ABSTRACT

This report provides a quantitative description of the commercial estuarine fisheries of temperate Western Australia. An account is given of the long series of historical events which influenced the development of the fisheries and led to their current status. All available catch and effort data covering the years 1898-1975 are presented. The use of this long series of historical catch and effort data as an aid to the management of the estuarine fisheries resources is discussed. It is emphasised that interpretations of these data cannot be undertaken effectively without a knowledge of factors such as life history strategies, fishing practices and the market demand of the various species.

The present day state of the fishery is discussed. Indications are that some stocks of black bream and to a lesser extent yellowtail perch, which are essentially restricted to estuaries, have declined throughout the history of the fishery. Although catches of all other species have shown extensive annual and seasonal fluctuations, no consistent long term downward trends are apparent.

Because most commercially important species utilise estuaries during only part of their life cycle, management initiatives need to be directed towards encouraging and maintaining the use of estuaries by the different species, while attempting to ensure that individual fishermen can continue to obtain an appropriate share of the resource. Because of the usually unrestricted movement of fish between estuary and ocean, localised seasonal overexploitation of a resource within a given estuary is possible. However, overexploitation of a total stock of any given species solely as a function of estuarine exploitation is unlikely, provided the species is not totally estuarine dependent as a juvenile or is an estuarine species sensu stricto.

I INTRODUCTION

The Western Australian commercial estuarine fishery is one of the oldest fisheries in the temperate area of the State, traditionally serving pioneering populations who normally settled on the shores of protected navigable waters such as estuaries. Although there was some conflict of interests in estuaries during these early years, professional fishing was acknowledged as one of the most important and proper uses of our estuaries. During later years, however, as population, urban and rural development increased and the economy expanded, the use of Western Australian estuaries became more intense and diverse.

In an attempt to provide the basic information necessary for the responsible management of the various estuarine resources, in particular their fisheries, and thereby help to resolve the inevitable conflict of various user interests, a detailed account of the important events in the development of this commercial fishery is needed. This paper attempts to present such information in the form of an account of the historical development of the fishery, together with an analysis of all available catch and effort data, covering the fishery from its inception until the introduction of the new combined fishermens return in 1975, and the accompanying modified technique of data analysis and different format of data printout.

II SOURCES OF DATA

A. Historical information

Section III, which deals with the historical development of the commercial estuarine fishery is based, to a large extent, on unpublished information contained in Department of Fisheries and Wildlife files, presently held either at the Departmental Head Office, the State Intermediate Records Repository, or the archives of the Battye Library.

B. Catch and effort data

(i) Review of data collection systems:
Prior to 1941, there was no formal method for the collection of estuarine fish production statistics. Estimates of fish production were variously obtained from a number of related sources.

Fisheries Inspectors' weekly district reports (Form "A") and monthly fish reports (Form"B").

Form "A" reports provided a descriptive account of the location, behaviour, average size and spawning condition of commercial fish caught each day, together with records of air and water temperature.

Form "B" reports provided information on the monthly quantity (lbs landed weight) of each species of fish taken by professional fishermen operating in different areas of the State. Summaries of this information were usually provided in the Annual Report by the Chief Inspector of Fisheries. (Form "B" data became the inspectors' monthly summary of production from his district).

Processing and marketing reports (Form "C") and fish canning reports (Form "G").

These reports were usually provided on a weekly basis by marketers and processors of fish. Reports were also prepared showing the quantities of fish that were caught but not sold through the metropolitan markets (File 222/49 Fisheries General Statistics - 1912).

Returns for fish dispatched by rail (Form "D")

Revenue from railway freight charges for fish transported to the Perth market was used to help estimate the amount of fish taken in the State annually. As all fish taken outside the metropolitan area and marketed in the metropolitan area were transported by rail to the markets for sale, these forms provide reasonably accurate information on the magnitude of these catches. However, as noted above, additional quantities of fish caught around the State were not marketed in the metropolitan area.

Early departmental files These contained catch and effort data other than these data provided by Forms A,B,C,D and G.

In 1941, a fisheries statistics collection system, based on the system used at the time in California was introduced by the then Chief Inspector (= Director) of the Department of Fisheries. In this system the ocean was divided into fishing areas or blocks of 1^{o} latitude by 1^{o} longitude. Four estuaries (Swan-Canning, 9501; Peel-Harvey, 9502; Leschenault, 9503; and Wilson Inlet, 9506) (Figure 1) were also coded as separate fishing blocks. All professional fishermen were required to submit a return each month to the District Inspector. These returns and a monthly summary sheet of production from that district (Form B above) were submitted to Head Office each month by the district Inspector. Data recorded for each block in this manner were the number of each species taken, gear used and hours worked catching the fish. Conversions from numbers to weight were made at Head Office. In 1949, separate monthly returns were required for each of the deep sea, rock lobster and inshore/-estuarine sections of the commercial fishery. Monthly

data collected from the inshore/estuarine component of the fishery were catch (wt) by species, by method, i.e. nets, drop nets, traps and set lines, and the number of men and boats and the days spent fishing (effort was recorded for all methods combined), in each estuary. Several other changes were made to the overall system during the period 1949-1974/75. The initial one was the introduction of a fourth type of return in 1963 to cater for the needs of commercial trawling operations. During 1964, four additional commercial estuaries, Princess Royal Harbour and King George Sound*, 9504; Oyster Harbour, 9505; Irwin Inlet, 9507 and Broke Inlet, 9508 (Figure 1); were added to the existing four, making eight estuaries in all for which the Bureau of Census and Statistics provided detailed monthly summaries of production data. Computer processing of catch and effort data commenced at the Bureau in 1967. Thus although the format of the return had changed over the years since 1947, the basic items of inshore/estuarine data collected over this period have remained essentially unaltered.

In July 1975 (i.e. the commencement of the 1975/76 financial year) a new commercial fisherman's return form was introduced. This single new form catered for all the above four fishing techniques, i.e. deep sea, rock lobster, inshore and estuarine fishing and trawling, and thus superseded the previous system which required separate forms to be completed for each of these techniques. The catch and effort data available from this new system are rather more detailed than previously available as they provide separate catch and effort data for each fishing method used during each month. Thus the catch from, and effort expended using, beach seine and mesh (gill) netting techniques are able to be separated. There is also provision on the form to record in more detail the fishing effort expended each month. For example, in addition to the number of days spent fishing, there is provision for recording the number of hours spent fishing per day.

At the beginning of the 1977/78 financial year, and following the introduction of the conditional licence management regime (Section III), the following eleven additional south coast estuaries were designated as commercial fishing blocks;

*Listed as a commercial estuary, but in reality is a marine embayment.

Name	Block Number	Position of entrance to ocean Lat.	Long.
Hardy Inlet	8501	34°20'S	115°8'E
Parry Inlet	8502	35°1'S	117°10'E
Beaufort Inlet	8503	34°27'S	118°55'E
Wellstead Inlet	8504	34°23'S	119°25'E
Gordon Inlet	8505	34°16'S	119°30'E
Dempster Inlet	8506	34°4'S	119°40'E
Hamersley River	8507	33°58'S	119°55'E
Culham Inlet	8508	33°56'S	120°3'E
Oldfield River	8509	33°53'S	120°47'E
Torradup River	8510	33°52'S	121°1'E
Stokes Inlet	8511	33°51'S	121°8'E

This report is intended to cover the period up to the introduction of the present commercial fisherman's return, i.e. the beginning of the 1975/76 financial year. However, production data in the old format are obviously only available up until the end of the 1974/75 financial year (i.e. June 1975). Thus to complete the data for the 1975 calendar year, the first six months data recorded under the new system had to be reprocessed under the old format.

(ii) Data available for analysis:

Catch:

Pre 1941

Unfortunately much of these early catch data have been either lost or destroyed. However, there are some records remaining on old Departmental files, many of which are presently stored at the State Intermediate Records Repository and the Western Australian State Library Archives.

A proportion of these data were in the form of annual catch of the various species in each estuary and were thus able to be used in this paper. However, much of this information is of limited use as it is in the form of annual catch by species or total catch of all species by district, no distinction being made between fish caught in the ocean or estuary. Nevertheless, for completeness, these data are presented in Tables 2(a)-(d).

1941-1951

Although catch data were submitted via the District Inspector to Head Office each month, the only data which appear to be available today are those from the Swan-Canning, Peel-Harvey and Leschenault estuaries, and Wilson, Irwin and Broke Inlets, which reported annual catch of selected species, and which had apparently been manually tabulated from the monthly file summaries. (Tables 3(a-c), and (f)-(h)).

1952-1963

Monthly catch data for all species is available from each of the above six estuaries throughout this period.

1964-1975

Monthly catch data is available for all species from each of the eight commercially important estuaries. (Tables 3(a)-(h)).

Fishing effort:

Pre 1951

Although fishing effort, in the form of the number of men and boats operating monthly in each estuary, and the hours worked catching the fish (pre 1941-1948) and later (1949-1951), days spent fishing each month were allegedly forwarded to the Department of Fisheries and Wildlife Head Office each month, only intermittent records of the number of men and boats operating annually from each estuary seem to have survived.

1951-1975

While estimates of the numbers of men, boats and days spent fishing were allegedly provided by the fisherman's monthly return system, only the first two provide a reliable available monthly index of effort. In this report the average numbers of men and boats operating monthly was preferred as a measure of fishing effort because it enabled comparisons to be made over a much longer period of time.

A summary of all available annual catch and effort data, together with explanatory notes which aid interpretation are presented in Tables 2 and 3. Additional interpretive guidelines regarding the actual species included under the various common names are provided in Appendix 1.

III HISTORICAL DEVELOPMENT OF THE FISHERIES

A. The early years

The Western Australian coast received many early exploratory visitors, such as Vlamingh in 1697, who named the Swan River (Gentilli 1969). However, official settlement was not made until 1829 (Colbatch 1929). Initial colonisation and settlement of new countries has usually been made on the shores of protected navigable waters, in close proximity to arable fertile land. Thus the shores of the river systems, and to a lesser extent protected marine embayments, have been prime settlement targets. Western Australia was no exception. One of the very first colonies, which was later to become the capital city, was established on the banks of the Swan River, approximately 19 km from its mouth where the new port of Fremantle was subsequently sited.

Although some food supplies were obtained from other established countries (particularly the homeland) new settlers must have depended to a large extent on the natural food resources of their new country, particularly those close at hand. Thus estuarine fish populations were probably amongst the State's first commercially exploited aquatic resources.

It follows therefore that the Swan-Canning river system supported the State's first commercial estuarine fishery which, as will be explained later, was followed in the period up to 1930 by the development of fisheries in the Peel-Harvey, Leschenault, Vasse and Wonnerup estuaries, Princess Royal Harbour, and King George Sound, Oyster Harbour and Wilson Inlet, and later the Blackwood, Broke and Irwin Inlets and finally in the Murchison River and some of the estuarine systems between Albany and Esperance.

During the period from 1829 to approximately 1890, the documentation of the development of the State's estuarine fisheries was very poor, and catch and effort statistics were apparently not recorded. It must be concluded from the documents relating to the post-1890 fishery that the first sixty or so years of the fishery was a rather haphazard affair, with no formal marketing system, catering almost entirely for local demand in the various settlements along the Swan and other similarly located estuarine settlements in other areas of the State.

Indeed, because of the very small State population at the time, the fishery would have been understandably small and largely based in the Swan-Canning system, however with some supplementation from the waters off Fremantle and in Cockburn Sound.

B. The late ninteenth century

The period of the fishery from the late 1880's until approximately 1920, was reasonably well documented but good catch-effort records are lacking.

During the late 1880's and early 1890's, considerable quantities of processed fish were being imported into the colony (Saville- Kent 1893-4) (Table 1). It can only be assumed that during this period the continued operation of canning factories (the first of which opened in 1876) in the Mandurah district and attempts at curing local fish were aimed at cutting the amount of imported fish products being consumed in the colony (as well as obviously providing a profit for the various operators). Sea mullet, yelloweye mullet and Perth herring were the major species processed in this manner. Aparently sea mullet produced the best canned product. Although Perth herring smoked well and was very popular, the numerous fine bones characteristic of the species lessened the appeal of this smoked product.

It is of interest that the mud oyster (*Ostrea angasi*) populations in the embayment and estuarine waters of the Albany district had already been overfished during this early stage of the State's settlement. Restricted populations still exist in Oyster Harbour and Irwin Inlet today. However they are only fished to a very limited extent commercially, and are only occasionally taken by those amateurs prepared to dive.

The paucity of the freshwater component of the fish fauna of the estuarine systems, particularly those species of economic value, was quickly recognised by members of the early community. A number of attempts were made to rectify the situation, including the building of a fish hatchery on the Preston River in order to stock suitable river systems with trout and redfin perch; and the introduction of Murray cod, Murray perch and silver eel from Victoria into the upper reaches of the Swan-Avon River system. These types of introductions were common during these early years of the colony (Saville-Kent 1893-4). As a legacy of these early attempts at fish introduction, today's remaining fresh streams and rivers of the south-west of the State support breeding populations of redfin perch, and rainbow and brown trout. However their overall breeding success has been insufficient to enable the cessation of the re-stocking of these freshwater areas with trout from the State's Pemberton Hatchery.

From available reports (such as Thompson 1898) it was also clear that fisheries developed in estuaries adjacent to other outlying population centres such as Albany, Bunbury, Busselton and Mandurah during the early 1890's. The Peel-Harvey estuary had been supplying fish to the town of Mandurah for some time evidenced by the fact that as early as the late 1840's concern was being expressed about overexploitation of the stocks and certain closed water regulations were introduced in an attempt to curb this unsatisfactory situation.

Fishermen in the Peel-Harvey estuary were frustrated because of the lack of rail communication with the metropolitan area. Fish caught commercially in the estuary either had

34416—3

to be carted overland to the Perth-Bunbury rail-link and then to Perth by train, or to Fremantle by sea. Factors such as the extremely hot summer conditions, the shallow estuary sand bar, periods of rough weather and poor quality of available cooling facilities made regular transportation to the metropolitan area an economic impossibility. However despite all these problems some progress towards a solution was being made because a cool storage facility capable of taking 18t of fish per week was established on the banks of the Murray River.

Two canneries were processing fish from the Peel-Harvey estuary. This relieved the marketing problem to some extent, because it helped prevent unnecessary wastage of fish and provided a product that could be periodically transported to the metropolis without the fear of decomposition enroute.

One of the earliest documented instances of user conflict in these estuarine systems was between the commercial fishermen and aborigines who used a fish trap or "Mungah" on the Serpentine River which flows into the Peel-Harvey estuary (Figure 1). Commercial fishermen claimed that the continual operation of the trap had adversely affected their catches in the estuary.

Other estuaries in the south-west had also begun producing quantities of fish. However, since they were remote from the metropolitan area, their full potential was clearly not realised. Nevertheless, Princess Royal Harbour and King George Sound, Oyster Harbour and Wilson Inlet produced good quantities of fish for the Albany district, the adjacent goldfields, and for ships which visited the port of Albany.

An estuarine fishery had also developed in Leschenault estuary (Bunbury). A number of closed water areas were declared in this estuarine system to help conserve the fish stocks of the area.

In the Busselton district, the Vasse-Wonnerup estuary contributed only a very small amount of fish to the commercial catch from the lower west coast. The majority of the catch from this district was taken from Geographe Bay, an adjacent marine embayment.

The Bunbury district had a distinct advantage over the nearby Mandurah district in that it was linked to Perth directly by rail. Fishermen thus had the extra convenience of being able to transport their catch in refrigerated railcars for sale in the metropolitan area.

Farther north at this time, however, doubts were being registered regarding the ultimate capability of the Swan-Canning estuarine system to be a major producer of commercial fish. Both the intense conflicts of usage

which already existed between commercial and amateur (domestic) fishermen and other recreational users, and the disturbing influence on the system of activities associated with the busy sea port of Fremantle were reasons forwarded in support of this view. There was apparently a body of opinion which considered that the estuarine fish and crustacea should be left for the more sedentary inhabitants of the city to exploit during their leisure hours. Thus although a number of commercial estuarine fisheries had been established in the State by about the beginning of the 20th century, they were not without their problems. The more significant of these are summarised below:

(i) Transportation of produce from outlying areas to the metropolitan area was difficult due to:-

(a) inadequate modes of transport;

(b) inadequate cool storage in transit;

(c) transportation distances were great;

(d) since fish were not cleaned prior to transportation, the quality of fish landed in Perth was often poor.

(ii) Once the fish reached the metropolitan area there were no central marketing facilities, and those facilities which were available were inadequate in many ways. For example there was no control over supply, and consequently there was wastage when fish were plentiful, and when fish were in short supply, they were expensive to buy.

(iii) The freight rates from country areas were excessive, making the fish relatively expensive once it was landed in the metropolitan area; with the inevitable result that once the wholesalers and retailers added their profit margin, only the wealthy class of consumer could afford to buy the product. Thus the demand for and importation of the cheaper dried, salted, pickled and preserved fish continued to rise (Table 1).

(iv) User conflict was developing rapidly in the estuarine systems adjacent to the largest population centres of the State.

Further there was no statistical system for the collection of the catch and effort data essential as a basis for both biological and economic management of the fishery.

C. Years following the proclamation of the first Fisheries Act

In 1899 the first Fisheries Act was proclaimed. Although the industry had been operating for some time, it only then appears to have achieved sufficient importance for the

Government to gather together all existing fisheries-related regulations (initially passed under other Acts) and have them included under this separate Act.

During this early period of the fishery, when Greeks and Italians far outnumbered the British members of the fishing industry, there was great concern expressed that the use of seine nets in many of the estuaries and more particularly the use of hauled prawn seine nets in the Canning and "dredged" or dragged nets in the Melville Water region of the Swan was destroying many juvenile fish (Gale 1900). As a consequence a number of small estuaries were completely closed to netting. It was also advocated that prawners should only be allowed to use hand prawn nets but be permitted to fish in the whole Swan-Canning River system, rather than just the Canning. However, restrictions on prawn nets were not introduced until 1916 when the Government announced that they were all to be hand hauled and limited to 9 feet in length (Aldrich 1917).

Area closures, and a number of gear related regulations were being more widely introduced into estuarine fisheries during the early 1900's, particularly that of the Peel-Harvey system (Gale 1902). With increases in the number of regulations came the need for increased levels of surveillance by the various District Inspectors, in an attempt to halt the increasing trend in breaches of these regulations (Gale 1908). It was encouraging to note that at this time increases in the catches from the Peel-Harvey system were attributed to the closure of the Murray and Serpentine Rivers and the estuary channel to netting (Gale 1908).

It had become clear also that natural environmental conditions in the different estuarine systems fluctuated markedly from year to year, particularly the extent of the winter freshwater flush (Gale 1904, 1906, 1908, 1910). This was also true of the condition of the sand bars at the estuary mouths, notably those of the Peel-Harvey and Leschenault systems (Gale 1902, 1904). These factors, together with the variable breeding success of the different species from year to year, affected recruitment of these species into the estuarine system and consequently catches of these species fluctuated accordingly from year to year (Gale 1901, 1902).

Fluctuating catches, together with the still unsatisfactory transportation and marketing arrangements continued to make the supply of estuarine fish to metropolitan consumers uncertain and expensive (Gale 1902).

During the early 20th century, the activities of amateur fishermen were very intense, particularly in the Peel-Harvey estuary and the Swan-Canning estuary where in some years domestic net fishermen caught as many prawns annually as professionals (Aldrich 1917). Amateur fishing activity was also intense in the Leschenault estuary which at this time was completely closed to all forms of netting (Gale, 1904, 1906, 1908). All fish taken commercially from this

estuary were handlined, and sold in nearby Bunbury before the fishermen from the ocean areas arrived into port. This practice created considerable conflict between these two groups of fishermen in the area (Gale 1910).

During these early years of the 20th century three canneries operated in the Mandurah district (Gale 1906), making use of summer catches that could not be marketed and would otherwise have been wasted. However, the high cost of this operation, in part due to the heavy import duty on tin plate and solder, meant that the product was very expensive.

During 1907 a central marketing system was finally established in both Perth and Fremantle (Gale 1908). This resolved many of the earlier marketing problems and encouraged more fish to be forwarded from outlying centres. However, predictably it adversely affected the role of the metropolitan fish hawkers.

Despite earlier problems with the relatively high cost of tin plate and solder, the three Mandurah canneries continued to operate into the 1920's (Aldrich 1922) and produced, as well as the canned product, small quantities of smoked fish (Aldrich 1917).

By the late 1920's and early 1930's commercial fish catches from the estuaries of south-Western Australia had begun to increase (Tables 2 and 3). Outlying centres such as King George Sound and Princess Royal Harbour, Oyster Harbour and Wilson Inlet became the major commercially fished estuaries of the south coast. However, the cool storage process during rail transportation was still too inefficient to guarantee that fish arriving from Albany at the Perth metropolitan markets were in good condition. Added to this, freight was charged on the weight of the fish,the ice and the box, not just the fish. This severely reduced profit margins for fishermen and discouraged them from transporting fish to the metropolitan markets (Aldrich 1927). Thus much of the fish caught in these southern estuaries continued to be consumed by the local population, by towns people on the Great Southern Railway and in the adjacent goldfields (Aldrich 1929a).

Good catches of fish, principally black bream, yelloweye mullet and sea mullet were beginning to be taken from the estuaries between Albany and Esperance. The fish was transported from these estuaries to the Perth-Albany rail link by truck, and then by rail to the markets in Perth and Fremantle. However a number of these fish marketed during the summer were condemned. Thus fishermen were advised not to send fish from the estuaries east of Albany to metropolitan markets during the summer months (Aldrich 1928). Those men who fished in the more westerly located south-coast estuaries, such as the Blackwood River estuary and Broke and Irwin Inlets were similarly disadvantaged by inadequate storage and transport facilities.

Because the entrances of most of the estuaries east of Albany were closed temporarily or permanently by sand bars, it was soon clear that intense fishing while the bars were closed rapidly depleted fish stocks within these estuaries. Thus netting in these eastern estuaries was prohibited (Aldrich 1929b).

Although the marketing system had improved in the metropolitan area, there was still a major problem in that there were no cool storage facilities at these markets. The cool storage that was available was privately owned and not located on the market sites.

As the community expanded economically, the contribution of estuarine fisheries to the total commercial fish catch of the State decreased, having to compete with the small but rapidly growing sectors of the fishing industry which were operating in the inshore-marine environment, i.e. rock lobster and deep sea fishing (snapper and jewfish) industries. However, estuaries still produced good quantities of fish and crustaceans principally for the local fresh fish market. In fact the majority of the crabs and prawns consumed by the people of Western Australia still came from the estuaries of the temperate regions of the State, particularly the Swan-Avon and the Peel-Harvey, and to a lesser extent from Leschenault. Throughout the period between 1920 and 1930, annual State prawn catches ranged from a low 30 800 kg in 1923 to a high of 65 800 kg in 1928, while catches of crabs varied from 10 400 kg in 1923 to 22 300 kg in 1926 (Aldrich 1921 to 1931).

From the 1930's onward, the estuarine fishery progressed through a period of unchecked but relatively slow expansion, mostly in terms of men employed in the industry, but also in terms of actual total catch (Tables 2 and 3). However factors such as the relatively small population of the State; the great distances involved and difficulties of communication; the availability of ample agriculturally derived protein; and later the advent of World War II from 1939-1945, all continued to constrain the rate of expansion of this fishery.

During the late 1940's and early 1950's the development of a lucrative and expanding export market for rock lobsters (Sheard 1962) encouraged increasing numbers of fishermen to participate in the rock lobster (then known as "crayfish") industry in preference to the wet fishery. Those fishermen employed in the wet fishery found that their products could not compete on the open export market, nor locally with the relatively cheaper and more convenient frozen imported product. Apart from a further attempt to establish fisheries in the estuaries east of Albany (Table 4), and a further attempt at canning fish at Mandurah in 1956, very little effort was made to undertake new initiatives in estuarine fisheries.

Thus particularly during the 1960's, wet fishermen, many of whom were part-time, were receiving a decreasing income from fishing. Inducement for fishermen to remain in the wet fishery was further eroded firstly by the establishment of an export market for Shark Bay-Exmouth Gulf prawns in 1962 (Slack-Smith, 1978) and later by additional local and export markets for scallops and abalone respectively.

Marketing difficulties which had been experienced throughout the early history of the wet fish industry continued. The channels of distribution, particularly from centres outside the metropolitan area remained long and at best only marginally profitable. The quality of the perishable product was often badly affected as a result of being transported on outmoded rail facilities. Also the arrival of the product in Perth more often than not did not coincide with market times.

These forementioned problems were compounded by the fact that fishermen often sold to the highest bidder, showing only limited allegiance to the one buyer. Buyers ranged from metropolitan market agents, co-operatives, wholesalers, canning or other processing companies, fish shop proprietors and the general public.

Once in the hands of processors/wholesalers, the product from estuaries was mostly too small (because a larger proportion of them were juveniles; see Section V A(i)) to be filletted, frozen and packed economically to compete with the frozen imported product. Retailing whole fresh fish was also difficult because the consumer preferred the cheaper more convenient already processed frozen product that was being imported.

Although high quality species such as whiting and cobbler were always in demand as food fish, there were insufficient quantities of these species available to support the large number of estuarine fishermen operating in the State. Thus many fishermen were forced to catch species that could be sold as rock lobster bait, noting that it was often very difficult to dispose of many of these bait species such as mullet or Perth herring at an economic price.

Because of the nature of the estuarine fish resource (see Section V C) and the rapidly increasing demands of other users of estuarine areas, e.g. recreational fishermen (Lenanton, 1979), boaters etc, the potential for growth of the commercial fishery was clearly limited.

Being aware of these and other similar problems in the inshore- marine wet fishery, the Government commissioned, in 1969, a firm of consultants to investigate the wholesale and retail marketing of all wet fish in Western Australia. As a result of Steering Committee guidance the consultants were eventually only required to undertake a "pilot study". Their resultant report to Government (Scott 1969) generally outlined the situation reported above.

One of their most important conclusions from the pilot study was:-

"There are more professional net fishermen than the industry can or is likely to be able to economically support. A large proportion of these fishermen are estuarine fishermen".

Following on from this conclusion, it was recommended that government should:-

"Do what it can to reduce the numbers of fishermen, particularly estuarine fishermen in the industry and only issue new professional fishing licenses where there is a strong economic case for doing so".

The factors which are believed to have contributed to this "oversupply" of estuarine fishermen have been discussed above and were mentioned briefly in the Scott report. However, irrespective of the precise reasons for the development of this situation, the end result was that there were too many professional estuarine fishermen, many of whom were part-time, for each to receive an economical return from his catch.

The Government accepted the above recommendation and proceeded to try to reduce the numbers of professional fishermen operating in the State's estuarine fisheries. However while acknowledging the existence of too many estuarine fishermen, the Government firmly believe that professional fishing is a proper use of the estuarine fish resource. Their view is best summarised in two extracts from State of the Fisheries of Western Australia 1977-78 (Department of Fisheries and Wildlife 1978).

"The estuaries are being used to an increasing degree by the community for many forms of recreation including water skiing, boating, and amateur fishing, crabbing and prawning. These forms of activity are, of course, a proper usage of the estuarine resource, but each increased activity has the potential to affect adversely the catch of the professional fisherman. Many of these fishermen have been actively engaged in providing fresh fish for the Perth markets over decades of time, and planned usages of the estuaries must take into account the needs of the professional fishermen even though their numbers are small compared with that of the touring and sporting public".

"In considering the use of a fishery resource in the estuaries it is necessary to note that both professional and amateur fishermen are operating in a responsible manner. The professional is providing fresh fish for the public and in doing so he is maximising his income, whilst the amateur is taking fish for himself and his friends and at the same time maximising his enjoyment".

Thus, since 1969, the Department of Fisheries and Wildlife has endeavoured to reduce the number of fishermen fishing in estuaries to a level at which individual fishermen are able to achieve a worthwhile economic return from fishing alone. This is being achieved by:-

(i) Not issuing any new estuarine fishing licenses.

(ii) Not renewing estuarine fishing licenses that have expired, either as a result of the death of the fisherman, or the unwillingness of the fisherman to continue in the fishery.

Although in terms of commercial production this document only covers the development of the fishery up to and including 1975 (see Section I, II B), it is important that more recent developments in the fishery involving some important policy decisions be reported.

For Departmental management purposes, the estuarine fisheries of temperate Western Australia have been divided into the following distinct fisheries, termed conditional license estuarine fisheries.

	Name	Number of Fishing Units Operating, 1979
1.	Hardy Inlet Estuarine Fishery	4
2.	Leschenault Estuarine Fishery	18
3.	Mandurah Estuarine Fishery	45
4.	Swan-Canning Estuarine Fishery	32
5.	South Coast Estuarine Fishery	72

The first four of these, together with the appropriate instructions to licensing officers (rules) were declared by Ministerial approval during 1976, although at that stage, 1 and 2 above were combined, and it was not until prior to their eventual gazettal that the two fisheries were separated and considered as independent entities.

During 1978, the south coast fishery was added to the initial group of four fisheries. The initial four of the above five fisheries were then gazetted together on February 23, 1979, including instructions to licensing officers (rules) together with a schedule of the names and class of fishermen, and the registration numbers of the authorised fishing vessels, which comprise each fishing unit.

Except for a schedule containing a description of each fishing unit the south coast fishery was gazetted on February 8, 1980. The number of units in the south coast fishery was, at the time of publication, fixed. The number of units operating in the other four fisheries are subject to review from time to time.

34416—4

IV FISHING GEAR AND TECHNIQUES

The design and use of present day fishing gear varies considerably from estuary to estuary. Historically these differences have developed in response to circumstances related to the exploitation of the various target species in physically different estuarine systems. It is the intention here to report in general terms the various types of gear and techniques used by professional and amateur estuarine fishermen, noting that although the basic fishing techniques have changed little over the years, the specific gear dimensions such as length and mesh size have changed and are likely to continue to change in future years.

A. Professional fishermen.

Setting and hauling gill nets are the two main methods used by commercial fishermen in the estuaries of Western Australia (Figure 2). Except when fishing for cobbler and crabs, fishermen practising these two techniques mostly use the same basic nets. The two methods differ, however, in that setting involves fishermen leaving gill nets unattended overnight in areas where fish are likely to be caught. In contrast, hauling is principally a daytime technique involving actual searching for and hauling schools of known species of fish. Historically there are four methods of hauling fish. "Circling" is the most commonly used method (Figure 2). After a school of fish is detected over clear hauling bottom, the net is laid around the school. One end is attached to the boat while the other end of the net is slowly hauled into the boat. As the circle gets smaller, the fish tend to panic and are meshed in the remaining net before being hauled into the dinghy. The other three methods involve frightening fish that are lying over bottom that cannot be hauled conventionally, away from such areas and into an appropriately positioned net where they mesh. The first of these, "bull ringing" involves completely circling the area with net; "half-mooning" involves surrounding the area where the fish are located with a semi-circular shot from the shore, while "bashing" involves laying the net in close proximity to the fish in any configuration except the two mentioned above. The most common method of frightening the fish is to strike the surface of the water with an oar.

Some hauling is still done from small netting rowboats. However, in most hauling and setting operations, gear is laid and retrieved from open motorised netting dinghies, which are normally approximately 5 m in length. In earlier days inboard motors were preferred to outboards because they ran more quietly. However, in recent years outboards are increasingly being used because the more modern motors are more powerful and are now built to run more quietly.

In the lower west coast estuaries (Figure 1) sea mullet, yelloweye mullet, cobbler, Perth (boney) herring, whiting and garfish are the main target species, with quantities of most other species resulting from incidential catches when fishing for target species. Basic haul and set nets are often in excess of 500 m in length. The minimum stretched

mesh size for these nets in the Swan-Canning is 57 (54 mm for yelloweye mullet only) and 63 mm respectively. In addition there is a haul net called a "sunk net" which can only be used in Melville water during certain times of the year, a feature related to the periods of peak abundance of the species being sought. This net has, amongst other design restrictions, 76 mm wings and a 57 mm bunt. In Leschenault Inlet and the Peel-Harvey estuary, the minimum mesh size for basic (haul/set) nets is 51 and 47 mm respectively. When hauling for whiting, cobbler or garfish a shorter smaller meshed "bunt" or "pocket", with a mesh size of 44, 44 and 28 mm respectively is attached to one end of one of the larger basic nets (Figure 2). In the process of hauling all fish are worked down into the terminal bunt allowing all legal sized fish to be retained, while undersize fish escape through the mesh of the bunt. In the case of cobbler, which tangle very easily in lighter ply nets, the bunt is made of extra heavy monofilament or multifilament twine, which acts as a "seive", allowing the undersized fish to escape unharmed (Figure 2). Bunts or pockets are not usually used when hauling for the mullet species.

As mentioned above, when setting for all species except cobbler most of the same basic nets are used. Set nets for cobbler however, have a minimum mesh size of 76 mm, and a restricted net depth.

Crabs can be taken in all commercial west coast estuaries by means of drop nets, hand scoop nets and set nets (Figure 2). In the Swan-Canning set nets must have a minimum mesh size of 63 mm, and are subjected to a restricted overall length. However, the use of special larger meshed crab set nets in estuaries other than the Swan is unregulated. Cobbler and crabs are also caught incidentally in basic haul and set nets when they are used to catch other species such as mullet. However, when caught in this gear, both species are likely to be under the legal minimum size. Thus fishermen have learnt to avoid such problems by only using the appropriate gear in areas inhabited principally by legal sized individuals of these two species.

In those estuaries situated from Albany westward on the south coast, sea mullet, yelloweye mullet, cobbler, whiting and garfish are still the major target species, with Australian herring and flathead also sought. Cobbler set nets are the same as those used on the west coast. In Wilson Inlet garfish are able to be taken on a seasonal basis in 44 mm mesh net of special design. In Irwin Inlet, a black bream set net must have a minimum mesh size of not less than 89 mm. All other set nets used in Irwin Inlet, Wilson Inlet, Oyster Harbour and Princess Royal Harbour have a minimum mesh size of 57 mm. All nets used in Broke Inlet must have a minimum mesh size of 63 mm.

In commercial estuaries east of Albany, black bream, sea and yelloweye mullet are the main target species. Gear restrictions apply only in the Bremer and Pallinup estuarine systems where there is a minimum mesh size of 76 mm; and in Bandy Creek ($33^{o}50'$ S latitude, $121^{o}55'$ E longitude) where mesh or set nets must have a minimum mesh size of 89 mm, and a "seine

net" must have minimum mesh sizes in the wings and bunt of 76 and 25 mm respectively. Length restrictions also apply to both these Bandy Creek nets.

In all commercial estuaries prawns can be caught legally as an incidental catch in gear used to catch other species. Usually, however they are caught by a hand trawl net with maximum length of 3 m, or a hand dip net with 61 cm maximum diameter. A hand operated dredge net with 120 cm maximum opening width and a beam tide trawl with a maximum width of 4 m are legal only when used in certain areas of the Peel-Harvey estuarine system (Figure 2). All the above prawn nets must be constructed with net of not less than 16 mm stretched mesh.

Fish traps (Figure 2) are able to be used commercially in most estuaries. However this method is not commonly used, except to catch cobbler in the Swan-Canning and to some extent in the Peel-Harvey estuary, and to catch leatherjackets in Princess Royal Harbour.

Although a net of a certain miminum mesh size is specified for each major species, under certain circumstances fishermen do deviate away from this minimum in order to maximise the efficiency of their operation and the quality of the product. One strategy which is widely practised by estuarine fishermen involves the use of nets with slightly larger mesh sizes. For example in the cool winter months fish tend to be more sluggish and greater numbers of smaller ones are caught in the nets of legal minimum mesh size. To offset this, and thus reduce the chance of catching more undersize fish, fishermen tend to use slightly larger mesh sizes during these months. However other situations demand the use of nets with slightly smaller mesh sizes. For example, during the summer and autumn of 1981, Peel-Harvey yelloweye mullet were apparently in very poor condition. In order to retain all legal sized fish, a net with slightly smaller mesh size was used. However, normally during that period of the year larger yelloweye mullet are abundant, and in very good condition. Under these circumstances the use of haul nets with slightly smaller mesh sizes will result in all legal sized fish being "nosed" rather than being conventially meshed. Thus rather than having to be individually unmeshed, fish can be shaken out of the nets "en masse". The quality of the marketed product is thus improved by reducing the time taken to catch and box the fish during these hot summer months.

A third basic netting method which was more popular during the early history of the fishery is beach seining (Figure 2). These nets are often up to 1000 m in length. The main section of the net (equivalent to the wings) is normally constructed of 51 mm stretched mesh, with 25-31 mm mesh bunt situated either terminally or more commonly in the middle of the net between two wings. The net is laid in a semicircle from the shore and hauled back onto the beach; or it can be laid over offshore banks and hauled in from an anchored dinghy. This method is still used in south coast estuarine systems, notably Wilson Inlet, Oyster Harbour and Princess Royal Harbour. However its

successful operation is dependent on the availability of a smooth sandy hauling bottom. Such conditions are increasingly difficult to locate in an estuarine environment plagued by abundant macroalgae which is proliferating as a direct result of increased levels of nutrients derived mainly from agricultural practices in catchment areas.

Because they are less visible to fish, monofilament nets tend to produce higher catch rates than multifilament nets. Thus virtually all haul and set nets used in the present day fisheries are made of monofilament twine. The replacement of multi with monofilament nets has been gradual from the time of their first introduction into the Peel-Harvey fishery during the late 1960's. However, the visibility of nets to fish is not a factor which affects the catch rates of beach seine nets. Thus, beach seine nets are still constructed from multifilament twine, particularly because of the added advantage that substantial lengths of this type of netting can be handled more easily during netting operations, and can be stacked more efficiently in the netting dinghy.

B. Amateur fishermen

Set and haul nets are also used by licensed amateur fishermen Both net types have length restrictions of only 60 m; and the former a minimum mesh size of 57 mm, while the latter is 63 mm, and is not to be constructed with a "pocket" or "bunt". Amateurs are also permitted to use fish traps in certain areas in most estuaries, and can catch crabs by means of drop nets or hand scoop nets, and prawns by means of a hand held trawl net and hand dip net. Dimensions and mesh size for crab and prawn nets are the same for both amateurs and professionals.

V CATCH AND EFFORT DATA

A. Interpretation of catch and effort data

The amount of fishing effort expended each month by a given estuarine fishing unit varies greatly and in practice ranges in some cases from 1 to 31 days per month. Under these circumstances, the time spent fishing would clearly be the most accurate index of effort. Although such data are available over some of the past years for the fisheries of several of our estuaries, they are not available continuously throughout the history of the entire fishery, and thus were not able to be used to explore the long term trends in these fisheries. The only consistently available unit of effort for our estuarine fisheries is the number of men and boats, which would seem to represent an extremely gross estimate. However, analysis of some recent catch and effort data from the Swan-Canning and Peel-Harvey estuaries (Lenanton et al. ms. submitted) has shown that the number of days spent fishing is directly proportional to the number of boats fishing each month. Therefore, at least for the above two estuaries, the magnitude of catches is equally well related to the time spent fishing (effective effort) and the number of boats (measured effort).

It is clear from the data listed in Table 3 (a)-(h) that catches fluctuate considerably between species, between estuaries and from year to year, and that these fluctuations are apparently not entirely related to different levels of expended effort. Although it may be desirable, it is not possible within the scope of this paper to discuss these catch trends for every species taken commercially from each of the eight comercial estuaries. However, it is important to identify and understand in relatively general terms the following most important factors which contribute to these catch fluctuations:-

(i) The life history strategies of the different species in the areas able to be fished;

(ii) The manner in which fishermen harvest these stocks i.e. the fishing methods;

(iii) The market demand for a given species;

(iv) The accuracy of the recorded catch and effort statistics.

(i) *Life history strategies*

Fish adopt a number of different life history strategies in order to utilise the south-Western Australian estuarine environment (Lenanton 1974a, 1977, 1978; Chubb et al. 1979).

There are basically three strategies involved:-

(1) Some fish are able to undergo the whole of their life cycle within the estuarine environment. Included in this group are black bream and yellowtail perch (yellowtail trumpeter). Also included in this group are cobbler, flathead, flounder and whitebait which, provided estuarine conditions are suitable, can undergo their entire life cycle in the estuary in a similar way as they would in the inshore-marine environment. With the exception of whitebait all stages of the life cycle of the above species are exposed to commercial fishing operations in estuaries.

(2) Some fish use the estuary predominantly as a nursery area. This group includes mostly essentially marine fish such as the mullets, whitings, silver bream (tarwhine), and tailor. It is principally the immature component of populations of these species which are subjected to commercial exploitation in our estuaries.

(3) The third category of fish use the estuary as a feeding ground at some stage after their first year of life, i.e. for maturing and mature individuals. Many species such as the leatherjackets and the red gurnard which are only caught intermittently or are represented in the commercial estuarine catches in very small numbers and the "marine stragglers" of the Swan Avon River system (Chubb et al. 1979), adopt this life history strategy.

There is a fourth group comprising freshwater species. However, this group is represented by only a few species none of which contributes to the estuarine commercial fish catch (Lenanton 1977, 1978).

The abundance of each species will depend to a large degree on how successfully it copes with both natural environmental variables (hydrological, topographical and biological), and the man-made environmental perturbations to which it is subjected. These will be examined in the following sections.

Environmental factors

Natural environmental factors such as salinity, temperature, dissolved oxygen, turbidity, available food and shelter all influence the manner in which the different species utilise the estuaries (Lenanton, 1977, 1978) and each cannot be thought of as operating entirely independently of the other. However, the single factor which clearly has the most influence is salinity. The manner in which salinity, and indeed the other parameters listed above, fluctuates seasonally in Western Australian estuaries is well documented (Hodgkin 1974; Lenanton 1974b, 1977, 1978). Thus, species which are able to cope with both winter periods of reduced salinity, and the prolonged periods of exposure to the summer hypersaline conditions (i.e. the more euryhaline species), and thus are able to be present in the estuarine environment throughout the year, will, all other things equal, contribute more towards the annual commercial estuarine catch, than species that can only cope with a very narrow range of either seawater or freshwater salinities (stenohaline species).

The monthly catch rates of four commercial species of fish from the permanently open Peel-Harvey estuary (Figure 3) serve to illustrate this point. As noted above the majority of species which adopt the third life history strategy are to a greater or lesser degree stenohaline. Thus, they are most commonly present and caught in the estuary only when the salinities are approximately equal to seawater salinities, i.e. during the summer months. Therefore, the annual catches of species such as sea garfish are generally relatively low (Table 3, Figure 3). Significant estuarine catches are more likely to be of those species which adopt the first or second strategy above, which is indeed the case. Clearly, the species which adopt the first strategy, by definition, could be expected to be caught right through the year. Good examples of this are provided by species such as Perth herring (Table 3, Figure 3). The ability to cope with the freshwater flush of the winter months varies markedly between species which adopt the second strategy. Some such as sea mullet are clearly able to cope better, being caught consistently right throughout the year in many of the State's estuaries (Figure 3). Other species such as tailor, apparently have some trouble coping with excessive periods of low salinity, with the result that winter catches of these species do

tend to fall away, relative to other more euryhaline species (Figure 3).

It should be noted that year-round catches of species such as sea mullet may occasionally be taken from the normally closed estuarine systems as a result of their being trapped in the estuary at times when a sand bar forms, blocking the entrance of the estuary to the ocean.

To further illustrate the points made above, knowledge of the biology of each species has been used to identify the life history strategy which each species adopts, and to relate this to the order of magnitude of the annual commercial catch of each species (Table 5).

Topographical variables

The most important topographical variable is the nature of the entrance of the estuary to the ocean. South Western Australian estuaries can be grouped arbitrarily into permanently open, seasonally closed, normally and permanently closed systems (Lenanton 1974a, 1974b; Hodgkin and Lenanton 1981). Clearly, any closure of an estuarine system has the potential to affect greatly the recruitment of fishes which adopt strategy two and three (Table 5). The less frequently the estuary opens to the ocean, the fewer the species that are found in the estuary, or simplistically the lower the species diversity (Lenanton 1974a; Hodgkin and Lenanton 1981). Comparisons of the number of species of fish and commercially important crustaceans recorded from the different categories of estuarine systems of temperate Western Australia (Table 6) serve to illustrate this point.

Sea and yelloweye mullet are two of the most important fishes taken commercially from many of the more eastern south coast estuaries which are normally closed. Often these two species are only available if there is substantial rainfall to provide sufficient catchment runoff to generate an opening of the estuary to the ocean, thus allowing recruitment of these species from the ocean into the estuary. Then the salinity of the estuary must remain sufficiently low for long enough to allow the recruits to grow to a marketable size.

The long term closure of estuary entrances by sand bars can also have a marked effect on the truly estuarine species such as black bream. During long dry periods, black bream become restricted to the upstream riverine pools, because salinities of the lower estuary of some systems are often too high for the survival of any species of fish. Heavy sustained catchment runoff can result in these bream colonising the lower estuary in great numbers (presumably aided by recruitment of juveniles through successful reproduction); and as was

the case with mullet, if the hydrological conditions of the lower estuary remain favourable for long enough, fish are able to grow to marketable size, and thus are worthy of exploitation.

Human interference

Perturbations generated by human activities can have a more subtle effect on fish species and thus can be much more difficult to detect.

One of the most common disturbances is the relatively frequent occurrence of increased levels of suspended solids in estuaries, mostly as a result of catchment clearing, or dredging in the estuarine systems. The effects of suspended solids on fish and fisheries has been extensively reviewed (Wilber 1971; Moore 1977) and include reports of a wide range of effects on fish reproduction, metabolism and behaviour. This form of disturbance has also been discussed in the context of fishes of Western Australian estuaries by Lenanton (1974b, 1978).

Possibly the most significant effect in terms of estuarine fish catches, is the manner in which such disturbances can influence fish distribution. For example in the Swan-Canning* River system, relatively high concentrations of suspended solids, particularly during periods of winter flushing, could conceivably force fish out of commercial fishing areas such as Perth and Melville waters into more downstream areas such as Mosman Bay and Blackwall Reach which are closed to commercial fishing.

Although only of recent occurrence in Western Australia, it is important to note that the input of nutrients from surrounding agricultural land into the Peel-Harvey estuary, has substantially increased the biomass, first of macroalgae and later of phytoplankton (Hodgkin et al. 1981; McComb et al. 1981). It has been demonstrated that these increases in algal biomass have been respectively beneficial to commercial fish catches from this estuary, (Lenanton et al. in press), and detrimental to commercially important fish species (Potter et al. 1983).

It is also as well to note here that chemical pollutants, such as heavy metals and pesticides, can also indirectly or directly affect the estuarine fish stocks and thus commercial fish catches. The mechanisms, and examples of problems resulting from such pollution are reviewed by Johnston (1976). In this context it is worthwhole noting that the available evidence (Marks et al. 1980) showed that the muscle tissue of fish from the Swan-Avon, Western Australia's most heavily utilised river system, was not seriously contaminated by heavy metals.

* Swan-Canning = Swan Avon

It should also be noted that physical disturbances created by other users of the estuaries, such as boaters and water skiers, can also influence the estuarine environment (Zieman, 1976), its fish populations (Lenanton 1974b), including eggs and larval stages (Morgan et al. 1976) and thus ultimately catches.

(ii) *Fishing methods*

There can be considerable variation in the estuarine areas fished, relative to the areas where the commercially important fish are distributed. For example, the lower portions (approximately equivalent to the channel to the ocean) of both the Swan-Canning and Wilson Inlet systems are completely closed to professional fishing (Figure 1). It is in these areas that a good proportion of the estuarine stocks of a number of important commercial species occur, and it is the fish in these areas that are the sole domain of the amateur angler. Some of the more important species include mulloway, flathead, flounder in the Swan-Canning estuary, and King George whiting and Australian herring in Wilson Inlet. Thus the magnitude of the commercial catch in these estuaries depends greatly on the distribution of the fish in relation to fishing effort. However, seasonal closures of whole estuaries also clearly affect the magnitude of the commercial catches from those estuaries. For example for many of the years for which this document presents catch data both Irwin and Broke Inlets were subjected respectively to nine and between five and ten month closures. This needs to be taken into consideration when making comparisons between the catches from different estuaries.

Varying seasonal and annual catchability of the different species can also contribute to fluctuations in catch rate and thus catches within one estuary, and between estuaries. From research in the Blackwood River estuary (Lenanton 1977) it was concluded that for a given sampling team using the same units of gear in a similar manner throughout a given time period, i.e. a year, the catchability of an individual seine caught species varied both with respect to sampling location within the estuary, and seasonally at any sampling location within the estuarine system; and the catchability of gill net-caught species varied seasonally within the estuary, but probably not between locations at any selected sampling time.

It is appropriate to consider the gill net findings in the context of all commercial estuarine fisheries which use the basic techniques of hauling and setting gill nets. Variables such as environmental conditions, gear design and fishing methods need to be considered. Over the years, there have been similar seasonal and annual trends in gear design and fishery methods in the various estuarine fisheries. Thus catchability of species within these estuaries could be expected to have reflected these trends. However there clearly can be dissimilar seasonal and annual trends in environmental

conditions within and between estuaries, which have the capability to influence catchability and catch rate of species within estuaries.

(iii) *Market demand*

Market demand is another very important factor which contributes towards catch fluctuations. There are numerous examples throughout the history of the fishery to illustrate how strong and persistent market demand generated greater catches. For example, during the latter years of World War II, when imported food was scarce and canning was commonly practised, the demand for species such as Perth herring and sea mullet was intense. Thus, the catches of these species were elevated, particularly in the Peel-Harvey estuary during 1941 and 1942 (Table 3).

More recently during the early 1970's, there was an increased demand for Perth herring and mullet for use as rock lobster bait, because of the limited availability and increased price of the more traditional baits (Morgan and Barker 1974). Thus, the catches of Perth herring and mullet again received a boost, particularly from the Swan-Canning and Peel-Harvey systems which are both located in close proximity to the rock lobster fishery.

However, there are other species, such as whiting, cobbler and crustaceans which are always in demand as a prime quality food item. Historically, fishermen would have consistently sought these species, and catch rates of these species would more reliably reflect trends in actual abundance.

(iv) *Accuracy of recorded data*

Explanatory notes attached to Tables 2 and 3 cover most problems which have arisen in this area. However, it is as well to note that in particular, inaccurate information from fishermen and to a lesser degree coding errors during data processing can contribute to the observed fluctuations in catch rates and catch. For example, in Table 3(h) 36483 kg of Australian salmon were listed as having been caught in Broke Inlet in 1970. Compared with the relatively small catches of all other years, the 1971 reported catch is very high, particularly from only two fishermen who fished for only three months of the year (the period during which the estuary is open to commercial fishing) and who reportedly also caught 8931 kg of other species. Clearly, the fish were caught outside the estuary, but have been incorrectly assigned, most probably by the fishermen, as having come from the estuary. Fortunately, most such obvious instances can be identified and appropriate allowances can be made when using such data.

B. Use of catch and effort data

Estuarine fisheries differ from most traditional single species marine fisheries, in which the assumptions are made that:

(i) environmental conditions are usually relatively stable,

(ii) the entire unit stock is available for exploitation,

(iii) the distribution of fish in relation to fishing effort is uniform or random, the chosen unit of recorded effort accurately reflecting the more subtle changes in fishing intensity.

In this situation fluctuations in catch are usually directly related to the levels of effort expended, and provided the effort is standardised, then catch per unit of effort (CPUE) usually provides the best available index of stock abundance.

Compared with traditional single species resources , estuarine species display the greatest population variability for only a moderate population magnitude (or expectation) (F.A.O. 1978). In addition, estuarine exploitation regimes are complicated. In Western Australia although only a few species normally predominate in the catch of any one of a number of different unit operations i.e. seine netting, trapping, gill netting, and handlining (mostly amateur), up to ten species can be taken simultaneously in one of these operations. Target species can vary daily, seasonally, and also between estuaries; and mostly effort is not applied randomly or uniformly over the unit stock. In other words estuarine fisheries can be thought of as multistock, multispecies, and multigear fisheries. It is not always possible to allocate proportionally the recorded effort (men and boats) to each species in such fisheries. In practical terms this precludes the use of available CPUE data as an index of overall stock abundance. Further, for fishes which adopt strategies 2 and 3 above, there is the additional complication that those fish which are present within the estuary comprise only part of the whole stock, the oceanic component of which is not confined to coastal waters where commercially fished estuaries are located, but is distributed a considerable distance to the north of the west coast estuaries and east of the commercial south coast estuaries (Chubb et al. 1979). Thus at best CPUE data provide a rather poor index of the overall unit stock abundance of the majority of commercial species that are caught in the temperate estuaries of Western Australia. Nevertheless, CPUE data can provide a relatively good index of the abundance of that part of the stock of a particular species present in a given estuary, such as the Swan-Canning or Peel-Harvey (Lenanton et al. in press). As such it also provides an index of the condition or state of an estuarine fishery.

VI THE STATE OF THE FISHERIES

A. Comparisons between species

Noting the reservations referred to in the previous section the recorded catch per unit of effort (CPUE) data can be used to provide an indication of the state of the individual fisheries of each of the commercially important estuarine systems. This is particularly true of fishes which adopt strategies two and three (V(i) above). When reviewing the CPUE trends of these species in an individual estuary, and having noted (Section V) that the numerous factors which affect the magnitude of catches vary from estuary to estuary, it is most unlikely that there would ever be a consistantly decreasing trend in the CPUE of a given species in all estuaries simultaneously. However, if one was detected it would be reasonable to conclude that the overall level of stock abundance of that species may be declining. Although this type of trend could also be interpreted as the estuarine habitat generally becoming less "useful" to the species, such an explanation is less likely because it would be unusual for all estuarine habitats to deteriorate or change in such a way as to preclude the same species from each system simultaneously. Habitat change would be much more likely to be estuarine specific and thus result in the changing trends in CPUE in a single estuarine system e.g. such as those that have recently occurred in the Peel-Harvey (see p. 46), rather than in all systems.

From Table 5, it is apparent that the catch of eleven of the group of some thirty six commercial "species" of strategies 2 and 3 usually exceeds 10 000 kg annually. The long term CPUE trends for each of these species show fluctuations, which in some instances are rather extreme. However, there appears to be no consistent long-term downward trend in the CPUE of any one of these species, either simultaneously throughout all estuarine systems, or in any one estuarine system (Table 3).

Fishes of strategy 1 e.g. black bream, do present rather a different situation. Provided, as is implied by the definition of the strategy, that for a period there is no interchange between the populations in the estuary and those in the marine environment or in other estuaries, then of the four species which adopt this strategy whose catches exceed 10 000 kg annually (Table 5), possibly the CPUE trends of cobbler, flathead and anchovy/whitebait from selected estuaries may provide an index of the state of their respective unit stocks over that period during which they were confined to that estuary.

Although it is believed that the remaining member of the group, i.e. Perth herring, can reproduce and live till at least maturity entirely within an estuarine system, older fish do move between the estuary and the ocean and perhaps other estuaries. Thus individual estuarine CPUE trends probably provide little indication of overall stock levels of this species although because it is a fluvial anadromous* (Nikolsky 1963) species, decreasing CPUE trends may indicate that conditions which favour breeding or young survival and growth have deteriorated.

*Moving from the sea to the upper estuary/lower riverine regions to spawn.

Although they do not contribute greatly to the commercial estuarine catch, black bream and yellowtail perch are two species which are truly estuarine, a separate discrete population of each of these species being supported in individual estuarine systems. Thus despite obvious constraints imposed by closed waters CPUE trends within these estuaries probably provide an indication of the status of the respective estuarine stocks. Accepting this, indications are that black bream populations are declining in the Peel-Harvey estuary, Wilson Inlet and to a lesser degree Oyster Harbour. Similarly yellowtail perch populations in the Swan-Canning, Peel-Harvey and Leschenault estuaries appear to have declined noticeably. However, this trend could in some way be influenced by the reduced demand in recent years for this species for use as rock lobster bait.

B. Comparisons between estuaries

Examination of the composition of the various estuarine catches has enabled many interesting comparisons to be made between the fisheries in each of the different commercial estuaries of the State. The most obvious is that generally speaking, species that are able to, tend mostly to utilize estuaries which lie well within their range of geographic distribution. For example sea mullet, yelloweye mullet, cobbler and King George whiting which are all widely distributed in both the lower west and south coasts are all important contributors to the fish catch from the temperate estuaries of both coasts. Catches of others such as western sand whiting are more plentiful in west coast estuaries while Australian herring is a dominant component of the catches from south coast estuaries. Although these two species occur in waters off both the west and south coasts, western sand whiting tends to be most abundant in lower to middle west coast areas, in particular the Shark Bay area (Lenanton 1970), while Australian herring is most abundant in waters off the south coast.

In contrast to species mentioned above such as the mullets, there are some species which are confined to either the west or south coasts and which are only represented in catches from estuaries situated on these coasts. Perth herring, a major contributor to the west coast estuarine catch, and to a lesser extent yellowtail perch are both restricted in distribution entirely to the west coast. Similarly the long snouted flounder, and the commercial leatherjacket species taken in waters off Albany, do not occur on the west coast. The significance of the south west corner, or more specifically the Cape Naturaliste area of the State as a zoogeographic barrier is discussed in more detail by Chubb et al (1979).

In contrast to other permanently open south coast estuarine systems, it is notable that Princess Royal Harbour-King George Sound (block 9504) supports a rather diverse commercial fish fauna, the principal components (annual catch exceeding 10 000 kg, Table 5) consisting of the basically stenohaline species such as pilchard, Australian herring and leatherjacket

(Table 3). This is clearly due to the fact that Princess Royal Harbour and King George Sound receives very little freshwater input, and thus the salinity is usually relatively stable annually at about seawater concentration. Thus, the environment is one more typical of a marine embayment being able to support a diverse and abundant fish fauna of inshore-marine stenohaline species.

One of the most interesting comparisons is the striking difference between the fisheries of the two permanently open and adjacently situated Swan-Canning and Peel-Harvey estuarine systems. Historically, greater catches of western sand whiting, King George whiting, sea garfish and prawns have come from the Peel-Harvey system, while greater catches of flathead, pilchards, and to a lesser extent flounder have been taken from the Swan-Canning system, even though all these species are common to both systems (Table 3) (Chubb et al. 1979).

Recently it has been noted (Chubb et al. 1979) that certain species, such as King George whiting, western sand whiting and sea garfish, that could be expected to utilise extensively the Swan-Canning system are only present in very small numbers. The explanation offered by the authors is that these species tend to move away from the frequent and extreme disturbance created in the water and river bottom by the movement of the many large ships that enter the narrow Fremantle Harbour which is located in the lower estuary. These species are in fact much less abundant in the Swan-Canning than in adjacent relatively undisturbed systems such as the Peel-Harvey.

This point of view is not new. It was first expressed as early as the 1890's (Thompson 1898). At that time it was considered that the Swan-Canning system could never be important commercially because the "varied disturbing influences of the variety of operations common to sea ports so largely frequented by shipping as Fremantle is, must affect the fish entering the system, particularly the anadromous species". Several years later, Gale (1901), stated that during 1900, blasting in order to construct Fremantle harbour tended to stop mullet entering the estuary. However, in 1901 when the blasting ceased, many more mullet came into the river (Gale 1902).

Clearly, there are other possible explanations. The differences in catch composition could also be related to the rather different habitat offered by the two systems; extensive shallows in the Peel-Harvey compared with greater areas of deeper water in the Swan-Canning. However, whatever the reason, the difference in catch composition between the two estuarine systems is certainly significant both with regard to the commercial and amateur fishery.

C. The status of estuarine catches

Table 7 has been prepared in an attempt to place the commercial estuarine fisheries in perspective with the scale fisheries of the remainder of the State. This table enables the comparison of the estuarine catches of the 15 most important estuarine fish

species together with crabs and prawns, with the total State production of these species in each of the years 1965, 1970 and 1975. Man days and boat days expended are also included as is the total State production of all species of scale fish for these years.

Although this exercise has only been done for three years over the 1965/75 period of the fishery (there are insufficient data to treat earlier years in the fishery in the same manner) it serves to illustrate some important trends.

(i) Over the 10 year period an increasing proportion of the State's commercial catches of yelloweye mullet, sea mullet, cobbler, Perth herring, western sand whiting, tailor, mulloway and flathead have come from the estuarine fisheries of temperate Western Australia, while fishing effort in terms of man and boat days remained relatively stable. Although the estuarine catches of a number of other species listed in Table 7 have also increased, the catches made from areas other than estuaries have increased by a greater amount causing the estuarine catches, as a percentage of the overall catches, to decrease. This is particularly true of crabs and pilchards, both of which have been caught in increasing numbers in Cockburn Sound over recent years as a food item for metropolitan consumers, and rock lobster bait respectively.

(ii) In 1975 over 90% of the State's annual commercial production of yelloweye mullet, cobbler, Perth herring and flathead; and over 50% of sea mullet, King George whiting, tailor, mulloway, leatherjackets and crabs came from the estuarine fishery of temperate Western Australia. Thus the temperate estuaries of Western Australia produce significant quantities of the State's bait fish such as Perth herring, yelloweye mullet and pilchards; and good quantities of high quality seafood such as cobbler, flathead, King George whiting and crabs.

D. Potential for increased commercial catches

Historically the estuarine commercial catches of most of the species have fluctuated around a relatively stable mean level (Table 2). Thus it is difficult to envisage any real prospect of significantly increasing these estuarine catches markedly above those highest levels that have been achieved in past years, particularly when considering the increasing rate of both habitat alteration and estuarine recreational usage which has been experienced over recent years. However, if the overall level of commercial catches were to be increased, it is most likely that they would result from measures to increase productivity (Nikolsky 1969). A number of techniques which have been employed to improve productivity and ultimately fisheries in coastal lagoons and estuaries in developing countries throughout the world have been reported by Kapetsky (1981). They include hydraulic management, predator control, stocking, artificial nursery areas, brush park fisheries and

aquaculture. Hydraulic management has been attempted with some success in Western Australia (Lenanton 1974c).

Aquaculture could possibly be employed in an attempt to increase the productivity of several commercial species. However, in view of the present regime of estuarine usage in Western Australia, it is difficult to envisage the significant development of such techniques; with the possible exception of cage culture of selected species such as trout, or cobbler, or the culture of mussels or oysters.

Uncontrolled enrichment is commonplace in our estuarine systems as a consequence of human activities associated with this environment in particular river catchments. The Peel-Harvey estuary is a good example of a system that during the initial period of increased levels of enrichment experienced an increase in fish production (Lenanton et al in press).

There appears to be very little potential for the exploitation of additional species. However, the introduction of new processing procedures may encourage some species, which at present are principally caught as bait species, to be used for human consumption. For example whitebait, formally only used as angler bait is now in demand as a deep fried gourmet item in Perth restaurants. Perth herring are excellent marinated, and according to earlier reports (Saville-Kent 1893-4), a very edible product when smoked.

Thus, the capacity to increase commercial fish catches from our estuaries significantly would appear to be limited. The best that can be hoped for is to ensure that both the existing fish stocks and the estuarine environment are well managed.

VII PRESENT AND FUTURE MANAGEMENT

Besides having a good knowledge of the catching characteristics of estuarine fisheries, it is important, from the point of view of responsible management of these fisheries to understand and ideally predict, the effect of all forms of exploitation on both the estuarine component and total stock of each economically important fish species.

It is clear from Section VI, that single species models cannot be used to gain an understanding of the effects of exploitation on abundance of the estuarine component of fish stocks.

Also, for the same reasons as those referred to above, it is difficult to see how any of the multi-species models reviewed by Hongskul (1979) could be used.

A start has been made on the process of understanding inter-specific relationships in estuarine fish communities, with priority at present being given to economically important species. Studies of natural history, particularly early life history, movement and feeding habits have been undertaken (Chubb et al. 1981) with a view to ultimately achieving a good

understanding of the energy pathways of the fish and related communities of the estuarine ecosystem. Certainly this approach has been practised in other parts of the world (Milne and Dunnet 1972; de Sylva 1975). However, the success of modelling such systems depends critically on the quality of the data on which the models are based. Attempts have been made to model fish production in estuaries in a number of countries of the world, with a view to maximising the harvestable crop (Saila 1975). However, it will be some time before sufficiently good data are available to enable the dynamics of Western Australian estuarine ecosystems to be accurately modelled in this way and thus provide a capability to enable a more precise prediction of the effects of fishing on the estuarine fish and related biological community.

For the time being, managers must be content with using the accumulating knowledge of the life history and food web structure of these estuarine fish communities, as a biological basis for management.

Political, economic and social considerations, arising out of problems such as estuarine resource usage strategies and conflicts, clearly also must play a large part in the ultimate management decision in this heavily utilised area of the coastal aquatic environment.

Because of the variation in these factors and the biological characteristics between estuaries, precise management regulations are likely to vary from estuary to estuary (i.e. regionally). This is particularly true of regulations relating to closed seasons, closed areas and gear specifications.

However, the overall management objective is to achieve a satisfactory economic return to professional fishermen, while providing amateurs with acceptable levels of recreational opportunity; and at the same time taking care not to overexploit the fish stocks. This objective generally applies throughout all estuarine fisheries in this State. However it is important that the number of professional fishermen that are able to share this relatively constant supply of fish should not exceed a level whereby each fisherman ceases to receive an economic return for his efforts.

At present the conditional licensing system is attempting to ensure that this does not happen for the commercial fishermen. However, amateur fishing, much of which is conducted in estuaries, and aimed at species such as whiting, bream, tailor, mulloway and flathead is growing very quickly (Caputi and Lenanton 1977; Lenanton 1979) and presumably taking a larger share of this relatively stable resource (Lenanton and Caputi 1975; Lenanton and Hall 1976). Furthermore amateur fishermen are able to exploit fish populations to a very low level, because unlike professionals they are not concerned with obtaining an economic return for their efforts. Thus sustained intensive amateur effort may seasonally reduce the abundance of certain species to levels which would make commercial exploitation unacceptable economically. Therefore it would be useful,

and perhaps in the very near future necessary, from the point of view of responsible management of our estuarine fisheries, to determine the relative proportions of the estuarine fish resource taken annually by the licensed and unlicensed components of the amateur fishery.

VIII SUMMARY OF CONCLUSIONS RELEVANT TO MANAGEMENT

Presented below is a brief summary of conclusions relevant to the management of the commercial estuarine fisheries of south Western Australia.

A. Commercial estuarine fisheries of south Western Australia are multispecies in nature, with over twenty species being taken in a single estuary annually using only two basic fishing methods; i.e. setting and hauling gill nets. Although only a few species normally predominate, at times as many as ten species can be taken in a single fishing operation. Thus, it can be difficult to determine the proportion of the total effort which was expended in order to catch each species. This together with factors such as the varied life history strategies adopted by the different species, distribution of effort relative to stock distribution, and fluctuating demand for the different species practically precludes the use of available CPUE data as an index of overall stock abundance. However, it has been shown that for some estuaries, days spent fishing is directly proportional to the number of boats fishing each month. Therefore, catch per boat is equivalent to catch per day, and provides a good index of abundance of the proportion of the particular species stock present in a given estuary.

B. Catch per boat also provides an index of the condition of each of the individual estuarine fisheries (i.e. Swan-Canning, Peel-Harvey, etc.,) from year to year, noting that in some instances, commercial catches may be much less than amateur catches taken over the same period.

C. The nature of the estuarine fisheries makes the use of traditional multispecies models to gain an understanding of the dynamics of these fish populations extremely difficult. Thus, an ecological approach has been attempted in order to achieve an understanding of the interspecies relationships in estuarine fish communities. At present this involves the study of the natural history of selected species in particular the early life history strategies and feeding habits, and is being used as a biological basis for management. Ultimately, it is hoped that this information will contribute towards an understanding of the energy budgets of fish and related communities of the Western Australian estuarine ecosystem.

D. Particular attention should be focussed on all economically important species, particularly those which adopt the estuary as their only permanent habitat, as clearly

the potential for these populations to be overfished is far greater than it is for the other species which use the estuary either basically as a nursery area, or a protective feeding area for the maturing and mature portions of their populations.

E. In most instances, estuarine populations of species which adopt the latter two strategies mentioned above, should be managed on a seasonal basis with the principal objective to ensure that all potential users obtain a worthwhile share of the resource while it is present in the estuary. In this regard it should be noted that the economic return to each commercial fishing unit to a large extent dictates the number of units permitted to operate in each of these fisheries. It is important to note here that there is no control on the amount of amateur effort expended on estuarine fish populations.

F. One of the major considerations in regard to (iv) and (v) above is to ensure that the estuarine environment remains in a condition that is most acceptable to exploited fish species. This will tend to maximise the utilisation of this environment by these species, and consequently provide the opportunity for maximum catches for professionals and amateurs alike.

VIII ACKNOWLEDGEMENTS

Thanks are due to Technical Officer Mr K. Carhart for gathering and collating much of the historical information, to Miss J. Shaw, Mr M. Cliff, Miss E. Laczo, Mr N. Hall, Mr P. Rogers for their help in gathering and processing the catch and effort data; and the latter two persons together with Dr D.A. Hancock and Professor I.C. Potter for critically reading the manuscript. Mr C. Ostle assisted with the preparation of the section on Fishing Gear and Techniques. Mr M. Cliff kindly prepared the figures for publication.

TABLE 2. ALL AVAILABLE CATCH (KG) AND EFFORT (MEN AND BOATS) DATA FOR COMMERCIAL FISH AND CRUSTACEANS TAKEN FROM THE MAJOR COASTAL WATERS OF TEMPERATE WESTERN AUSTRALIA DURING THE EARLY PERIOD OF THE FISHERY, 1898-1940.

2(a) Swan River

2(b) Mandurah

2(c) Bunbury area

2(d) Albany area

Explanatory notes

Tables 2(a) - (d)

1. Yelloweye mullet (*Aldrichetta forsteri*) were commonly called pilchard during the early period of the fishery.

2. Crab weight (kg) was estimated from dozens assuming 1 dozen = 2.7 kg.

3. Prawn weight (kg) was estimated from gallons assuming 1 gallon = 3.5 kg.

4. Mandurah catch can be considered as having come from Peel-Harvey estuary, because all fish caught in adjacent marine waters could not be landed at Mandurah because of the sand bar across the entrance of the estuary. Thus they were taken direct to Fremantle by sea.

5. Bunbury area catches can be considered as having come from the ocean beaches of Geographe Bay (in particular Koombana Bay) where much netting was carried out; the Vasse-Wonnerup estuary where little net fishing took place, and Leschenault estuary where during these early years, most fish taken were caught by hand line because the estuary was closed to netting.

6. Albany area catches can be considered as having come principally from the waters of Oyster Harbour, Princess Royal Harbour, King George Sound and Wilson Inlet.

7. During the early period of the fishery mullet = sea mullet and Kingfish = mulloway.

TABLE 3. ALL AVAILABLE CATCH (KG) AND EFFORT (MEN AND BOATS) DATA FOR COMMERCIAL FISH AND CRUSTACEANS TAKEN FROM THE ESTUARIES OF TEMPERATE WESTERN AUSTRALIA BETWEEN THE EARLY PERIOD OF THE FISHERY AND 1975.

3(a) Swan-Canning Estuary

3(b) Peel-Harvey Estuary

3(c) Leschenault Inlet

3(d) Princess Royal Harbour and King George Sound

3(e) Oyster Harbour

3(f) Wilson Inlet

3(g) Irwin Inlet

3(h) Broke Inlet

Tables 3(a) - (h)

1. In the Swan-Canning during the years prior to 1922, crab and prawn weights (kg) were derived using respectively the following conversions:

   1 dozen = 2.7 kg; 1 gallon = 3.5 kg.

2. The total wetfish figure for Wilson Inlet during the period 1941-51, is clearly an underestimate because it excludes catches of important species such as Australian herring and southern trevally.

3. The catches from Irwin Inlet and Broke Inlet must be considered in the context of the annual open fishing season which usually extends for only 3 or 4 months of the year, depending on the dates when the sand bars across the entrances to these systems opened and closed.

4. Although juveniles of Australian salmon are known to occur in some of the estuaries of south-Western Australia, very large catches clearly comprise quantities of fish from the adjacent marine waters which have wrongly been assigned as having come from the estuary.

5. Some professional fishermen, particularly those of the south coast, refer to yelloweye mullet as "pilchard" or "pilch". Thus at times, this species may have been incorrectly coded as pilchard (*Sardinops neopilchardus*).

6. It is most likely that the occasional records of catches of both yellowtail perch and Perth herring from some of the south coast estuaries are inaccurate, because there is no scientific record of these species occurring in estuaries or coastal waters of this section of the coast.

7. Both whitebait and anchovy are taken commercially from a number of estuaries in south-Western Australia. Whitebait is consistently in demand, primarily as an angling bait, and increasingly as a gourmet food item. However, at present there is little demand for Anchovy. Quite often both species are taken in the same catching operation. Collectively they have been recorded in the fisheries statistics as Anchovy. However, in reality, most of these catches consist of whitebait.

8. Records of catches under the headings of bream, cod, herring, mullet, or whiting "mixed" were only made on occasions when it was not clear from the fisherman's return precisely which species had been caught.

9. There is no scientific record of sand mullet (*Myxis elongatus*) having been taken from the estuaries of south-Western Australia. Recorded catches of this species were probably sea mullet (*Mugil cephalus*).

10. The single recorded catch of catfish from the Swan-Canning estuary was most likely to have been cobbler (*Cnidoglanis macrocephalus*).

11. The following species rarely enter Western Australian estuaries, occuring mostly in the inshore-marine environment off the lower west and south coasts of this State:- barracouta (snoek), bonito, buffalo bream, cod, southern rock cod, grouper, Westralian jewfish, yellowtail kingfish, leatherjacket, blue mackerel, dusky morwong, red mullet, short finned pike, red fish, samson fish, shark, skates and rays, queen snapper, sole, sweep, skipjack tuna, and southern bluefin tuna. Thus with the exceptions of perhaps Princess Royal Harbour and King George Sound, which are really marine embayments, relatively large catches of these species would not normally be expected from our estuaries. Therefore, records of such estuarine catches are most probably the result of either fishermen incorrectly assigning their marine catches of these species to an adjacent estuary, or an error in coding the data prior to computer analysis.

    Scaly mackerel and pilchard would normally be included in this group. However over recent years, large catches of pilchard have been taken from the Peel-Harvey estuarine system and the lower reaches of the Swan-Canning estuary.

12. Westralian jewfish is an inshore-marine species which has never been scientifically recorded from the estuaries of south-Western Australia. Thus catches of this species have been wrongly assigned as having come from the estuarine environment. In reality the catches have probably come from and should have been assigned to the adjacent marine commercial fishing block.

13. "Other jacks" = other species of trevally.

TABLE 4. RECORDS OF A * SINGLE FISHERMAN'S CATCH FROM THE PALLINUP ESTUARY (BEAUFORT INLET) OVER THE PERIOD 1945-1954.

YEAR	BLACK BREAM	SEA MULLET	YELLOWEYE MULLET	AUSTRALIAN SALMON (TROUT)	OTHER	TOTAL	EFFORT (DAYS FISHED)	COMMENT
1945	7695	308				8004	48	In 1944 all fish except black bream died.
1946	2568					2568	20	All other species too small to catch legally.
1947	5899	8802	(NOT FISHED)	251		14952	50	Good fishing year.
1948	2493	10900	2995	892	304	17585	56	Good fishing year.
1949	784	9719	3019		261	13737	49	Good fishing - bar broke.
1950	3294	2163	799		210	6467	18	Poor season. Most species too small to catch legally.
1951	3242	5040	2099	50	304	10735		By late winter, water level low, fish in poor condition. Invertebrates dying.
1952	NIL							All fish had died by the winter of 1952.
1953	NIL							February floods - bar broke. Constant flooding throughout winter prevented fishing.
1954	523	9841	(NOT FISHED)	355	295	11014	56	

* 3 - 4 other parties also fish the estuary.

TABLE 5. THE LIFE HISTORY STRATEGIES, AND THE USUAL MAGNITUDE OF ANNUAL CATCHES OF EACH OF THE COMMERCIAL SPECIES TAKEN IN THE ESTUARINE FISHERIES OF TEMPERATE WESTERN AUSTRALIA.

Life history strategy	Species	Annual catch (kg) from all commercial estuaries			
		<1 000	1 000-10 000	10 000-100 000	>100 000
Estuarine-populations mainly juvenile from marine spawning.	Garfish, sea		x		
	Mullet, sand		x		
	Mullet, sea				x
	Mullet, yelloweye				x
	Mulloway			x	
	Salmon, Australian			x	
	Snapper		x		
	Tailor			x	
	Tarwhine (Silver bream)		x		
	Trevally			x	
	+Trumpeter	x			
	Whiting, King George			x	
	Whiting, Western sand			x	
Entire life cycle within estuary	*Anchovy/whitebait			x

	*Cobbler				x
	*Flathead			x	
	+*Flounder	x			
	Herring, Perth				x
	Perch, yellowtail		x		
	+Roach	x			
Occasionally present in estuaries as adults	Barracouta (snock)	x			
	Bonito	x			
	Bream, buffalo	x			
	Cod	x			
	Cod, southern rock	x			
	Grouper		x		
	Herring, Australian				x
	Jewfish, Westralian	x			
	Kingfish, yellowtail	x			
	Leatherjackets			x	
	Mackerel, blue	x			
	Mackerel, scaly		x		
	Morwong, dusky	x			
	Mullet, red	x			
	Pike, short finned	x			
	Pilchard				x
	Redfish	x			
	Samson fish		x		
	Shark		x		
	Skates	x			
	Snapper, Queen	x			
	Sole	x			
	Sweep	x			

*Provided conditions are favourable, these species can reproduce and mature entirely within the estuarine environment.

+ Catches of these species are low because they either are not in great demand commercially, or they mostly occur in areas where commercial fishing is difficult or not permitted.

TABLE 6 THE NUMBER OF FAMILIES AND SPECIES OF THE CLASSES TELEOSTOMI, ELASMOBRANCHII, PETROMYZONES, AND OF COMMERCIALLY IMPORTANT CRUSTACEA RECORDED FROM THE DIFFERENT CATEGORIES OF ESTUARINE SYSTEMS OF TEMPERATE WESTERN AUSTRALIA.

			WEST COAST			SOUTH COAST			
	Families	Species	*PO	SC	NC	PO	SC	NC	PC
TELEOSTOMI									
Freshwater native	4	9	4	4		4	4	3	1

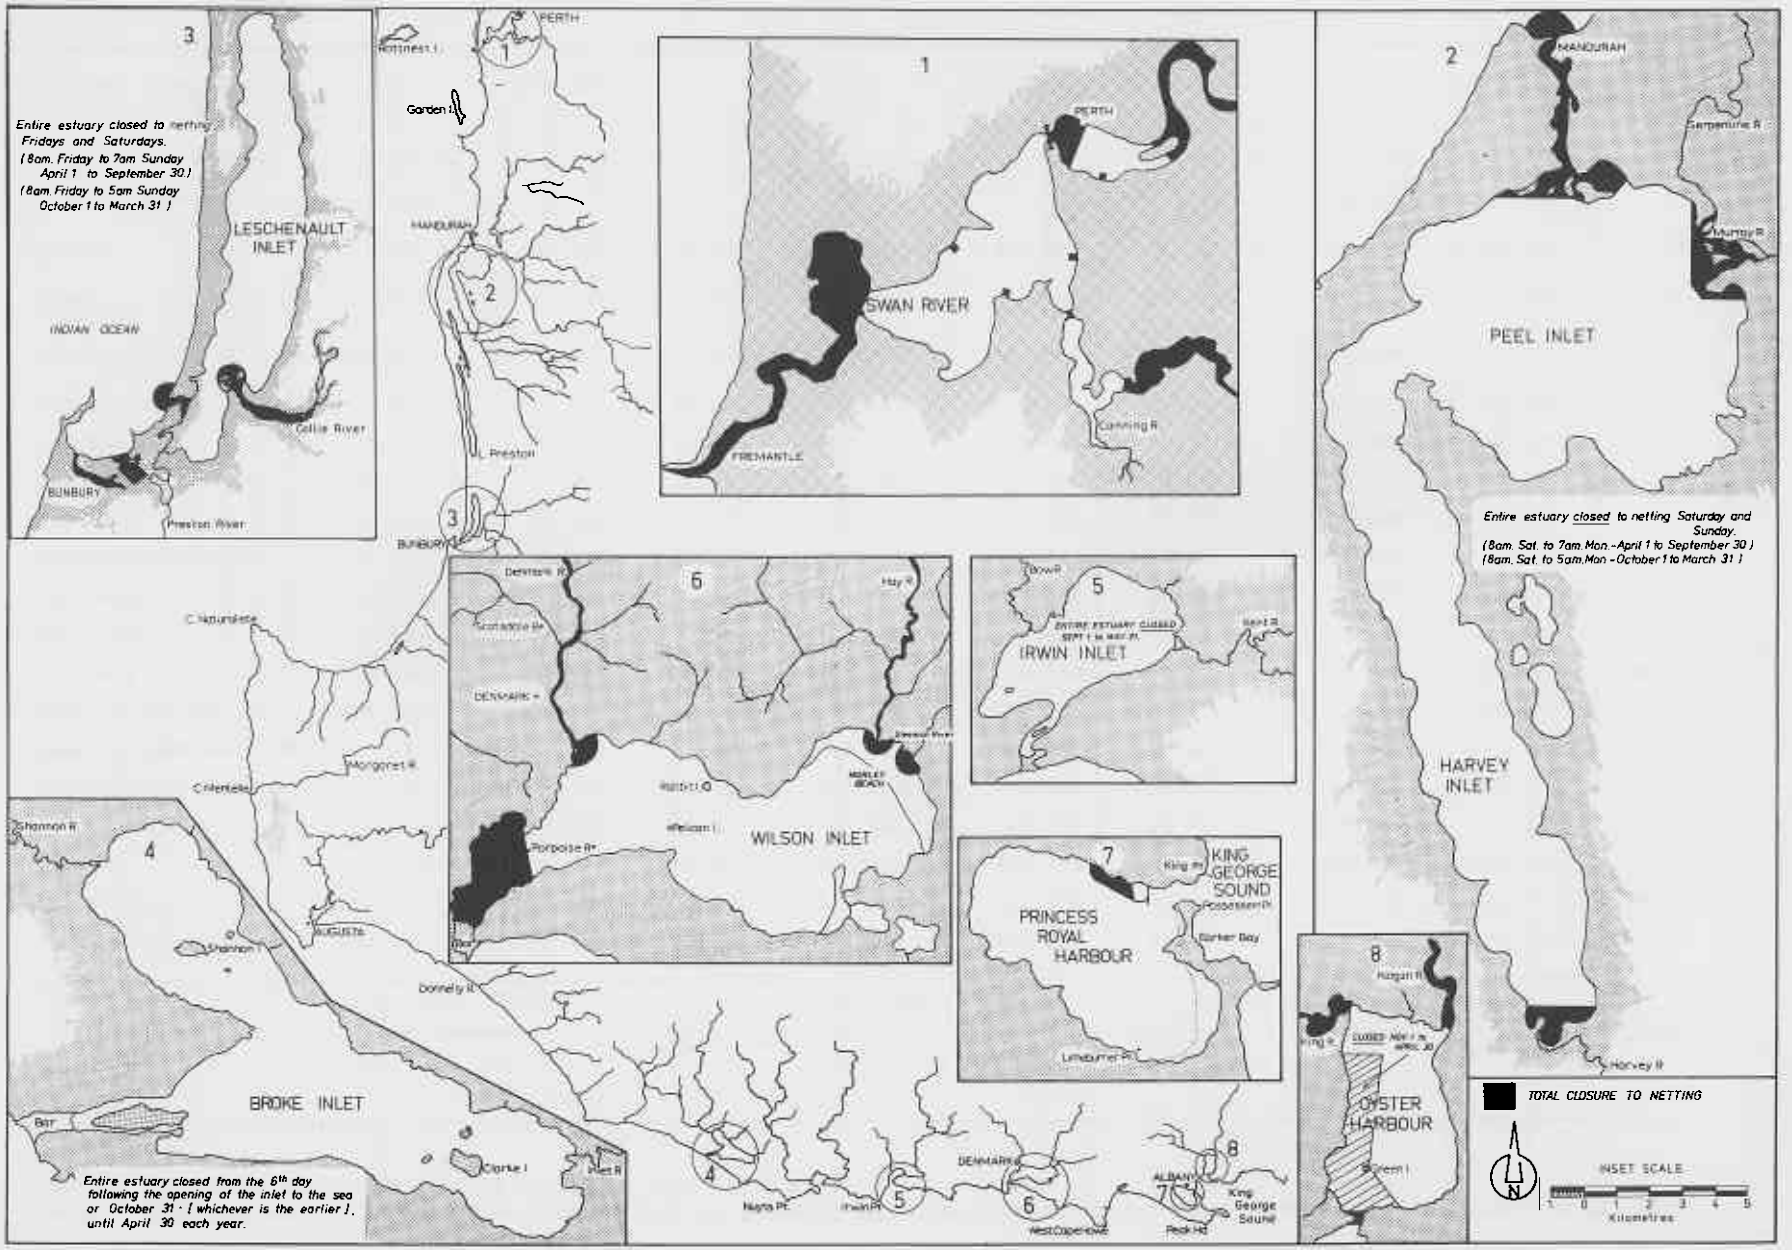

Figure 1. The commercially coded estuaries of temperate Western Australia, prior to June 1977.

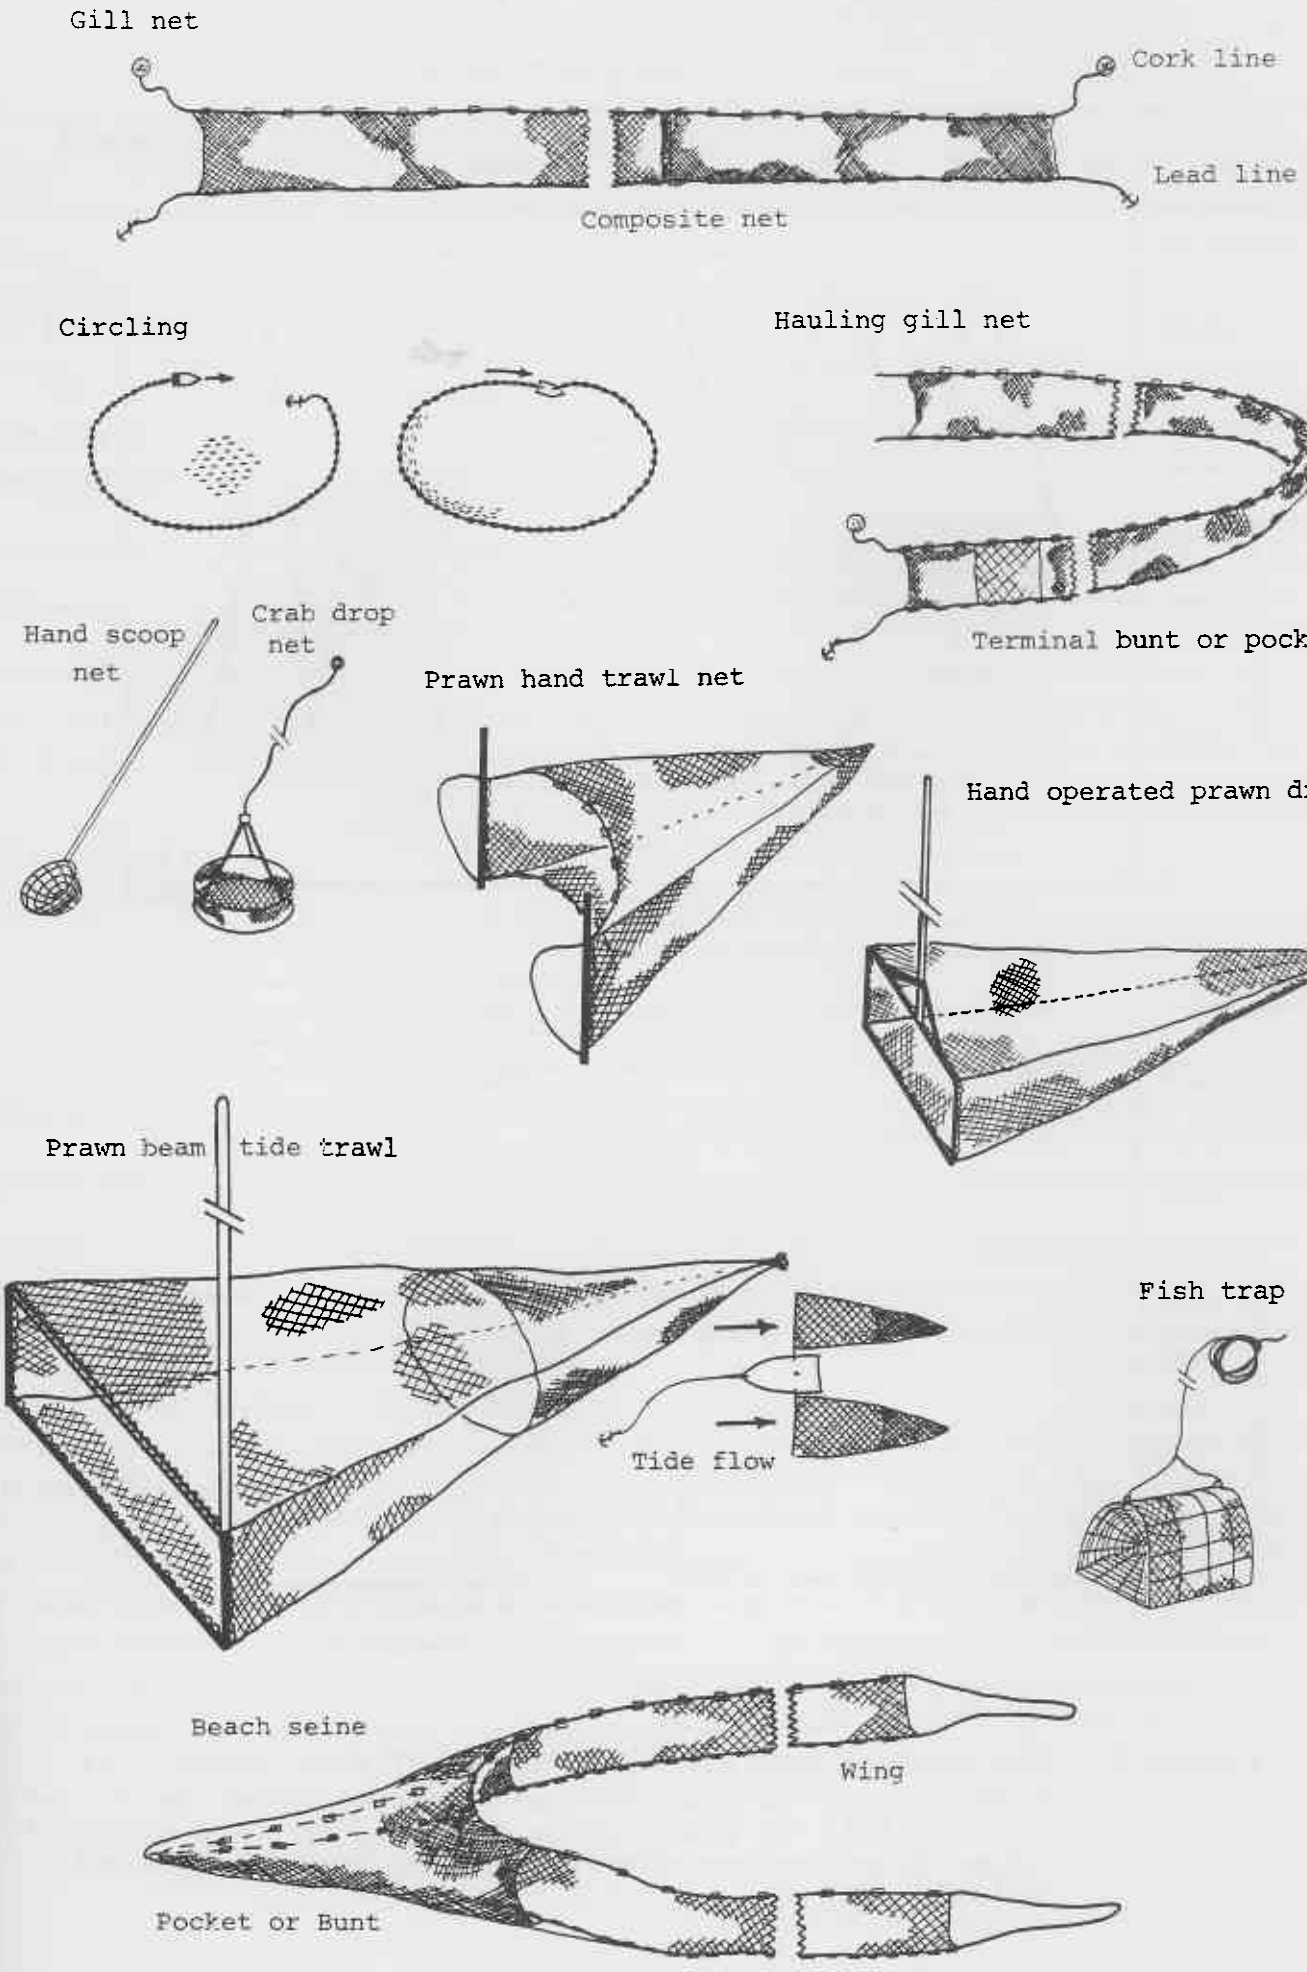

FIGURE 2 ILLUSTRATIONS OF THE BASIC TYPES OF FISHING GEAR USED IN ESTUARIES BY BOTH PROFESSIONAL AND AMATEUR FISHERMEN

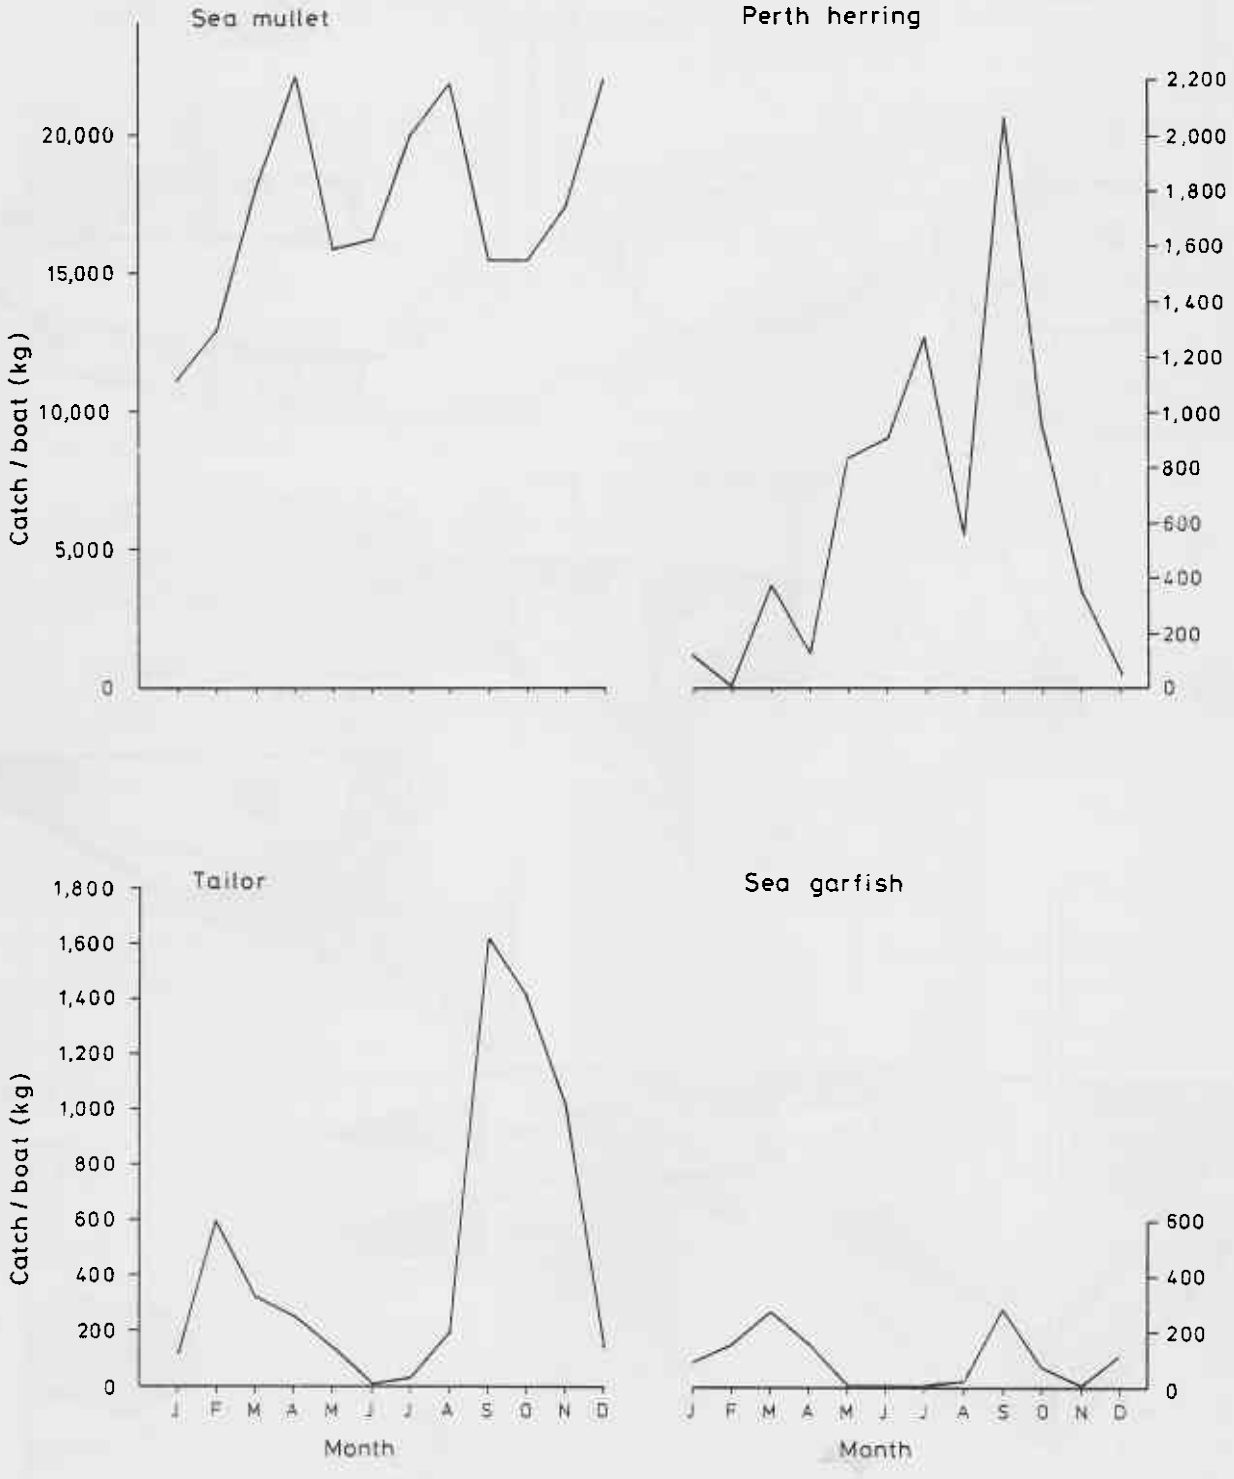

Figure 3 The average monthly catch rates of four commercial fish species ranging from extremely euryhaline (sea mullet) to practically stenohaline (sea garfish), taken from the Peel-Harvey estuary over the period 1972-74 (incl.).

Appendix 1 Guidelines for the interpretation of the species included under the various common names used in the Australian Bureau of Statistics fish production figures.

Common Name	Commercial Block 9501	9502	9503	9508	9507	9506	9505	9504
Anchovy	*Engraulis australis*							
Barracouta (or Snoek)	*Leionura atun*							
Bonito	*Sarda orientalis*			*Sarda australis*				
Bream black	*Acanthopagrus butcheri*							
Bream buffalo	*Kyphosus sydneyanus*							
	Kyphosus cornelii							
Bream mixed	*Acanthopagrus butcheri*							
	Rhabdosargus sarba							
Catfish	*Cnidoglanis macrocephalus*							
	Tandanus bostocki							
Cobbler	*Cnidoglanis macrocephalus*							
Cod	*Epihephelides armatus*							
Cod mixed	*Epinephelides armatus*							
	Acanthistius serratus							
				Physiculus barbatus				
Cod southern rock				*Physiculus barbatus*				
Flathead dusky				*Platycephalus speculator*				
	Platycephalus longispinis							
				Platycephalus sp.				
	P. endrachtensis							
	Platycephalus haackei							
	P. isacanthus							
	Platycephalus laevigatus							
Flounder	*Pseudorhomous jenynsii*							
				Ammotretis rostratus				
Garfish sea	*Hyporamphus melanochir*							
	Hemiramphus regularis regularis							
Grouper	*Achoerodus gouldii*							
Herring Australian	*Arripis georgianus*							
Herring mixed	*Arripis georgianus*							
	Nematolosa vlaminghi							
Herring Perth	*Nematolosa vlaminghi*							
Jewfish Westralian	*Glaucosoma hebraicum*							
Kingfish yellow-tail	*Seriola grandis*							
Leatherjacket	*Fam. Monocanthidae*							
Mackerel blue	*Scomber australasicus*							
Mackerel scaley	*Amblygaster postera*							
Morwong dusky	*Psilocranium nigricans*							
Mullet mixed	*Mugil cephalus*							
	Aldrichetta forsteri							
Mullet red	*Upeneichthys porosus*							

Commercial Common Name	Block 9501	9502	9503	9508	9507	9506	9505	9504
Mullet sand				*Myxis elongatus*				
Mullet sea			*Mugil cephalus*					
Mullet yelloweye			*Aldrichetta forsteri*					
Mulloway			*Argyrosomus hololepidotus*					
Perch Yellowtail	*Amniataba caudavittatus*							
Pike short-finned			*Australuzza novaehollandiae*					
Pilchard			*Sardinops neopilchardus*					
Redfish			*Centroberyx affinis*					
Roach	*Gerres subfasciatus*							
Salmon Australian			*Arripis trutta esper*					
Samsom fish			*Seriola hippos*					
Shark	Most important commercial species i.e. *Mustelus antarcticus, Furgaleus ventralis, Carcharhinus spp., Orectolobus spp.*							
Shark other	Incidental captures of less important species.							
Skates, rays other	Fam. Rajidae, Order Myliobatiformes							
Snapper			*Chrysophrys unicolor*					
Snapper Queen			*Nemadactylus valenciennesi*					
Sole				Fam. Soleidae				
Sweep				*Scorpis aequipinnus*				
				Scorpis georgianus				
Tailor			*Pomatomus saltatrix*					
Tarwhine			*Rhabdosargus sarba*					
Trevallyeastern					*Caranx nobilis*			
Trevally other jacks			Probably *Trachurus mccullochi*					
Trevally southern			*Pseudocaranx wrighti/P.dentex*					
Trumpeter			*Pelates sexlineatus*					
Tuna skipjack			*Katsuwonus pelamis*					
Tuna southern bluefin			*Thunnus maccoyii*					
Whitebait			*Hyperlophus vittatus*					
Whiting King George			*Sillaginodes punctatus*					
Whiting mixed			*Sillaginodes punctatus*					
			Sillago schomburgkii					
	Sillago maculata							
Whiting trumperter	*Sillago maculata*							
Whiting western sand			*Sillago schomburgkii*					
Wetfish other			*Portunus pelagicus*					
Crabs			*Penaeus latisulcatus*					
Prawns	*Metapenaeus dalli*							
Octopus			*Octopus sp.*					
Squid			*Loligo sp.*
