MONITORING OF UNDERGROUND AND STREAMWATER USING  
SELECTED OPERATIONAL COUPES AS EXPERIMENTAL CATCHMENTS

Project 4 studies began in 1975, their objective to provide an early warning system of any effects that heavy cutting practices used in the license area might have on stream and groundwater. Four experimental catchments were chosen to represent different conditions of rainfall, soils, and forest types (Table 1). Each catchment covers between 100 - 200 hectares and samples the complete range of topographical situations and associated forest types (Kelsall 1980).

TABLE 1: Soil and Forest Types and Rainfall Data for the Project 4 Coupes

| COUPE    | SOIL TYPES                             | FOREST TYPES          | MEAN ANNUAL RAINFALL (MM) |
|----------|--|-----------------------|---------------------------|
| Crowea   | podzolics on upper slopes              | jarrah-marri          | 1380                      |
|          | red earths in valleys                  | karri                 |                           |
| Poole    | podzolics<br>red earths                | jarrah-marri<br>karri | 1290                      |
| Iffley   | laterites<br>(extensive)<br>red earths | jarrah-marri          | 1220                      |
| Mooralup | podzolics                              | jarrah-marri          | 900                       |

LOGGING AND REGENETATION

All coupes were cut during the 1976/77 summer, after at least one year of monitoring in each case. Crowea and Poole coupes, predominantly karri, were burnt in April 1978 and planted with karri seedling in June 1978. Iffley and Moorilup coupes, where jarrah is the dominant species, was burnt in November 1979 and allowed to regenerate naturally.

### MEASUREMENTS AND INSTRUMENTATION

Rainfall or throughflow was measured by 6 bulk sampling rain gauges to test the level of precipitation and its seasonal distribution. Streamflow is measured by a V notch weir placed at the head of the catchment, in addition provides a sample collection point for analysis of water salinity and suspended sediment.

Ten bore holes were drilled in each catchment, as to sample different topographical locations, (ridge, midslope and valley). A further two bore holes have been drilled outside but close to the catchment to provide controls for comparison. All bores have been visited regularly to measure depth to water table and samples collected for laboratory analysis.

### RESULTS - Rainfall

Analysis of rainfall data of the Project 4 catchments for 1975-83 is presented in Table 2.

TABLE 2: Rainfall - (mm)

| <u>YEAR</u> | <u>IFFLEY</u> | <u>CROWEA</u> | <u>POOLE</u> | <u>MOORALUP</u> |
|-------------|---------------|---------------|--------------|-----------------|
| 1975        | 925           | 1164          | 1121         | 732             |
| 1976        | 897           | 1013          | 1023         | 673             |
| 1977        | 789           | 1090          | 953          | 669             |
| 1978        | 1037          | 1116          | 1023         | 767             |
| 1979        | 904           | 1085          | 915          | 668             |
| 1980        | 884           | 1158          | 1111         | 658             |
| 1981        | 927           | 1275          | 1279         | 815             |
| 1982        | 736           | 1238          | 898          | 611             |
| 1983        | 808           | 1215          | 1053         | 750             |

The within-coupe rain gauges used in the study have revealed an increase of approximately 10% in the amount of rainfall reaching the ground after cutting reduced interception by tree crowns (Kelsall Committee 1978). This agrees with local and eastern states results (butcher 1977, Smith 1974).

Analysis of rainfall for the three long term recording centres nearest the experimental catchments (Nannup, Pemberton and Manjimup) clearly shows that rainfall for the period 1975-79 has generally been below average (Table 3). This trend has continued to date.

TABLE 3: Annual Rainfall (mm) at the Long Term Recording Centres in the License Area.

| <u>YEAR</u>       | <u>NANNUP</u> | <u>PEMBERTON</u> | <u>MANJIMUP</u> |
|-------------------|---------------|------------------|-----------------|
| 1975              | 851           | 1117             | 922             |
| 1976              | 831           | 1124             | 1022            |
| 1977              | 739           | 984              | 898             |

| Long Term Average | 985           | 1258             | 1066            |

#### - Groundwater Observations

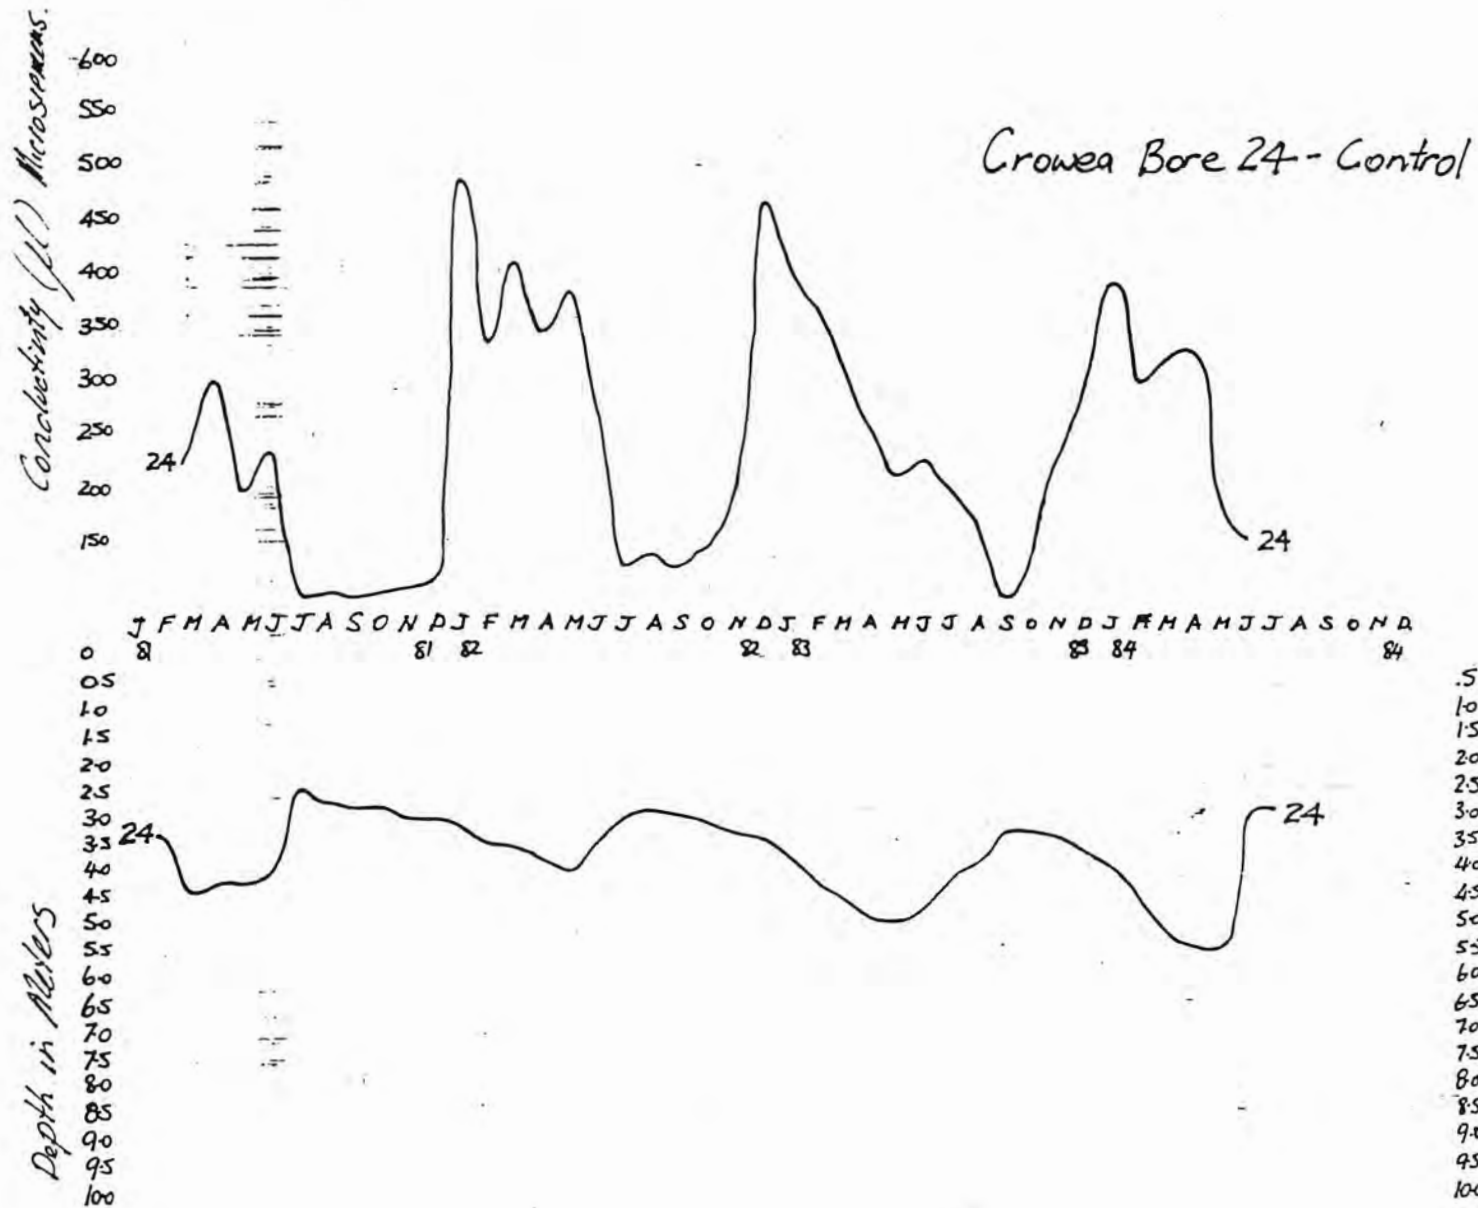

Water level movement within the bores has characteristic seasonal fluctuations, a pattern of steadily rising water levels during winter and spring, followed by a steady fall during summer and autumn.

Cutting commenced in the summer of 1976/77 and continued through most of winter 1977 for most coupes, Iffley the exception commenced in spring 1976.

As a generalisation groundwater tables rose in most bores within the coupes after cutting. Generally the rises in groundwater was not large averaging only 2 m in Poole and Crowea to 1 m in Iffley and only a few centimeters in Moorilup (Kelsall 1980).

Four representative bores are presented in Figure 1 from different topographical positions in the catchment. Bore 20 a ridge top bore, Bore 22 midslope and Bore 18 a lower valley slope. A further bore, Bore 24 is a control bore. Examination of the graphs reveals several trends. Firstly groundwater rose after September 1977, within 3 months of cutting. Secondly groundwater had stabilised at a new higher level until 1982, after which there is evidence of a gradual decrease in groundwater levels.

CROWEA BORE 22 - Mid Slope  
 CROWEA BORE 20 - Upper Slope.

Crowea Bore 22 - Mid Slope

Crowea Bore 20 - upper Slope.

The control bore (Bore 24) shows no increases in groundwater levels but exhibits common seasonal fluctuations in groundwater levels. Graphs of the bores of all the catchments are presented in Appendix 1.

Although Figure 1 presents graphs taken from the one catchment trends observed are common to all catchments.

#### - Streamflow

As stated previously recorded rainfall means are well below the long term mean. Although rainfalls in 1978 were close to the long term mean, streamflows in 1978 would be below average because of the preceding two dry years. Therefore the bias towards low flows in the recorded streamflow is likely to be higher than the bias in the rainfall.

Despite the considerable bias to low streamflow over the period of record the water balances of the catchment reflects an important general characteristic. Streamflow increases as a percentage of the rainfall from the low rainfall to high rainfall catchments. For example, 1978 flow in Moorilup (767 mm) represents 4.3% of rainfall while Crowea 1116 mm represents 39.6% of rainfall (Table 4).

The data presented in Table 4 shows that streamflow as a percentage of rainfall has increased since cutting although rainfall inputs are of similar amounts. Another trend emerging is that the catchments appear to be returning gradually to their pre-cutting levels, this is more evident in the higher rainfall coupes of Crowea and Poole where both 1982 and 1983 percentage of rainfall figures have reduced.

#### - Salinity

Streamwater salinity is shown graphically in Figure 2. Generally streamflow <sup>salinity</sup> has increased after cutting, however there is a trend towards lower streamflow salinities in later years. The P.W.D. found in their catchments that coupes which have groundwater tables less than 5 m from the surface have higher stream salinities than coupes where ground is greater than 5 m. This is due to the combining of fresh infiltration flow and higher saline water from the perched water table. However none of the catchments have

produced unacceptably high saline concentrations.

Total salt exports are related to volume of streamflow and stream salinity. From streamflow figures listed in Table 4, it can be seen that streamflow is highest from 1978 to 1981, which corresponds to the period of highest stream salinity. Hence total salt export for this period would be at its highest. The proceeding two years 1982/83 streamflow has reduced together with reduction in stream salinity.

- Stream Sediment Levels

Stream sediment levels have been measured by passing sediment samples through a 50 micron filter. Although summary data of sediment levels past 1979 is not available for this report a quick examination of records on file has revealed some characteristics. Firstly that results of sediment level are variable. Secondly concentration of sediment have not changed markedly, however as levels of sediment are dependent on volume of flow than general level of sediment would have reduced as streamflow decreased.

SUMMARY

1. Streamflow as a percentage of rainfall increases from low to high rainfall catchments.
2. Streamflow has increased since logging in all four coupes studied. The increase is attributed to increased throughfall following reduction in the overstorey. A trend in reducing streamflow in latter years is observed.
3. There has been a rise in the water table since logging, but similar to streamflow, indications are that bore levels are reducing as transpiration increases with increasing vegetative cover.
4. Total salt flow has increased in all four coupes. This is attributed more to increased streamflow than increased salinity. But a current trend of reduced streamflow from increased transpiration has lowered the total export of salts from the catchments.
