 2018b).

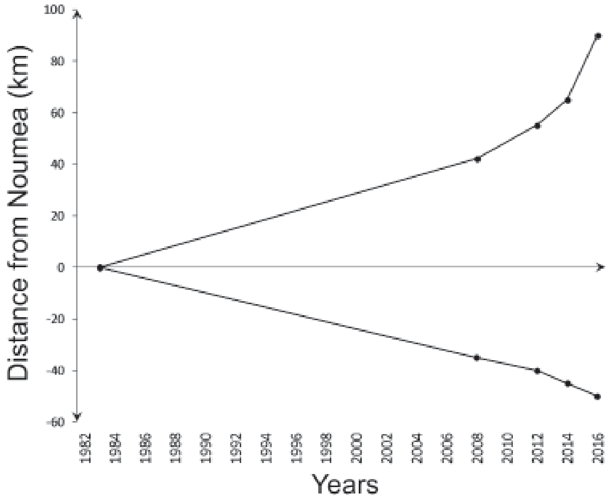

Fig. 2 Rate of red-vented bulbul dispersal toward the North and South of Nouméa.

Red-vented bulbul densities

Most birds were both heard and seen during our sampling sessions in inhabited areas. We fitted our data to a half-normal distribution (Thomas, et al., 2010) to calculate the detection function (Fig. 3**)**. Density estimates from the three sessions and from the pooled data set are presented in Fig. 4. Red-vented bulbul estimated density was six times higher in the city of Nouméa (*d*: 204 ± 23 individuals/km^2) than in the village of Tomo which is located 50 kilometres north (*d*: 31 ± 11 individuals/km^2, Table 1). Estimates from the two suburban areas, Robinson and Paita, were almost identical (*d*: 160 ± 32 individuals/km^2 and *d*: 131 ± 18 individuals/km^2, respectively). The density estimates are corrected by a detection function curve which represents the probability of an observer detecting a red-vented bulbul depending on its distance from the transect. In the four urban habitats we sampled, the average probability of detecting a red-vented bulbul was 50% when the bird was approximately 25 metres from the observer.

Red-vented bulbul diet analysis

We extracted and analysed the gut contents of 40 red-vented bulbuls. Results of the diet study are presented in

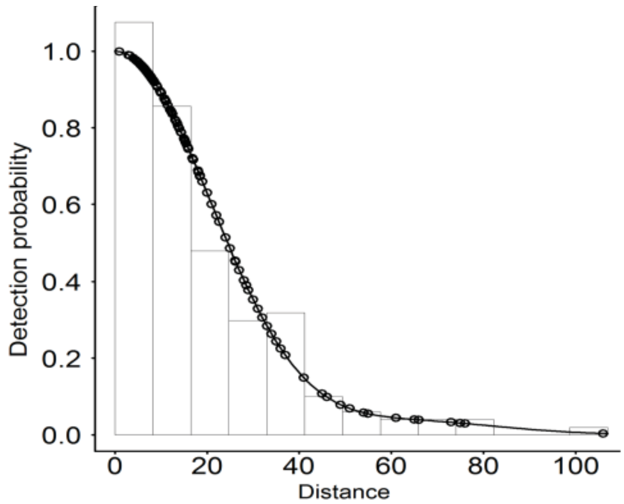

Fig. 3 Probability of detecting a red-vented bulbul individual as a function of distance from the transect in inhabited areas.

Table 1 Sampling statistics and density estimates at four urban sites within the current distribution range of the red-vented bulbuls according to distance from the introduction point. (n) total number of individuals over the three sessions.

Site	Distance (km)	Habitat	Area (m2)	n	Density estimate (ind/km2)	Standard error
Nouméa	0	urban	787.3	117	204	± 23
Paita	10	suburban	816.3	66	160	± 32
Robinson	25	suburban	492.8	65	131	± 18
Tomo	50	rural	993.3	15	31	± 11

Table 2 Occurrences (n) and frequency (%) of food items identified in the gut content of 40 bulbul individuals.

	n	F (n=40)
Fruit parts		
Whole fruit	16	40
Seeds	22	55
Fruit skin	7	17.5
Fruit flesh	17	42.5
Plant families	33	82.5
Myrtaceae	20	50
Passifloraceae	1	2.5
Sapindaceae	2	5
Solanaceae	4	10
Insects	22	55
Coleoptera	8	20
Diptera	1	2.5
Hemiptera	13	32.5
Hymenoptera	3	7.5
Odonata	1	2.5

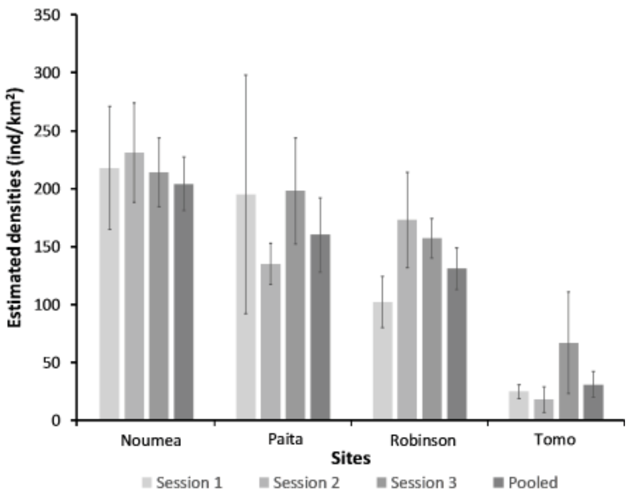

Fig. 4 Densities of red-vented bulbuls at each site calculated from the three sampling sessions, and from the pooled dataset.

Table 2. Mean weight of mature individuals was 38.3 ± 4.9 g for females and 44.1 ± 5.6 g for males. We found plant remains in the gut content of 33 individuals (82.5%) and animal items in 22 (55%). Among plant items, seeds (55%) and fruit flesh (42.5%) were the most frequent. The most frequent plant family was Myrtaceae (20 individuals), and the most consumed insect orders were Hemiptera (13 individuals) and Coleoptera (8 individuals). Identification of the remains highlighted the consumption of one endemic plant species (*Myrtastrum rufopunctatum*), two cultivated species (*Syzygium cumini* and *Lichi chinensis*) and two invasive alien species (*Passiflora foetida* and *Solanum torvum).* Exoskeleton parts from cicada individuals were frequent in this sample (F=32.5%). No vertebrate remains were found during this analysis.

Fruit colour selection

Colour selection tests were replicated 102 times. The first pecked fruit was red in 77% of samples, followed by green (10% of samples). The average number of consumed fruits per colour is presented in Fig 5. Red fruits were the most often consumed (5 ± 0.3), and yellow ones were consumed five times less often (0.9 ± 0.16). Colour explained the consumption of fruits significantly (ANOVA: F: 8.3; p<0.001). In our analysis, fasting period did not contribute to explain the choice of coloured fruits (ANOVA: F: 2.7; p=0.1).

Damage to crops

On our 20 plots, we produced a total of 2,310 tomatoes (345.5 kg). Unfortunately, three plots with nets were damaged by feral dogs just before the beginning of the fruiting season, and were thus considered to be unprotected. Red-vented bulbuls were the only birds that fed on tomato fruit during the experiment. Results are presented in Fig 6. On average, production per plot was homogenous in net-protected pots (18.5 ± 2.1 kg) compared to 'unprotected' ones (16.6 ± 2.3 kg). Losses due to bird damage were recorded almost exclusively in 'unprotected' plots and corresponded to 2.95 ± 0.24 kg per plot (17.5%), as only three tomatoes were pecked at the edge of protected plots (0.5% in weight). These losses were similar to those caused by other pests: 2.63 ± 0.3 kg in unprotected plots, and 3.9 ± 0.3 kg in protected plots. Pecked fruits were mainly red (ANOVA F: 7.6; p=0.009), between 50 and 70 mm in size and with high sugar levels (5°Bx, ANOVA: 5.95; p=0.016). Considering that 34 tons of tomato were sold at 3.18 USD/kg in September 2016 in New Caledonia, the 17.5% loss we recorded because of bird damage would have corresponded to an economic loss of approximately $18,355 USD for September 2016 alone.

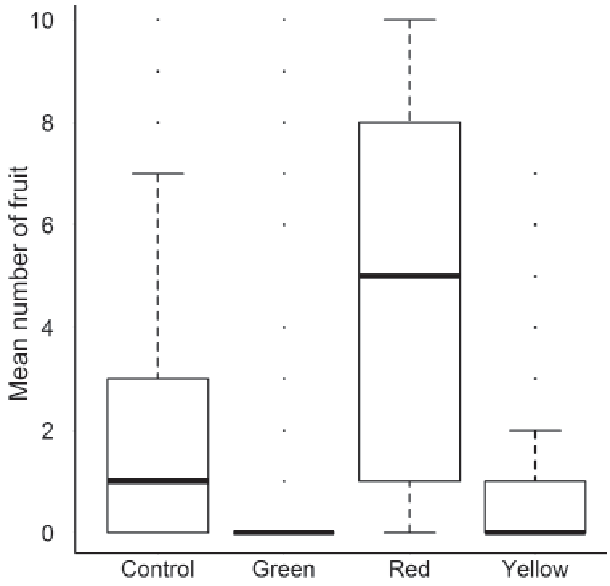

Fig. 5 Result of 102 colour preference tests with red-vented bulbuls. The y-axis represents the average number of fruits consumed by tested individuals during one session.

DISCUSSION

Dispersal along urban corridors

The red-vented bulbul has continuously increased its distribution range in New Caledonia since its introduction 25 years ago. The distribution map suggests that roads and urban habitats are the main dispersal pathways for the species. The dispersal rates we estimated were different depending on the direction. One reason for this may be differences in habitat to the north and south of Nouméa. The south of the main island of New Caledonia is dominated by ultramafic soils and the dominant vegetation type is the "maquis minier", a shrubland characterised by xerophytic plants (Jaffré, et al., 2003; Jaffré, et al., 2004) which may be less attractive in terms of food source for red-vented bulbuls. Considering the dispersal speed, we know that the red-vented bulbul's range expanded 40 kilometres toward the north of its introduction point in 25 years. Its range expansion then increased more quickly, extending a further 35 kilometres in just four years. This is consistent with findings of Aagaard & Lockwood (2014) on growth lag in alien bird populations and suggests that this range expansion could continue to accelerate. Our observation of a lagged expansion in the red-vented bulbul could thus be explained both by a demographic time-lag, inter-specific relationships, or by the carrying capacity of the different habitats.

Study of red-vented bulbul occurrence at the frontiers between urban and forest habitats confirmed the association of the species with man-modified habitats. Our results suggest that the red-vented bulbul is not spreading from invaded urban areas into either dry forest patches or into native rainforests. This is consistent with previous observations of Watling (1979) in Fiji. However, in Tahiti (French Polynesia) the red-vented bulbul is able to colonize native tropical forests with major impacts on native avifauna (Blanvillain, et al., 2003). Further monitoring of the distribution is thus crucial to anticipate potential shifts in the habitat occupancy and resulting threats on forest bird communities. A specific effort could be dedicated by managers to prevent future establishment of pioneer individuals out of the current range, toward the north, the Loyalty Islands or specific areas of high conservation/agricultural value. Quick detection coupled with control actions at the edges of the red-vented bulbul range will reduce the colonisation speed and prevent future negative effects.

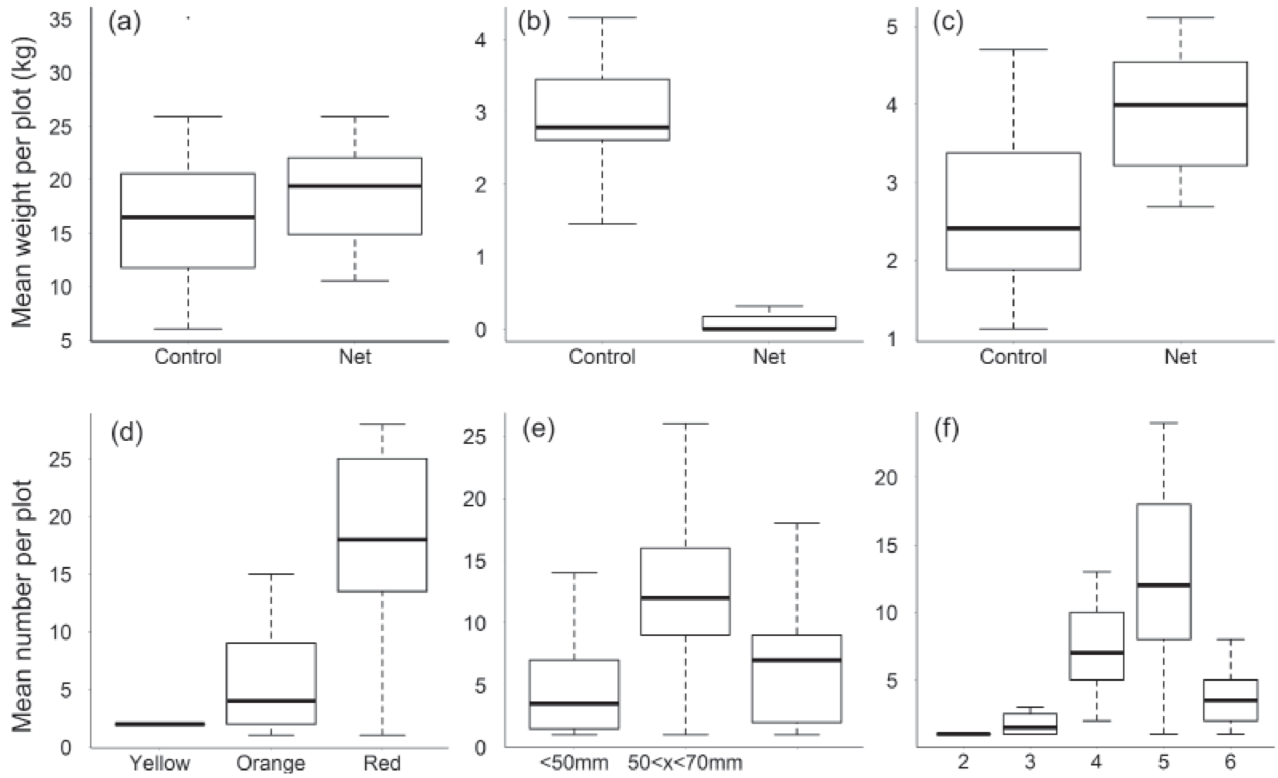

Fig. 6 Result of the open field test conducted with tomato plants. (a) Represents the global production weights for "net-protected" and "unprotected" treatments, (b) and (c) represent the mean weight of fruit damaged per plot by birds and other pests. (d), (e) and (f) represent the average number of damaged fruit depending on fruit colour, size, and sugar content, respectively.

Density gradient

Dispersal of bird species is partly related to population densities (Matthysen, 2005), so the anticipation of future dispersal events may be facilitated by the knowledge of bird density in specific locations. Our density estimates showed a density gradient in the red-vented bulbul, depending on the degree of urbanisation and the distance from the introduction point. This has been frequently observed in alien bird populations (Chace & Walsh, 2006). The density level we estimated in the rural village of Tomo was similar to those reported by Radhakrishanan & Asokan (2015) in two villages of the Cauvery delta region in Southern India, to which the red-vented bulbul is native. However, our estimates for the centre of Nouméa and suburbs are similar to those found for common bird species in European/American urban centres (Clergeau, et al., 1998). High bird densities in urban habitats are often associated with low bird-community species richness (Matthysen, 2005). Regarding its density, the red-vented bulbul is already a predominant species in Nouméa. Monitoring the change in red-vented bulbul densities over time will contribute to a better understanding of the species' dynamics. It will also allow the estimation of the density-impact relationship in further management programmes (Yokomizo, et al., 2009), as management of invasive alien species populations often relies on abundance/density reductions (Genovesi, 2005; Simberloff, et al., 2005). For example, control operations could be feasible at low densities, whereas mitigation of specific impacts could be more cost-efficient at high-density levels.

Predation and frugivory

Results of the diet analysis were consistent with previous observations elsewhere in both the alien and native range of the species (Watling, 1978; Bhatt & Kumar, 2001; Brooks, 2013 Bates, et al., 2014). The diet comprised mostly fruits and a significant part of animal remains. We observed several red-vented bulbul individuals feeding on house geckos (*Hemidactylus frenatus*) and skinks in the field, but we did not find any reptile or gastropod remains in the gut contents we analysed. Such food items have been reported in the red-vented bulbul native range (Bhatt & Kumar, 2001). Much of the gut contents we analysed (n=13, F=32.5%) contained remains from cicadas. Considering the periodic lifecycle of these insects (May, 1974), this observation suggests that red-vented bulbuls can adapt their diet to this temporary resource. Levels of endemism are high in New-Caledonia, with approximately 92% of reptiles and nearly 100% of cicadas (Smith, et al., 2007; Grandcolas, et al., 2008; Delorme, et al., 2016) being endemic. Predation by alien species such as the red-vented bulbul could thus represent an additional threat for these species of high conservation value.

Seeds and whole fruits were found in 50% of individuals. This observation emphasizes the red-vented bulbul's capacity to participate in seed dispersal, particularly in association with invasive alien plant species like *Miconia calvescens* or *Lantana camara* (Meyer, 1996; Spotswood, et al., 2012; Spotswood, et al., 2013). In our diet study, we identified several candidates for red-vented bulbul-mediated dispersal. Most of them were invasive or cultivated species, but we also identified one endemic (*Myrtastrum rufopunctatum*) that is used for mining-site restoration (Lemay, et al., 2009). Consumption of native species by the red-vented bulbul could result in a service, by improving the dispersal capacity of some species (Kawakami, et al., 2009). However, it can also lead to competitive interactions with native avifauna (Sherman & Fall, 2010; Thibault, et al., 2018b) which can turn into a conservation issue (Blanvillain, et al., 2003). New Caledonia is considered a biodiversity hotspot (Myers, et al., 2000) thanks to its plant diversity, with 3060 species of flowering plants recorded (78% endemic; Munzinger, et al., 2016). Exploring variations in the red-vented bulbul diet over different habitat, seasons and maturity stages will contribute to better prediction of the dispersal of both alien and native plants as well as potential negative interactions with endemic species. At a wider scale, such quantitative and qualitative data will contribute to the assessment of impacts caused by red-vented bulbuls (Thibault, et al., 2018a).

Colour selection and damages on crops

Diet and preference for specific resources plays a key role in impacts caused by vertebrate pest species (Herrero, et al., 2006; Gebhardt, et al., 2011). Sometimes, these preferences can be strong enough to aid bait selection for both hunters and environment managers. In our experiment, the red-vented bulbul preferred red, consistent with colour preference in the red-whiskered bulbul (*Pycnonotus jocosus*) (Duan & Quan, 2013). In a French Polynesian study, authors concluded that preference may sometimes be stronger than abundance in fruit selection by birds, including the red-vented bulbul (Spotswood, et al., 2013).

Such preference for specific fruits implies that red-vented bulbuls are likely to disperse or damage the fruit of some species more than others, and that predictions can be made about species that are likely to be most vulnerable. Observations made during our open field experiment were consistent with this hypothesis, with red tomatoes being damaged more than orange or yellow ones. In unprotected plots, damage caused by birds was equivalent to that of all the parasites and corresponded to 17.5% loss in weight of marketable fruit. This corresponds to the average losses presented in Oerke (2006) in their global estimation of economic losses due to animal pests over 11 production types including tomato, between 2001 and 2003. In this study, recorded losses attributed to animal species and other pathogens on unprotected crops were of 18% and 15%, respectively. Oerke suggested that pest control operations allowed a 39% reduction in losses due to animal pests. Here we showed that protecting tomato plants with nets efficiently protected 99% of fruits, reducing by 97% the loss in weight of marketable fruit. This early assessment of colour selection and damage on production suggests that red and sweet fruit/flower crops could be more sensitive to red-vented bulbul damages. Such information is already used in the development of trapping systems dedicated to this species. Indeed, fruit and fresh vegetables represented 5115 and 6292 tons, respectively, of production in New Caledonia in 2012, corresponding to 25% and 30% of the total plant production that year (ISEE, 2012). The red-vented bulbul is currently restricted to suburban areas in a limited range, but up to 35% loss has already been recorded on fruit production there (Caplong & Barjon, 2010). Future establishment of the species in cultivated areas of the main island could thus represent an additional risk to crop productivity.

CONCLUSION

The global distribution and population trends of red-vented bulbul have been poorly reported, relative to many other tropical invasive birds. The potential overlap in the impacts associated with tropical passerine species from south Asia, suggested by Kumschick et al. (2015), has not been explored either. Authors have claimed that introduced populations of red-vented bulbuls were harmless (Watling, 1979), while in other locations their role in noxious seed dispersal (Meyer, 1996), competition with native birds

(Blanvillain, et al., 2003, Thibault, et al., 2018b) and damage to crops (Walker, 2008) was suggested. New Caledonia must deal with the current dispersal of this species on its territory with only a few quantitative data available from the literature (Thibault, et al., 2018a). However, the establishment, on-going dispersal, and impacts of the red-vented bulbul deserve attention from conservation biologists, environment managers and local people. Perceptions of this invasive species differ across groups of people (Fischer, et al., 2014), but a coordinated joint effort is required to improve our knowledge of invasion mechanisms for the red-vented bulbul in the New Caledonia archipelago. New Caledonia recently produced a list of priority invasive species for management actions, and the studies we presented here contributed to the consideration of the red-vented bulbul among the six species on this list.

ACKNOWLEDGEMENTS

We thank Institut Agronomique Néo-Calédonien (IAC) staff members for their support in the field and their assistance in the determination of food remains. Thanks to M. Dubreuil, Y. Ititiaty, L. Bordez, V. Hecquet and H. Vandrot for the determination of plant remains. We thank L. Demaret for his contribution to the open field experiment. Thanks to N. Heurard-Cueato and P. Ajahpunya for their help in the field for the distribution monitoring and density estimations. We also thank the local hunters for their participation in the collection of red-vented bulbul cadavers. All the financial support was provided by IAC.

Population assessment of a novel island invasive: tegu (*Salvator merianae*) of Fernando de Noronha

C.R. Abrahão[1,2], J.C. Russell[3], J.C.R. Silva[4], F. Ferreira[2] and R.A. Dias[2]

[1]*National Center of Conservation of Reptiles and Amphibians, Instituto Chico Mendes de Conservação da Biodiversidade, Brazilian Ministry of Environment, Brazil. <carlos.abrahao@icmbio.gov.br>.* [2]*Laboratory of Epidemiology and Biostatistics, Department of Preventive Veterinary Medicine and Animal Health, School of Veterinary Medicine, University of São Paulo, Brazil.* [3]*School of Biological Sciences and Department of Statistics, University of Auckland, Private Bag 92019, Auckland, New Zealand.* [4]*Department of Veterinary Medicine, Federal Rural University of Pernambuco, Brazil.*

ABSTRACT Fernando de Noronha is an oceanic archipelago in the Atlantic Ocean, 345 km offshore from the Brazilian coast. It comprises 21 islands and islets, of which the main island (FN) is 17 km^2 with a rapidly growing tourism industry in the last decades. Despite being a protected area and bearing Ramsar and UNESCO World Heritage site status, it is threatened by multiple terrestrial invasive species since its colonisation in the early 16th century. Invasive species and the increasing tourism contributes to a list of at least 15 endangered or critically endangered species according to IUCN criteria. The black and white tegu (*Salvator merianae*) is the largest lizard in South America, occurring in most of the Brazilian territory and reaching up to 8 kg and 1.6 m from head to tail. As an omnivorous and opportunistic lizard, it feeds on a variety of available items, including smaller vertebrates and eggs. The introduction of the tegu to FN as well as its immediate impact on local fauna were not recorded; however, its ongoing impact is expected to be high. We captured and marked 103 tegu in FN during the months of February and November of 2015 and 2016. We also counted animals by line-transect census in a sparsely inhabited and an uninhabited area of FN. Body size affected the capture probabilities, while season and sex had little or no effect. Densities estimated by capture-recapture in the sparsely inhabited area varied from 2.29 to 8.28 animals/ha according to sampling season. Line transect census in the same area revealed a density of 3.98 (±1.1) animals/ha and in the uninhabited area 13.83 (±3.9) animals/ha. Home range was 10.54 ha, ranging from 7.36 to 15.33 hectares. Tegu activity decreased in the months of July and August of 2015. Results from this study can assist conservation managers and decision makers to implement a science-based tegu management programme in the future.

Keywords: conservation, invasive species, lizard, oceanic island, reptile, *Salvator*, Teiidae, *Tupinambis*

INTRODUCTION

Islands are simplified ecosystems where each species plays an important role in its functioning (Simberloff, 1974). In these environments, the loss of a species and its functional role are not easily replaced, as would be the case in more species-rich ecosystems such as on continents. Despite corresponding to only about 5% of land area globally, islands contain more than 15% of terrestrial biodiversity (Tershy, et al., 2015). A lack of certain behaviour or life-history traits makes native insular species more vulnerable to the impacts of invasive species (Vitousek, 1988; Tershy, et al., 2015).

Introduction of invasive species is one of the major causes of contemporary biodiversity loss (Vitousek, et al., 1997; Chapin, et al., 2000). On islands, it is probably the major cause (Veitch & Clout, 2002; Reaser, et al., 2007). Direct and indirect competition, predation and introduction of diseases are some of the negative influences that invasive species can bring to native populations (Wyatt, et al., 2008; McCreless, et al., 2016; Russell, et al., 2017). Invasive predators are implicated in at least 58% of the worldwide contemporary extinctions for birds, mammals and reptiles (Doherty, et al., 2016). The insular ecosystem frailty combined with invasive species results in islands bearing 37% of all critically endangered species and 61% of all recorded extinct species, according to the IUCN Red List (Tershy, et al., 2015). Furthermore, the impact of invasive species is not constrained to local biodiversity, but also affects the economy, agriculture, health and human culture (Russell, et al., 2017)

Some invasive species, such as rodents, are globally widespread and their impacts on islands have been well described (Reaser, et al., 2007; Russell, et al., 2017). However, some invasive predators are only found regionally or locally and their impacts and management are not fully understood (see Eales, et al., 2010; Powell, et al., 2011). Those less well-known species must not be overlooked, as their impact might be equal to, if not larger than, common widespread invaders (Phillips, et al., 2007; Simberloff, 2009; Dorcas, et al., 2012; Neves, et al., 2017; Russell, et al., 2017).

Fernando de Noronha

Fernando de Noronha archipelago consists of 21 islands and islets, 340 km offshore from the northeast Brazilian coast. The total land area of the archipelago is 18 km^2 where the main island, also called Fernando de Noronha (FN) is about 16.7 km^2. The archipelago is a UNESCO world heritage site (since 2001) and has recently been named as a Ramsar site. Fernando de Noronha archipelago is an important breeding site for several species of birds, sea turtles and reptiles, some endemic and threatened with extinction (Sazima & Haemig, 2012; Reis & Hayward, 2013). At the moment, at least 22 invasive species of plants and animals are known in the archipelago (Sampaio & Schmidt, 2014).

The local economy is fundamentally based on tourism, with minimal production of goods and other services. The number of inhabitants on FN has increased substantially within the last decade due to a lack of control from Pernambuco State and the opportunities created by the growing tourism (Gasparini, et al., 2007). The total number of human inhabitants is debateable, with available information varying from two to five thousand people, with an additional up to three thousand tourists per year in the peak seasons (Andrade, et al., 2009; Marinho, 2016; IBGE, 2017; Pernambuco, 2017).

Urbanised areas are restricted to the main island, in the environmental protected area (APA), a protected area with sustainable use of natural resources – IUCN category

In: C.R. Veitch, M.N. Clout, A.R. Martin, J.C. Russell and C.J. West (eds.) (2019). Island invasives: scaling up to meet the challenge, pp. 317–325. Occasional Paper SSC no. 62. Gland, Switzerland: IUCN.

VI – of approximately 8 km^2. The remainder of the main island, including the other islands and islets from the archipelago, is uninhabited and constitutes the National Park (PARNAMAR), where only indirect use is permitted – IUCN category II.

Tegu lizard

The black and white tegu lizard (*Salvator merianae* syn. *Tupinambis merianae*) (Fig. 1), hereby referred to as tegu, is the largest lizard in South America, up to 160 cm in total length and weighting up to 8 kg in its native range (Lopes & Abe, 1999; Andrade, et al., 2004). In their natural distribution in South America, tegu are commonly seen living and feeding close to inhabited areas, as well as forested areas (Oren, 1984; Sazima & Haddad, 1992; Bovendorp, et al., 2008; Winck, et al., 2011; Klug, et al., 2015; Muscat, et al., 2016). This omnivorous, opportunistic species feeds on fruits, vegetables, insects, small vertebrates, garbage and even carcasses when available (Sazima & Haddad, 1992; Kiefer & Sazima, 2002; Manes, et al., 2007; Bovendorp, et al., 2008; da Silva, et al., 2013; Muscat, et al., 2016). In South America, they can be found from south of the Amazon River to Argentina (Presch, 1973; Lanfri, et al., 2013; Passos, et al., 2013). In most areas where the tegu occurs, they are hunted for their skin and meat (Oren, 1984; Alves, et al., 2012), which has warranted the inclusion of the species on the CITES II appendix (UNEP-WCMC, 2014). In South America, adult females can lay up to 54 eggs per year (Donadio & Gallardo, 1984) and in captivity this species can possibly live up to 20 years (Brito, et al., 2001). The tegu is also considered an invasive species in Florida, where it is suspected to have a large impact on the already impacted local fauna (Pernas, et al., 2012; Mazzotti, et al., 2015).

Available data indicate that the tegu was deliberately introduced to the main island of Fernando de Noronha at the beginning of the 20th century (Santos, 1950), despite other publications suggesting a different period of introduction (e.g. Oren, 1984; Silva-Jr., et al., 2005). Whether to serve as hunting game or to help the control of rodents and toads, reasons for the introduction of tegu are speculative (Oren, 1984; Gasparini, et al., 2007; Ramalho, et al., 2009). Descriptions of FN fauna prior to the 20th century don't mention the tegu, despite mentioning the other endemic reptiles on the archipelago (Branner, 1888; Ridley, 1890). In the last century, very little was done to study the tegu population and impacts on the island ecosystem. Control or eradication methods were also never attempted, despite the management of the tegu being considered important to promote the conservation of endangered species living on the island (Brasil, 2004).

Fig. 1 Juvenile of *Salvator merianae* at Sancho Beach, Fernando de Noronha (photo: Vinicius Gasparotto).

We provide up to date information on the tegu population size and structure on Fernando de Noronha to contribute to an informed control programme to be undertaken by island conservation managers in the future.

METHODS

Study areas

To access the tegu population in the archipelago we selected two representative areas from the main island and visited the main vegetated islets that are used as nesting sites by resident birds. Land use in FN was simplified into three types, according to human usage: i) Densely inhabited areas, including hotels, houses and commercial buildings, paved streets and dense traffic, also with a higher density of uncontrolled dogs and cats; ii) Sparsely inhabited areas, including: rural areas similar to those found on the continent, and small villages with unpaved roads and sparse houses surrounded by crops and livestock animals. These two inhabited areas constitute most of the APA land; iii) Uninhabited areas, including areas of natural vegetation and secondary regeneration, with a few abandoned buildings and sporadic tourist usage. This area constitutes most of the PARNAMAR land (Fig. 2).

Within the inhabited areas, we chose the Boldró village that is a good representation of a sparsely inhabited area, with tourist visits, a small amount of commerce, paved and unpaved roads and houses of local workers. It is common to find domestic animals (dogs, cats, chickens), and crops and fruit trees in backyards. In the PARNAMAR we chose the southwestern Capim-açu region that represents the most intact? area of native vegetation on the main island (Mello & Adalardo de Oliveira, 2016). In Boldró village we performed a mark-recapture study and a line transect census study. In Capim-açu we performed a line transect census only.

Mark-recapture

To apply this method we chose the Boldró village located in a sparsely inhabited area of FN. This area is representative of the most common vegetation types on the main island and is subject to various levels of human interference while leaving space for native vegetation. Sampling seasons occurred during the years of 2015 and

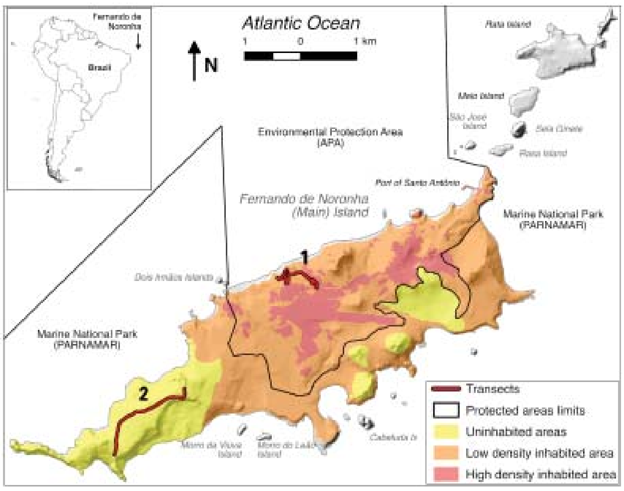

Fig. 2 Map of the protected areas of Fernando de Noronha Archipelago. Note: 1 is Boldró village transect, and 2 is Capim-açu transect (Land use layer by Vívian Uhlig – RAN/ICMBio).

2016, with 14 to 19 days of consecutive sampling in the beginning (Jan–Feb) and end (Oct–Nov) of the dry season. We opted to sample in the summer-spring as this species has been known to hibernate during the autumn-winter seasons on the continent (Andrade, et al., 2004; de Souza, et al., 2004).

We used ten funnel traps made out of PVC pipes (150 mm × 1 m) with one end closed. Those traps were placed in shaded spots next to vegetation borders, next to habitations, restaurants and areas that a tegu could use for hiding or foraging (Fig. 3). Each trap was placed in a stable position over trunks or stones in order to maintain at least a 20 degree angle to the closed end. The inclined position and lack of friction provided by the PVC material prevents animals from leaving the trap, where they remain until release. Raw chicken was used as baits and replaced every two days. Tegu locates the bait through smell (Yanosky, et al., 1993) and enters through the higher open entrance of the trap to get the bait that rests in the closed lower end of the pipe.

Traps were checked at the end of each day, when the individuals become inactive. Every animal was then restrained and marked with a transponder implanted subcutaneously. Snout vent length (SVL) was measured to the nearest 0.5 cm, with the use of a tape measure. The weight was taken using a Pesola® scale with a 10 g precision. Animals recaptured in the same season (e.g. less than 30 days interval) were considered to have the same weight and length, thus these data were collected only on the first capture of the season.

To estimate density (D) through mark-recapture data, we used the maximum-likelihood spatially explicit capture-recapture (ML SECR) package from R (Team, 2000; Borchers & Efford, 2008). We assumed a Poisson distribution of range centres (i.e. random) with a half-normal curve detection function parameterised by g_0 (probability of detection when trap and range centre coincide) and σ (spatial scale of the detection function). Removals from the population (i.e. poaching or death) are assigned known capture histories of 0 with probability equals 1 following death. The conditional likelihood was used to derive density, incorporating individual covariates of SVL and sex. Models were compared using an AIC framework, but due to sparse data, subsets of models on σ and then g_0 were considered independently. The area of capture exposure, which usually would be related to an individual's home-range, was approximated by a 95% circular probability density area of capture as:

$$HR_{95} = \pi(2.45\sigma)^2$$

Fig. 3 PVC Funnel trap to catch tegu mounted near a tree at the edge of a clearing.

Line-transect census

Two tracks were chosen to undertake the census counting (Fig. 2). One in the Boldró village, 1,820 m in length, to make possible comparisons between density methods in the same area, another in the Capim-açu track, 2,000 m in length, to make possible a comparison between a sparsely inhabited area and uninhabited area. A trained volunteer walked each track counting tegu in the high activity hours (10 a.m. to 2 p.m.). For six days, the Capim-açu track was walked in one direction and after a 30 min break at the farthest point, it was walked back. Atypical days with rain, temperatures below 25°C or excessive wind were avoided to prevent weather interference on abundance data. Counting along Boldró track was repeated nine times and Capim-açu 35 times during this study. When a tegu was sighted, the observer took the perpendicular distance of the animal from the centre of the track using a scale tape, to the nearest 0.5 m and up to 20 m distance. Any tegu sightings over 20 m of distance were discarded, but the thick vegetation in this region prevents seeing animals in the vegetated area on the transect borders.

We calculated the density of animals along the transect using distance sampling analysis, but zero spiking in the data (excessive observations close to the line) violated basic premises, likely due to a much higher level of detection, and potentially tegu abundance, along the clear open tracks in the dense forest. We subsequently used the line-transect census methodology (Burnham, et al., 1980; McDiarmid, et al., 2012) on a subset of the data, for observations directly on the open track only. Total number of individuals observed along the line-transect were used to represent the abundance on the track area, assuming every individual within the transect was observed. The area was calculated by using the average width of the track (measured every 100 m) and then multiplied by its length. Open areas were not measured and were assumed to have the same average width as the forested areas. Only animals observed within the established width of the track (e.g. clear area) were considered for such analysis.

We used a two-tailed t-test with unequal variances to compare daily density data between Boldró and Capim-açu. Only the high activity months (Feb–Jun, Sep–Nov) were used for this comparison, since we did not have data from the dry season in the Boldró area. The same method was used to compare densities observed on Capim-açu in the high activity months and low-activity months (Jul–Aug). To coarsely calculate the total abundance of tegu in FN, we stratified the map according to three main land uses: i): densely inhabited areas (226 ha); ii) sparsely inhabited areas (960 ha), and iii) uninhabited areas (417 ha) (Fig. 2). Average density and ranges from Capim-açu line-transect counts were used to estimate the abundance of tegu in the uninhabited areas of FN. The same method was used in Boldró to estimate the abundance of tegu in the sparsely inhabited areas of FN. Densely inhabited areas and areas with no vegetation (e.g. beaches, sand dunes and rocky areas – 97 ha) were excluded from the abundance calculations for they were not represented in the study area and were considered poor tegu habitat.

Islet surveys

We visited seven of the larger vegetated offshore islets of the archipelago (Rata, Rasa, do Meio, Conceição, Morro Dois Irmãos, Morro da Viuvinha and Morro do Chapéu) at least once during the study period (Fig. 2). We spent from one to twelve hours actively searching on each islet, searching for sightings or indirect signs of tegu presence (tracks or burrows). We also inquired with local inhabitants and other researchers for records of tegu presence on the other islands, since tegu can swim and also could have been brought to other islands intentionally in the past.

RESULTS

In the mark-recapture study we had a total of 190 captures over 69 trapping days in the Boldró village. From the 190 captures, we captured 103 unique individuals with 87 recaptures. Of the ten traps installed, two had to be moved in the last sampling season to avoid interference by people. These traps remained a total of 55 days in the first location and 14 days in the second location, less than 50 m away from where they were previously placed. Since tegu weight and size (SVL) were highly correlated (R^2=0.84), we have chosen only SVL as a covariate on σ and g_0. SVL also provides a better measure than total length, for it excludes the tail that can be lost or be regenerated to a variable size. Given the relatively low number of recaptures, we had to specify reasonable starting values for the likelihood maximisation with starting values of $g_0 = 0.1$ and sigma = 50 from a preliminary inspection of the data.

Ranging behaviour and probability of capture

We first fitted and ranked models combining the influence of sex and size on the ranging behaviour (σ) of the animals, while keeping a fixed capture probability (g_0). The simplest model, with fixed probability of capture and fixed ranging behaviour had 91% support, showing that size has no effect on the ranging behaviour of animals, while sex has little effect (Table 1).

Based on the best adjusted model for ranging behaviour, we kept σ constant across sessions and tested the influence of sampling period, sex and size on the probability of capture of the individuals. As seen in Table 2, the model including SVL had 44% support showing that body size as a continuous variable is the most important of the tested covariates to affect the probability of capture. Session also showed some importance in explaining the variation as seen in models 2 and 3.

Home-range

To produce real estimates for capture probabilities (g_0) and ranging behaviour (σ), we took the model including the most important covariates (session and size), for probability of capture and fixed ranging behaviour. The average size (SVL) used in the estimates was 30.2 cm (Table 3).

Based on real parameters obtained from the chosen model, we calculated 95% home ranges (HR_{95}) for average size and both sexes as 10.54 ha, ranging from 7.26 to 15.33 ha.

Density, abundance and activity

Finally, we estimated densities and sampled areas for each sampling season over the chosen model (Table 4).

In the line transect study, the Boldró transect (0.419 ha) was surveyed six times in the high-activity months (Nov 2015 and Feb 2016), with a total linear effort of 10.92 km. Only ten animals were sighted in this transect within the established transect width of 2.3 m during the period of study. The calculated density for Boldró is 3.98 (±1.1) animals/ha. The Capim-açu transect (0.492 ha) was surveyed 35 times from February 2015 to February 2016, with a total linear effort of 70 km. In this transect, 260 animals were sighted within the established average width of 2.46 m during the study. The calculated density for Capim-açu is 13.83 (±3.9) animals/ha.

Densities calculated using the line transect method were different between Boldró village and Capim-açu transects (t=6.45, P≤0.00001). There were no surveys in the Boldró transect during the low-activity months, thus, only densities from high-activity months in both transects were used to compare the densities averages from different areas. In Capim-açu, densities also differed between high-activity months and low-activity months (t=3.29, P≤0.01). The number of sightings on each occasion for Capim-açu transect is shown in Fig. 4 where a decline in number of sightings can be seen in the months of July and August.

To estimate the abundance of tegu in FN we used the calculated uninhabited area of FN as being 417 ha and the total sparsely inhabited area of FN as being 960 ha (see Fig. 2). Considering Capim-açu transect densities, calculated abundances range from 4,141 to 7,393 tegu in the uninhabited area. Using densities from Boldró transect for the sparsely inhabited areas, we estimated abundance from 2,765 to 4,877 tegu in that area. Total number of animals estimated for both calculated areas is from 6,906 to 12,270 tegu. High-density inhabited areas and non-vegetated areas of the island (463 ha) were excluded from this calculation for they were not represented in the samples; however, tegu are expected to be using those areas in a lower rate, thus abundance results should be taken as an underestimation of the whole population.

Population parameters

Males constituted the majority of the sampled population in all but the first sampling period. Males were also larger and heavier than females in all sampled periods. Male weight ranged from 400 g to 2,450 g and female weight ranged from 600 g to 1,940 g. Snout–vent (i.e. body) length for males ranged from 24 to 40 cm and for females from 26 to 36 cm. Averages and range by season and sex are given in Table 5.

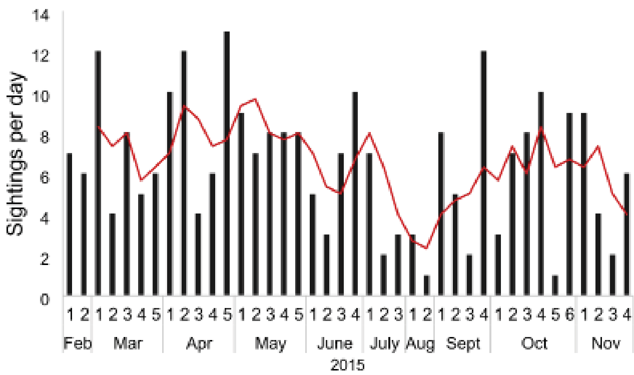

Fig. 4 Number of sightings of tegu in the Capim-açu transect during the 2015 sampling period. The line represents a moving average of three samples.

Table 1 Model results of tegu detection function for covariates of the scale parameter (σ) and the probability of capture equal to the home range centre (g_0).

Islets

From the seven visited islets of the archipelago, only Rata Island had indirect records of the presence of tegu. There was an effort of 58.5 person-hours of active searching, plus 72 trap-hours divided among three visits to Rata Island, but no direct sights or captures were made. Tracks, faeces and burrows were found, indicating the presence of tegu, possibly at a lower density than the main island.

DISCUSSION

Policy makers, managers and the general public need to be informed of the consequences of invasive species in order to manage their impacts. Understanding the population biology of an invasive species is a first step to acquire essential information for management decisions that may alleviate impacts. Despite Fernando de Noronha being inhabited since the 16th century, very little has been done to understand or prevent the impact of invasive species on endangered and endemic species that struggle to coexist in the archipelago (Sampaio & Schmidt, 2014; Mello & Adalardo de Oliveira, 2016; Dias, et al., 2017).

Ranging behaviour and probability of capture

Spatial detection models show that size and sex had little influence on tegu ranging behaviour on FN. Klug, et al. (2015) found that size differences were not likely to be contributing to movement differences for tegu. In a subtropical coastal region on southern Brazil, Winck, et al. (2011) found tegu to be more active when temperatures start rising by the end of spring and early summer. They also related peaks of activity while males were dispersing and after the emergence period, to be due to the beginning of foraging and sexual activity. The present study does not capture full seasonal variation because of time-constrained sampling, but a drop in activity was observed in July and August, as observed in other tegu studies (Winck & Cechin, 2008; Tattersall, et al., 2016). This small window of low activity of tegu on FN may not promote a significant variation in relation to the impacts it causes to other species. On the main island, only masked booby (*Sula dactylatra*) still nest on the ground in a small peninsula next to the end of Capim-açu track. Their eggs are laid in the first months of the year as observed by e Silva & Neves (2008) on secondary islands of the archipelago. The Noronha skink (*Trachylepis atlantica*) is also a common prey item in the tegu diet. Despite being relatively abundant, nothing is known about its reproduction. It is thought to reproduce throughout the year as for *Trachylepis sechellensis* on the Seychelles, another tropical archipelago (Bringsøe, 2008). Sea turtle nests are also preyed upon by tegu, as recorded by TAMAR project for *Chelonia mydas* on FN (Bellini & Sanches, 1996; e Silva & Neves, 2008), including predation of hatchlings (Ayrton K. Péres-Jr, pers. comm.). Turtles on FN nest from January to June, when tegu are active.

For the probability of capture, size was an important determinant, but population studies using traps often fail to collect a broad representative sample of the population as seen in Carter, et al. (2012). A hole of 3 cm diameter was made in the closed end of the pipe to avoid flooding of the trap and unwanted capture of native lizards. This safety measure may bias the sample as it allows small animals to escape. These animals would possibly not be able to be marked by transponder implant and thus were of less importance for this study in any case. Behavioural traits such as niche separation due to intraspecific competition could also explain a size interference on capture probabilities (Herrel, et al., 2006; Siqueira & Rocha, 2008). The observed small influence of season on capture probabilities is primarily in the first session and possibly due to adjustments of methodology following that

Table 4 Densities and estimated sampling areas in Boldró village for each season sampled derived from the best adjustment models.

Period	Density/ha	Std. Error	Min (95%)	Max (95%)	ESA
Feb/2015	4.19	0.93	2.72	6.44	7.40
Nov/2015	4.45	0.94	2.95	6.71	7.42
Feb/2016	3.59	0.84	2.29	5.64	7.52
Nov/2016	5.07	1.05	3.39	7.59	8.28

Table 5 Tegu sex, size and weight averages with ranges in each sampling season.

Period	Sex	n (%)	$\bar{x}$ SVL (cm)	SVL range	$\bar{x}$ Weight (g)	Weight range
Feb 2015	M	15 (42)	33.58	29–37	1,491.00	875–2,175
	F	21 (58)	31.22	28–36	1,051.67	640–1,940

	F	14 (40)	29.35	26–33	965.00	600–1,550
Feb 2016	M	18 (55)	33.28	28–37	1,368.89	660–1,930
	F	15 (45)	30.40	27–34	914.67	600–1,590
Nov 2016	M	47 (68)	32.53	24–40	1,294.26	400–2,450
	F	22 (32)	30.67	26–35	1,030.45	600–1,560

first sampling season. A variation in capture probabilities is not expected once sampling seasons were chosen within the high-activity periods for tegu.

Home-range

In the tegu natural distribution, older males have larger territories, while juvenile males and females have smaller territories with higher overlap. A peak of activity in males was observed at the end of the low-activity period (Winck, et al., 2011). A decrease in home range after the mating season was also observed in the El Palmar National Park, in Argentina (Fitzgerald, et al., 1991). Results from this study suggest little influence of sex on tegu capture in traps. Since SECR only estimates spatial exposure area to traps, sex could be affecting the ranging behaviour of tegu in FN but this method is not precise enough to detect such variation. This result may also have been affected by biases in the capture probability of certain tegu size classes (i.e. juveniles).

Lirio, et al. (2004) tracked six radio-implanted tegu in FN and estimated home-ranges varied from 0.73 to 7.8 ha (3.3 ha on average). The authors also comment that a gravid female was used in the study, representing the smallest home-range, and that the activity centre was usually close to the shelter. Winck, et al. (2011), found home-ranges from 0.05 to 26.4 ha for a continental population in southern Brazil. Home-ranges as measured in the present study are within the previous findings for the natural distribution of tegu and are a little higher than those described by Lirio, et al. (2004).

Since σ did not differ between sexes, estimated home-ranges were considered the same for males and females. Home-ranges can provide necessary information to set management on invasive species, such as the density of control devices (Hays & Conant, 2007; Howald, et al., 2007; Anderson, et al., 2016). For continental tegu, behavioural traits such as season, age and reproductive status can be implicated in home-range variation (Winck, et al., 2011). In FN, factors such as the lack of competitors, predators and resource availability could be also influencing tegu home ranges (Ballinger, 1977; Shine, 1987; Novosolov, et al., 2016). With an average home range (HR_{95}) of 10.54 ha, tegu on FN are quite mobile. This behaviour allows them to look for resources in a vast area and feed even when resources are not abundant (e.g. dry season). We also noticed an overlap of territories throughout the year, as juveniles forage together and coexist with adult males and females in the same area. Only youngsters seem to avoid larger tegu, having more secretive habits. In general a large home range also increases the probability of a species being exposed to a control method (Howald, et al., 2007). That means managers might need fewer traps (e.g. one every few ha) in order to control tegu on FN.

Density, abundance and activity

In Boldró village, density estimates from capture-recapture ranged from 2.29 to 7.59 animals/ha while estimates from the line transect census ranged from 2.88 to 5.08 animals/ha. Those densities are much higher than the 0.83 animals/ha observed for a tegu population living in Anchieta Island or the 0.63 animals/ha as seen in the Espírito Santo Atlantic rainforest, both in south-eastern Brazil (Bovendorp, et al., 2008; Chiarello, et al., 2010). These higher estimates could be due to a tropical climate in FN that favours reptiles with a low variation in temperature over the year. Abundance of resources and the lack of natural predators can also contribute to the higher density observed in FN as seen for other island invasive predators (Pekelharing, et al., 1998; Hays & Conant, 2007; Ferreira, et al., 2012).

Since density estimates from both methods used in this study (line transect census and mark-recapture) were similar, we opted to use values from the line transect census because it also provided density for the Capim-açu transect. Density from those transects was applied to the region represented by each transect to obtain abundance for both represented areas. There is a possible error associated with the extrapolation of the transect densities over the whole area, especially to areas with dense vegetation, as observers may find a higher number of tegu using the open areas, causing an overestimation of density. However, a similar density estimated by two different methods supports the idea of transect counts being a reliable method, despite the associated error. An estimate of abundance can help management decisions in quantifying the effort and costs required to control or eradicate (Holmes, et al., 2015; Keitt, et al., 2015). Density estimated in Capim-açu was higher than that estimated in Boldró and a broad list of factors could explain such differences, the most important are discussed here.

Animals are not distributed uniformly in the environment and they tend to occupy environments that seem more favourable, while less favourable habitats are occupied in lower densities (Diaz & Carrascal, 1991; Fraga, et al., 2013). In FN, presence of predators and competitors, such as cats, could negatively affect tegu populations by preying on juveniles and hunting other potential prey of tegu such as rats and other reptiles. In Boldró village and other high-density inhabited areas of the island, the influence of cats is higher, since the cat population is denser when closer to inhabited areas (Dias, et al., 2017). Dogs also inhibit presence of tegu by chasing and killing tegu when they cross territories, making inhabited areas again less suitable for tegu (C.A. pers. obs.).

Tegu are appreciated for their meat in the northeast of Brazil, where the species can be a delicacy and an important source of protein in poor communities (Mendonça, et al., 2011; Nóbrega Alves, et al., 2012). Poaching of tegu in FN is driven by different reasons, with tegu being commonly hunted by poultry farmers when they break into henhouses to eat eggs and chicks. Hunting in FN is done with fishing line and hooks, baited with fish or chicken, in the areas close to residences (C.A. pers. obs.). Tegu abdominal fat is also widely known as a medicine and is used by locals to treat sore throat, earache and other ailments (Nóbrega Alves, et al., 2012). Those properties are scientifically based since the anti-inflammatory properties of tegu fat has been proven (Ferreira, et al., 2010).

Tegu are generalists and feed on any available resources, including vegetation, fruits, insects, vertebrates and eggs (Vanzolini, et al., 1980; Kiefer & Sazima, 2002; Mourthé, 2010). Those adaptations do not restrict resources for the tegu population in FN, where it possibly lives with plenty of food throughout the year. A reduction in the tegu population is more likely to be present in human altered environments such as densely inhabited areas, with negative effects of domestic animals and poaching, despite a possible higher availability of food (crops, fruit trees and rubbish). Another factor that could be affecting the results is of behavioural origin. The negative impact of human presence seems to make the tegu population shift towards uninhabited areas that offer better habitat with less interference and still plenty of resources. Despite density underestimation being a possibility when failing to observe all animals on the transect (e.g. behaviour to avoid human contact in inhabited areas), the more intensive mark-recapture study showed similar estimates of density thereby disproving a possible methodological interference.

Population parameters

Size in this study was inferred by SVL and was also closely correlated to weight. Although, size can be affected by external factors when trying to infer individuals' ages (Halliday & Verrell, 1988; Adolph & Porter, 1996), weight can also reflect body condition and be influenced by the loss of the tail, a common finding in the FN population. Size can be related to sexual maturity (Fitzgerald, et al., 1993), while movement and home-ranges can be affected by sex and reproductive status (Winck, et al., 2011). Size is also related to reproductive capacity of females (Fitzgerald, et al., 1993). Tegu on FN seem to be smaller than those found in continental South America, thus, the female reproduction index in FN should be lower than in the continent (Fitzgerald et al., 1991; Winck et al., 2011). The smaller size on FN can also be related to a much higher density caused by lower competition and predation rates than the ones found in the continent (Novosolov, et al., 2016).

Males seem to be a higher fraction of the population on FN, which might influence reproduction and population growth (Le Galliard, et al., 2005). Sex ratio can be affected by average temperature (e.g. natality rates) or by any factor that increases mortality rates in only one of the sexes. Populations of tegu in Paraguay were consistently male-biased (Mieres & Fitzgerald, 2006), possibly leading to a higher fecundity rate of females or having a negative effect on lizard populations as observed by Le Galliard, et al. (2005).

Islets

Tegu are good swimmers and there are various sightings from local residents of tegu swimming or diving near to the main island. A video made by Elias Pereira and Nelly Burella shows a juvenile tegu voluntarily swimming across Baia dos Golfinhos, on the main island. Other than swimming, tegu could have been taken to other islands in the past for the same reason they were taken to the main island (either to control rats or serve as a food supply). Manoel P. dos Santos, who lived on Rata Island until 1986, says tegu were abundant there during that time. It seems that after his family left Rata, the population of tegu has decreased. However, the island seems to be big enough to maintain a small population of tegu. Some animals might also occasionally swim to other islets, but even a single animal could hardly live for long on the scarce resources available on those smaller islands, forcing them back to the main island.

Future steps

The reasons why the tegu was introduced to Fernando de Noronha, when it happened and the impacts this predator has caused to the archipelago were not documented and remain unknown. However, the understanding of impacts caused by invasive predators in islands worldwide provides sufficient evidence that management is required in order to protect local biodiversity. Eradication is usually the best option when the tools are available, but when they are absent, control measures may be better than the do-nothing approach (Fletcher, et al., 2015; Russell, et al., 2017).

On Fernando de Noronha, managing the impacts of tegu over native fauna is already on the list of priorities, as documented in the management plan of the APA (Brasil, 2004). However, providing up to date information on tegu population structure and biology in FN is expected to contribute to the implementation of a science-based invasive species programme in the future. Based on results from this work and field experience of the authors in FN, our contribution to this programme is offered here as a suggestion to local managers and decision-makers.

Measures of tegu control in FN should be placed in strategic locations where impacts on native fauna are considered higher, such as ground nesting sites for birds, nesting beaches for turtles and most preserved vegetated areas for other reptiles, crabs and even invertebrate fauna. Live or kill traps could be used, depending on the destination identified for the animals. Traps like the ones used in this study proved to be very efficient for adult tegu and seem very cost-effective. Considering the relatively high probability of capture observed, live traps needs to be checked at least once a day. Traps also need to be placed in the shade as lizards are easily prone to overheating in the tropics. Traps can be baited with eggs, bacon, chicken, fish or any other scent-driven attractant, since smell is the main sense for area exploration of tegu.

Considering the very high density of animals, an equally high number of traps should be required (one per ha or more). Control areas can be fenced by a tegu-proof fence to prevent quick reestablishment of the population by recruitment of juveniles. Traps should be placed preferentially in transition areas between vegetated and clear areas, where tegu transit to control body temperature during times of higher activity. Management effort should be stronger after the low-activity period, up to the end of the reproduction season (expected to be from September to March in FN). However, since there are animals active throughout the year, effort should also be made according to the reproduction of potential prey species such as the ground-nesting birds, sea turtle nests and crab spawning period. Control effort is expected to be up to four times higher in the uninhabited areas than in the inhabited areas of FN, given tegu density variation between those areas.

There are no specific tools available to control tegu and poison should not currently be considered as an option, since it would also threaten other endemic reptiles in FN. Hunting also requires special firearm permits and doesn't seem to be an option when in a tourist location like FN. For the moment, only fencing and trapping seem to be feasible solutions to manage tegu impacts on the archipelago's biodiversity.

CONCLUSION

Some invasive species are not commonly widespread and attract little attention of researchers. However, once established, those species can pose a real threat to native biodiversity (Simberloff, 2009; Neves, et al., 2017). Tegu have been established on FN for a century (Santos, 1950), but their population structure and impacts on native fauna remained understudied. This assessment provides focal information for a future control programme of tegu on Fernando de Noronha archipelago. We also aim to contribute to a larger ongoing process in Brazil, where invasive species move towards being a primary problem to be addressed for biodiversity conservation. Finally, we call on researchers worldwide to focus on other neglected invasive insular species as they represent a challenge and a frontier for island conservation.

AKNOWLEDGEMENTS

The authors would like to thank the Administration of the State District of Fernando de Noronha (ADM-FN), Instituto Chico Mendes de Conservação da Biodiversidade (ICMBio), National Marine Park of Fernando de Noronha and its volunteers, Area of Environmental Protection of Fernando de Noronha, National Center for Research and Conservation of Amphibians and Reptiles (RAN/ICMBio), Fire Department of Fernando de Noronha, Brazilian Institute for Conservation Medicine (Tríade) and Programa de Pó-graduação em Epidemiologia Experimental Aplicada às Zoonoses (VPS-FMVZ-USP). ICMBio and Capes (PVE Project Number 88881.065000/2014-1) provided financial support to this study. This study was taken under SISBIO permit no. 41682 and USP ethics committee no. 2724150515.

Abstract Invasive snakes can lead to the rapid extinction of endemic vertebrates on insular ecosystems, usually because snakes are an efficient and novel predator. There have been no successful (i.e. complete) eradications to date of invasive snakes on islands. In this study we assess a novel invasion on Gran Canaria in the Canary Islands. The invader, the California king snake (*Lampropeltis californiae*), arrived from California via several generations in the pet trade. King snakes are captive bred for various phenotypes, and first were detected in the wild on Gran Canaria in the 1990s. Because very little natural history data exist from within their native range, we focused on developing datasets from native habitats to compare with similar data for the introduced snakes in the Canary Islands. We found that most aspects of the snake's life history have not changed since invasion, except that there appears to be a lower level of juvenile recruitment along with an increase in the length and body mass of adult snakes on Gran Canaria. We identified environmental parameters for when capture/trapping could be completed to reduce effort and maximize success. Additionally, we show different trap success on the various life stages of the snakes. Risk assessments could be required prior to permitting pet trade or allowing captive bred snakes into regions where they are not native.

Keywords: California, Canary Islands, detection, *Lampropeltis californiae*, morphology, pet trade

INTRODUCTION

Invasive species on islands drive high levels of extinction globally (Jones, et al., 2016). No examples of eradications of invasive snakes are known from islands (DIISE, 2015). Unlike mammals, where successful methods of eradication exist and great conservation success has been achieved (Jones, et al., 2016), snakes continue to invade cryptically, often with dramatic impacts (Willson, 2017). The accidental introduction of the brown tree snake (*Boiga irregularis*) to Guam has led to the loss of almost all the bird and much of the lizard diversity of the island (Rodda & Savidge, 2007). When this invasion was recognised, major changes in the biodiversity of the island had already taken place (Savidge, 1987; Rodda & Fritts, 1992). The brown tree snake, like several other snake invaders, is poorly known biologically in its native range, and thus any biological changes to the invader during the invasion cannot be easily detected (Rodda & Savidge, 2007).

One of the main pathways for introductions of reptiles is the pet trade, which is linked to many invasive species issues globally (Krysko, et al., 2016; McFadden, et al., 2017). Little is known about the effects of having captive raised snakes released into the wild. In addition, there is little information regarding the biology (morphology, reproduction, behaviour, etc.) of non-native snakes when they are introduced to islands. California king snakes (*Lampropeltis californiae*; CKS) were originally caught and bred for the pet trade, and many are from San Diego County, California. The CKS has been a major element of the international pet trade since the 1980s (Hubbs, 2009). They have been artificially selected for certain coloration and pattern phenotypes in captivity, including albino, striped, and banded. They were originally imported to the Canary Islands as well as many other places to be bred in captivity and sold as pets. They were released accidentally or escaped into the wild and have subsequently been on the Canary Islands as an invasive species since the late 1990s, adversely affecting the native wildlife and currently occurring in two discrete populations (Cabrera- Pérez, et al., 2012; Monzón-Arguello, et al., 2015). There have been perceived morphological changes in the snakes, and their expansion could be exponential as they irrupt without competition or predation (Cabrera- Pérez, et al., 2012). When trying to compare the invasive snakes with those in their natural habitat, we found that there is little known of the life history of CKS from their native range, especially southern California, and most references cite only the regional field guides, without much primary literature to support this information. Recently for the first time, movement data, which is very useful for understanding the invasion process, has been published for this species (Anguiano & Diffendorfer, 2015).

The Canary Islands are isolated oceanic islands off the coast of West Africa. They have low biodiversity, but high endemism, with some species that have important adaptations (Rando, et al., 2008; Fernandez-Palacios, et al., 2011). These include endemic lizards, of which the lacertids (*Gallotia* spp.) are herbivorous and are important seed dispersers (Valido, et al., 2003). The islands contain no native species of snake. On the Canary Islands, the invasive CKS have become a major predator for all of the native lizard species and are therefore threatening this island's biodiversity (Cabrera- Pérez, et al., 2012; Monzón-Arguello, et al., 2015). As with other invasive species, CKS on the Canaries have gone after the most abundant prey first, so they have been preying on the native lizards primarily and then secondarily on invasive small mammals. Birds do not make up a large part of their diet yet (Cabrera- Pérez, et al., 2012), but there are endangered birds present that might become snake prey over time as other prey become exhausted (Carrascal, et al., 2017). In addition, there are limited control efforts over the spread of the snakes on the Canary Islands and potentially all of Macaronesia (Azores, Madiera, and Cape Verde Islands). This could potentially threaten the biodiversity of the entire area if they are not eradicated. The snakes appear to have no predators in the Canary Islands.

How snakes invade and the dynamics of the early invasion process, in particular the changes to their phenology, phenotype, and reproduction during the irruption phase, have not been previously studied. Most

snake invasions are more mature before study. The Canary Islands offer a unique opportunity to study these issues as it is a novel environment for snakes, and the snake invading is a species from the mainland of North America where numerous museum specimens and other field data are available. Because CKS are relatively well known, developing detailed life history parameters should be more straightforward than for other poorly known tropical species of snakes, such as brown tree snakes or Burmese pythons (*Python bivittatus*). The CKS is widespread from southern Oregon, south to the tip of the Baja Peninsula in Mexico, and east to mid-Nevada, southern Utah and the majority of Arizona; throughout its range it occurs naturally with many other snake species. The goal of this paper is to use museum and field datasets to resolve critical life history traits for this species, which can help to interpret CKS invasion dynamics within the Canary Islands and may be useful for optimising eradication/control techniques and efforts (i.e. trapping timing and placement).

MATERIALS AND METHODS

To document potential biological changes in the snake's natural history during the invasion process, we sampled CKS in their native range across 22.8°N to 40°N and made comparisons with the invasive snakes. Most samples were from southern California. Data were collected from 1,538 museum specimens (California Academy of Sciences, Natural History Museum of Los Angeles, San Diego Natural History Museum, University of California, Santa Barbara Cheadle Center for Biodiversity & Ecological Restoration) and augmented with records from wild caught CKS delivered to the San Diego Zoo (electronic supplementary materials). Additionally, we used southern California field data from 778 CKS captured between 1995 and 2012 in pit-fall and snake trap arrays by USGS (methods from Fisher, et al., 2008; electronic supplementary materials). These data from southern California included all snake species caught in these traps (n=4,708) and were used to assess the capture rate ranking of the CKS species compared to the other 24 native snake species for which we had contemporary capture data from these traps. We also obtained two different field datasets from the native range for CKS. One was a citizen science dataset from HerpMapper (HerpMapper, 2017) which had 1,299 records for the snakes from which we used capture/detection dates. The second was an unpublished dataset from Brian Hinds (BH) which represented 717 detections with associated observation dates. We compared these four native-range datasets to the Canary Island dataset, which encompassed 668 snakes (hand and trap caught from 2012 to 2014) on Gran Canaria Island (28°N), all from the western of the two populations on the island.

The museum specimens of CKS were measured for snout-vent length (SVL) and tail length using measuring tapes. Adults were defined as >600 mm in SVL (Hubbs, 2009). Sex was determined either through dissection or tail length and width. Some snakes were found dead on road (DOR) and the sex could not be determined. Many of the older museum specimens were missing reproductive systems; therefore, only a subset of data was available from these. Specimens missing their organs were used for length comparisons, but not for sex or reproductive status. Dorsal patterning and evidence of tail breaks were recorded and tail breaks were documented photographically.

The pit-fall and snake trap samples were collected from the wild in the native range in southern California primarily from south of Los Angeles to the Mexican border. Individuals were sexed, weighed, measured, and released. Data for colour pattern and tail status were lacking for most specimens. We also analysed the total capture for all snake species from these traps to look at the relative capture success of CKS compared to all other snakes for which we had data in the native snake community in California. To further look at activity phenology within their native range, we used data from HerpMapper (2017) and BH to assess observations by month as a recent sample to compare against our older native range data sources. Many of these records are from active searches under artificial cover (AC), and others are from night driving. Both of these are techniques that might have high seasonal biases in detections. This is because snakes under AC could be non-active, but using the cover to environmentally thermoregulate; whereas snakes detected on roads at night would be animals that are actively moving. These behaviours would change seasonally based on climatic conditions.

Samples from Gran Canaria Island were collected by hand or by trap then euthanized and frozen for later dissection. Sex, weight, SVL, tail breaks or scarring, were recorded.

Comparisons were made among these five study population samples for the relevant metrics and controlled for differences in sampling types. For example, the museum series is similar to the invasive population in that animals were collected by hand, trap, or opportunistically, but no comparison of weight could be completed, as the preserved weight of the museum snakes is not comparable to live weight. In contrast, live weight and length of the pit-fall and snake trap series could be compared to the invasive series, but reproductive states could not be compared, as these data were not available for the trapped and released snakes from their native range. These trap records are from snakes that are actively foraging, as they have to be moving in the landscape to encounter a trap. The last two field data sets (HerpMapper and BH) could only be used for detection/capture date comparisons with the other data sets, as they involved primarily active searches, especially under artificial cover, and not necessarily surface-active snakes. They also lacked length/weight measurements for individual snakes. We used means of the top decile to highlight comparisons between populations.

RESULTS

Snake community structure in California

Within a community of 25 native snake species captured via pit-fall and snake trap arrays in southern California, CKS was found to be the second most abundant species following the California whipsnake (*Masticophis lateralis*) and represented approximately 17% of the 4,708 captures across these species (Fig. 1). Snakes in this dataset were captured when snakes entered traps; no active searching for snakes took place. Thus, these records would be biased towards species more frequently moving over the landscape. These data indicate that within its native range the CKS is one of the most abundant snakes captured with this technique.

Trap success by size class

Using the USGS pit-fall and snake trap dataset, we were able to look at the effect of trap type on capture success by snake length, as a proxy for age (Fig. 2). We found that pit-fall trap buckets (18.9 L) buried in the ground were most successful, capturing snakes less than 500 mm in length. Wire-mesh snake traps had the greatest success with snakes exceeding 500 mm in length. Additionally, there was no trend in body size of CKS incidentally observed while conducting sampling using these traps.

Snake detections by month

We plotted the monthly detections/captures across five different datasets to assess variability across months.

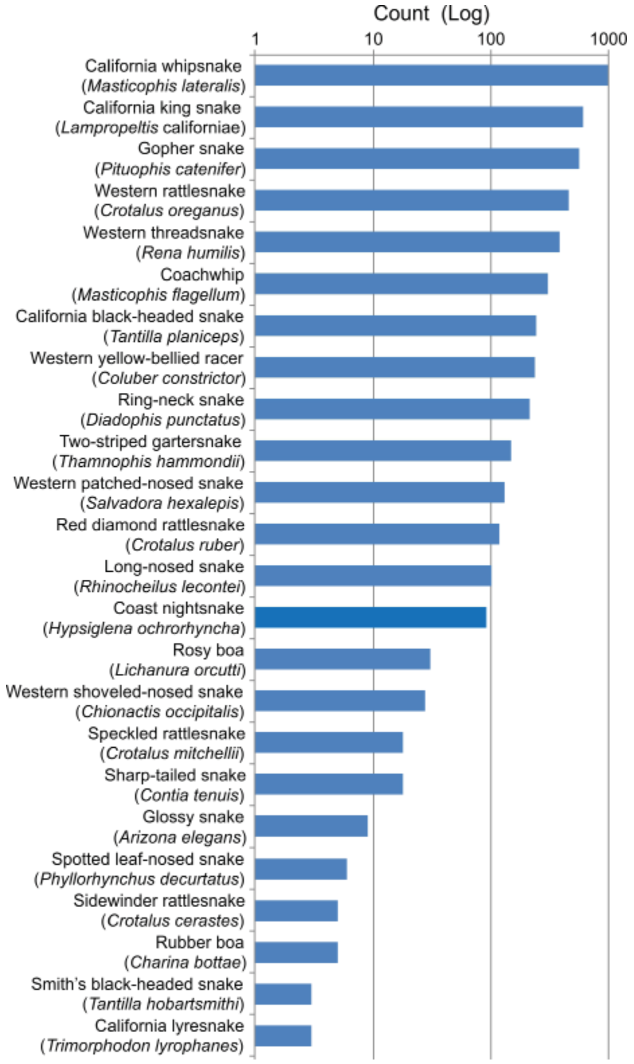

Fig. 1 All snake captures in southern California from the USGS pit-fall and snake trap study (n=4,708). *Lampropeltis californiae* is the second most common snake species captured.

Overall, monthly detections across datasets were highest between March and June, with the various peaks being due to variance in detection technique used. The citizen science (HerpMapper) and BH datasets, where they were actively searching for snakes, had peaks between March and April.

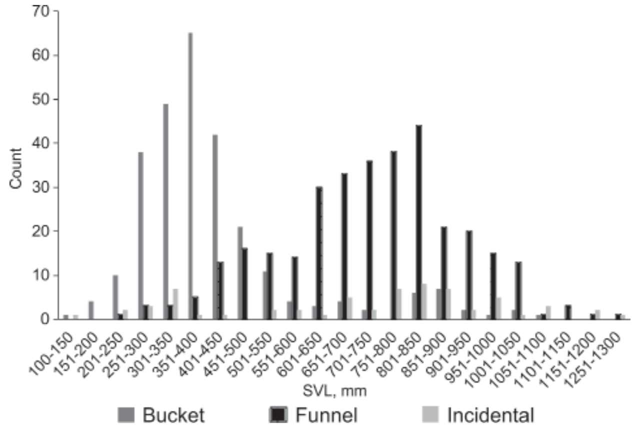

Fig. 2 Body size of *Lampropeltis californiae* by trap type for southern California. This figure has 50 mm breaks in size groups and highlights the different capture success of the two different trap types (pit-fall versus snake trap).

The museum and Canary Island datasets both had their peaks in the month of May, and these were identified using a variety of detection types, including active searching and traps. Finally, the pit-fall and snake trap dataset, with its passive traps for detections, had its peak in June. This last dataset was the only method based solely on active snakes. From August to January there was <10% per month of total snake detections across all datasets and from November to January there was <5% per month of total snake detections (Fig. 3).

Sex ratios, body size, and tail injury comparisons between California and the Canary Islands

We were able to make more detailed comparisons across three datasets, two from the native range (museum and pit-fall/snake trap) and the Canary Islands (Table 1). We found that there was a greater proportion of adults captured in the Canary Islands compared to the native range pit-fall/snake trap captures or museum specimens. There was no difference between the two native populations in the percent of juveniles, with about 49% of the samples representing juveniles; in contrast, only 22% of the invasive snakes were juveniles (Table 1). Thus, there were 2.3 times more juveniles detected in the native range than in the Canary Islands regardless of dataset used (museum or pit-fall/snake trap). For the pit-fall/snake trap and Canary Island captures, we compared the frequency by 50 mm size classes to see where this juvenile/adult bias was

Table 1 Morphological comparisons between native and invasive populations of *Lampropeltis californiae*. Differences between values of the invasive versus native populations were calculated as percentages to illustrate variance from 100%. Values in parentheses in table are sample sizes for top deciles.

	Gran Canaria Island	Southern California field	Museum specimens	Difference Gran Canaria Is. vs California
Total	668	780[a]	1,538[b]	
Total # adults (>600mm)	519	335	769	
Percent non-adults	21.9	49.6	48.4	0.44
Mean SVL (top decile) (mm)	1,071.7 (n=52)	1,069.1 (n=33)	1,032.2 (n=77)	1.00
Largest SVL (mm)	1,474	1,290	1197	1.14
Mean weight (top decile) (g)	412.8 (n=52)	334.9 (n=28)	-	1.23
